Most studies on the morphometric characterization of horse breeds on the African continent have focused on the Barb breed in North Africa. Chabchoub et al. (2006) conducted a study on 23 morphological parameters of 41 pure Barb horses from Tunisia (Chabchoub et al. 2006). Subsequently, a study in Algeria by Rahal et al. (2009) delved into the morphometric characterization of 18 quantitative parameters and four semi-qualitative parameters measured on 35 Barb horses in the Tiaret region (Rahal et al. 2009). Another evaluation was carried out on 151 pure and presumed (uncertain origins) Barb and Arab-Barb horses in Algeria, revealing that the Barb horses studied adhere to the international standard (Guedaoura 2012). Similar results were obtained by Benhamadi et al. (2017, 2019) in their study of 58 Barb horses in Northwestern Algeria (Benhamadi et al. 2017). This research concluded that the Algerian Barb horse possesses eumetric characteristics, is mid-linear with a body index of 0.955 (a square horse), boasts a median size of 152.5 cm, and a chest circumference of 175.5 cm (Benhamadi et al. 2017). Boujenane et al. (2008) studied morphometric characteristics of Arab-Barb horses in Morocco (Boujenane et al. 2008). A similar study in Algeria, Mebarki et al. (2018) found higher height at the withers and lower chest circumference than similar measures reported by Boujenane et al. (2008) in Morocco. These results could help establish a standard for the North African Arab-Barb horse, potentially leading to the creation of a closed studbook.

While research on other African horse breeds is less common, there was a study in Senegal 150 focused on the morpho-biometric parameters of traction horses, revealing similarities with earlier studies on indigenous breeds (Rischkowsky and Pilling 2007). Kefena et al. (2012) studied Ethiopian horse populations (Kefena et al. 2012), examining 17 selected variables on 503 horses from five of the eight communities in Ethiopia. Their results revealed three major breed groups and five distinct horse populations. A morphological study was undertaken comparing Arab horses with Desert Egyptian, Polish, and Polish-Egyptian ancestry, within the Arabian breed in Egypt (Machmoum et al. 2019). The results indicated significant morphological differences between the three lines, with the Desert Arabian breed and Polish Arabian line showcasing distinct profiles, while the Straight Egyptian profile fell in between.

11.5.2 Immunogenetic and Biochemical Studies

Biochemical parameters encompass the concentrations of molecules that offer insights into an organism's condition. Of these, the most widely utilized pertain to hepatic functions: alanine aminotransferase (ALAT) and aspartate aminotransferase (ASAT); serum proteins like albumin and globulins; milk proteins; and blood group proteins. Notably, blood group proteins have been extensively employed in equine breed characterization, serving as a crucial tool in parentage control until 2000. In resource-constrained African countries, they present an attractive alternative to molecular tools, especially with their confidence rate exceeding 98%.

It is important to consider breed variations when establishing reference intervals (RIs) for blood parameters and interpreting blood tests (Witkowska-Piłaszewicz et al. 2021). Horse hemotyping entails the analysis of red blood cells and genetic serum markers, constituting a vital tool in paternity and/or maternity verification. Its applications extend to identification, diagnosis, and the management of neonatal isoerythrolysis, as well as selecting blood transfusion donors (Bowling and Clark 1985). Cothran and Van Dyk (1998) examined genetic variability across seven blood groups and ten biochemical genetic loci in the Nooitgedacht, Boerperd, and Pony Basuto South African horses (Cothran and Van Dyk 1998). They subsequently extended this investigation to wild horse populations in Namibia (Cothran et al. 2001). The studies unveiled intermediate heterozygosity among domestic South African horses, with the Boerperd displaying the highest and the Basuto Pony the lowest heterozygosity (Cothran and Van Dyk 1998). All three breeds demonstrated greater genetic similarity with each other than with other domestic horse breeds (Cothran and Van Dyk 1998).

When compared to international breeds, South African horse breeds exhibited closer genetic ties to the Thoroughbred, Holstein, Trakehner, Hanovarian, and North American breeds like the Saddlebred, Standardbred, and Morgan Horse (Cothran and Van Dyk 1998). In contrast, genetic variability in feral Namibian horses was notably lower compared to domestic horse breeds, likely due to recent small population and founding sizes. These horses exhibited the highest genetic similarity to Arabian-type horses, although their conformation did not closely resemble that type (Cothran and Van Dyk 1998). Podliachouk and Quéval (Podliachouk and Queval 1961) studied 59 horses in Chad, looking at the distribution of erythrocyte factors (Podliachouk and Queval 1961). They concluded that Chad's horse population primarily stems from the Aryan and Mongolian breeds (Podliachouk and Queval 1961). They exhibited varying levels of purity, mixed with environmental and farming system influences. Four types were differentiated: Arab, Barb, Dongola, and Kirdi Pony from Logone (Podliachouk and Queval 1961). Despite such heterogeneity, the horse population in Chad remains relatively homogeneous even within regions, with the various types frequently intermixed. The study found that the frequency of various globular factors in Chadian horses closely resembled that observed in Garches (France), indicating comparable distributions. Chabchoub et al. (2006) conducted a study on the Mogod pony in Tunisia, a breed adapted for mountainous terrain in the northwest of the country (Chabchoub et al. 2006). Electrophoretic analysis of six protein systems in 47 Mogod ponies revealed allele frequencies and highlighted genetic differences between this breed and the Arabian, Barb, and Arab-Barb Thoroughbred horses.

There are relatively few studies on the biochemical parameters of heavy horses in Africa. Bathily et al. (2014) studied traction horses in Senegal, analyzing biochemical parameters of 97 male horses across different age groups and body condition scores using commercial kits (Bathily et al. 2014). Variations were observed in parameters such as phosphorus, calcium, cholesterol, urea, AST, and creatinine, with significant differences based on region and age. In Algeria and Morocco, studies on Barb horses and Arab-Barb breeds found that hematological indices fell within the reference range for warm-blooded horses (Chikhaoui et al. 2018; Talbaoui 1986). Notably, differences in hematological parameters

between these groups have been reported, including lower hematocrit in cold-blooded horses and higher erythrogram values in warm-blooded horses (Weiss and Wardrop 2010).

11.5.3 Molecular Studies of the Diversity and Structure of Horse Populations

Very few studies have been conducted in African countries to gain insights into the genetic structure of horse populations on the continent. Most of these employed the international panel of 17 microsatellites recommended by the FAO-ISAG International Panel on Animal Genetic Diversity Advisory Group for global equine breed identification and origin control. This situation presents an intriguing opportunity for data compilation across various African nations. In Algeria, Benhamadi (2020) used these markers to characterize eight horse breeds (Benhamadi 2020). Their study revealed a significant loss of genetic variability due to uncontrolled crossbreeding in populations of Algerian horses, such as the Barb, Barb of unknown origin, Arab-Barb, Arab, Thoroughbred, French Trotter, and Algerian Saddle horse (Benhamadi 2020). A similar alarming situation was expressed by Jamali (2020) regarding the genetic diversity of the Barb horse (Jamali 2020). They found that horse breeds in Algeria could be categorized into three major groups, each warranting separate preservation efforts to maintain their genetic diversity.

Berber et al. (2014) undertook a molecular characterization and genetic differentiation of five horse breeds in Algeria (Barb, Arab-Barb, Arab, Thoroughbred, and French Trotter) using 14 microsatellite markers (Berber et al. 2014). Their research indicated clear genetic differentiation between indigenous Algerian horses (Barb, Arab-Barb) and other breeds. The Barb and Arab-Barb breeds showed close genetic relatedness. Guedaoura (2012) characterized the Barb horse and its main variations by analyzing molecular polymorphism with eleven microsatellite markers (Guedaoura 2012). They reported that the Barb breed exhibits high allelic richness (57 alleles in total), an average heterozygosity rate (H) of 0.6651, and an inbreeding coefficient (F) of −0.0620 (Guedaoura 2012). The study calculated probabilities of identity and exclusion, revealing that the probability of identity (PI) is 1.98×10^{-9}, and the probability of exclusion (PE) is 96.4% with only one known parent and 99.99% with both parents known. Analysis of phylogenetic relationships indicated that the Garrano Portuguese pony is genetically closest to the Algerian Barb horse, sharing the maximum number of alleles in common (Guedaoura 2012).

In Tunisia, Haddad et al.74 conducted a molecular characterization with 13 microsatellites on indigenous horse breeds (Sebbag 2002). Their study highlighted a high rate of homozygosity and inbreeding within the analyzed Barb population, emphasizing the urgent need for genetic conservation and management. The molecular characterization of Tunisian Barb horses confirmed the existence of a genetic subdivision into two ecotypes, namely the Central East and Central West ecotypes. The variation previously attributed to environmental factors such as terrain and diet was found to have a genetic origin. Another study evaluated genetic diversity using ten microsatellites on 63 individuals from the pony population of Mogods in Bazina and Nefza, Northwestern Tunisia. The researchers demonstrated the presence of two genetically distinct ecotypes, one specific to the Bazina region and the other to the Nefza region (Sebbag 2002).

Jemmali et al. (2015) investigated the genetic diversity of the Barb and Arab Barb breeds in Tunisia, amplifying 17 microsatellites in a study involving (FAO 2019) horses (Jemmali et al. 2015). The research revealed slight heterozygosity deficiencies in the two populations. The overall population exhibited less heterozygosity compared to each population separately. Principal component analysis, dendrogram results, and factorial correspondence analysis all indicated overlapping genetic makeup, confirming a shared genetic basis between the two breeds (Fig. 11.52) (Piro et al. 2019).

A comparative analysis and genetic comparison of Barb horses from Morocco and Tunisia

Fig. 11.52 A chestnut Arab-Barb stallion tied up in front of its owner's home in Tozer, Tunisia. (Charles 2022)

was carried out by Piro et al. (2019). This study establishes phylogenetic relationships between the Barb horse and other existing breeds in Morocco using 17 microsatellites. They concluded that the Barb populations from both countries are heterogeneous and almost identical, with similar average heterozygosity rates (Piro et al. 2019). Comparison of the Barb horse's genetic structure in this study with other breeds (Thoroughbred, Arabian, and Arab-Barb) highlighted specific alleles and strong heterozygosity, showing maximum genetic distance from the Thoroughbred. The phylogenetic tree indicated a significant clustering of the two Barb populations and distinct separation from the other three breeds (Thoroughbred, Arabian, and Arab-Barb) (Piro et al. 2019).

In South Africa, Breytenbach et al. (2020) investigated mutations associated with gait and height in SA Boerperd horses, analyzing the genetic diversity using 17 microsatellite markers (Breytenbach et al. 2020). The study found that observed heterozygosity remained consistent with levels from 15 years ago, while inbreeding levels decreased from 8.4% to 3.2%. Despite this, the population structure analysis indicated the contributions of two distinct founder populations to the current breed formation. Compared to nine European breeds, SA Boerperd horses exhibited above-average heterozygosity and numerous private alleles (17.6%) (Breytenbach et al. 2020).

In a recent study in Ethiopia, molecular biology tools were employed to analyze mitochondrial DNA polymorphism in indigenous equine populations (Kefena et al. 2021). The study revealed poor genetic differentiation among the studied animals. The authors also attempted to trace the matrilineal genetic roots of native Ethiopian horses by analyzing haplotypes and reference sequences from the GenBank (Kefena et al. 2021). The network analysis indicated separate clusters formed by haplotypes from native Ethiopian horses, suggesting distinct genetic origins. This study encourages further exploration of the genetic heritage of native African horses by analyzing additional mtDNA sequences from the GenBank for African and Eurasian horses (Kefena et al. 2021).

11.6 Conservation Programs of Horse Genetic Resources in Africa

11.6.1 Current Situation

The equine population census in Africa was conducted in only 37 out of the total 54 African countries (FAO 2019) (Table 11.2). Only 46% of African countries provide information on equine breeds while reporting rates are higher in other regions, such as 100% in North America, 93% in Asia, 91% in Europe and the Caucasus, 65% in Latin America and the Caribbean, 58% in the Near and Middle East, and 23% in the South-West Pacific (FAO 2006a). Horse breeds contribute significantly to the total number of mammal breeds worldwide (14%), even though their contribution in terms of population size is comparatively (FAO 2006a). This indicates a considerable genetic diversity within this species. The African equine population represents 6% of the global equine population, with 7% of the ethnological diversity compared to reported breeds worldwide (FAO 2006a). This corresponds to 34 local (indigenous) breeds out of the 570 breeds reported globally.

It is important to note that the reported number of horse breeds in Africa and worldwide can vary depending on the organizations and methodologies used for studying equine diversity. Different sources report different numbers. For instance, in June 2010, the Oklahoma State University Livestock Breeds' Database 202 listed 217 horse breeds worldwide. Earlier, Hall and Raune (1993) reported 427 breeds (Hall and Raune 1993) while the European Association of Animal Production (EAAP) genetic data bank contained 707 entries representing 110 horse breeds in 1992 (Simon 1992), Mason's breeding dictionary included 592 horse breeds including breed varieties (Mason 1988), and a study by Koenen et al. (2004) indicated 527 horse breeds worldwide (Koenen et al. 2004). In Africa, there are 48 local breeds, 9 regional transboundary

Table 11.2 Risk statue of African horse breeds (FAO 2019)

N°	Breed	Country	Situation
1.	Basotho Pony	Lesotho and South Africa	Extinct
2.	Calvinia	South Africa	Extinct
3.	Cape Harness	South Africa	Extinct
4.	Cape Horse	South Africa	Extinct
5.	Namaqua Horse	South Africa	Extinct
6.	Nefza Pony	Tunisa	Extinct
1.	English WB	South Africa	Critical
2.	Horse (Uganda)	Uganda	Critical
1.	Nooitgedacht	South Africa	Endangered
2.	Pony European WB	South Africa	Endangered
3.	Horse (Tanzania)	Tanzania	Endangered
4.	Namib horse	Namiba	Endangered
5.	SA Miniature horse	South Africa	Endangered
6.	Somali Pony	Somalia	Endangered
7.	Vlampeerd	South Africa	Endangered
1.	El-Ghazal	Tchad	Not at-risk
2.	Bandiagara	Mali, Niger	Not at-risk
3.	Dongola	West Africa (Chad, Eritrea, Mali, Sudan)	Not at-risk
4.	Egyptian	Egypt	Not at-risk
5.	Locale		Not at-risk
6.	Logone pony	Cameroun	Not at-risk
7.	Sudan Country breed	Sudan	Not at-risk
8.	West African Barb	West African	Not at-risk
9.	Western Sudan Pony	Sudan	Not at-risk
1.	Abyssinan	Ethiopia	Unknown
2.	Beledougou	Mali	Unknown
3.	Bhirum Pony	Nigeria	Unknown
4.	Bobo	Burkina Faso	Unknown
5.	Boer	South Africa	Unknown
6.	Bornu	Nigeria	Unknown
7.	Chadian	Tchad	Unknown
8.	Cheval de Nioro	Mali	Unknown
9.	Djerma	Niger	Unknown
10.	Dombi	Mali	Unknown

29.	Tsawana	Botswana	Unknown
30.	West African Dongola	West Africa	Unknown
31.	West African Pony	West Africa	Unknown
32.	Yagha	Burkina Faso	Unknown

breeds, and 26 international transboundary horse breeds reported by the FAO in 2006 (FAO 2006a). Notably, the number of African countries reporting the presence of Arab, Thoroughbred, Arab-Barb, Barb, and Dongola horses was 8, 7, 6, 6, and 3, respectively (DAD-IS 2008).

Globally, there are 272 horse breeds with an unknown risk status, 52 breeds in critical situation, 10 in continued critical situation, 95 in danger, 24 in continued danger, 246 not at risk, and 87 missing. FAO statistics (2006b) show that 384 breeds of African mammalian species, including horses (with population size unreported for over two-thirds of these populations), are in an unknown risk situation (32 breeds) (FAO 2006b). Regarding horses, 6 breeds have been officially declared extinct in Africa 208. Among African international transboundary horse breeds, the Barb breed is highly represented, and the Dongola breed is well-known among regional transboundary African breeds. The Nooitgedacht breed is an example of an African regional transboundary breed that is endangered (Rebts 2017). With only 400 identified individuals, it qualifies as a rare breed (Khadka 2010).

The lack of comprehensive knowledge about the current status of various African horse breeds creates challenges for coordinated efforts in the establishment of conservation priorities. There are several crucial reasons for classifying the risk status of breeds, including genetic uniqueness (Mendelsohn 2003), high endangerment levels (Gandini et al. 2004), economic, cultural, scientific, and ecological value, as well as the efficient allocation of resources (Simianer et al. 2003). However, the future prospects of breeds, whether equine or of other species, are heavily influenced by their current and potential roles within husbandry systems. As circumstances change, certain breeds might fall into decline and become threatened with extinction, unless alternative strategies are implemented (Hiemstra et al. 2006). Various conservation methods offer advantages beyond traditional technologies and enhance their efficacy in the characterization, preservation, and utilization of equine genetic resources. While a detailed discussion of classic selection methods is beyond the scope here, it is undeniable that such methods have been and will continue to be extremely valuable within the African equine sector.

11.6.2 Reproduction Management

Equine genetic resources serve as the fundamental foundation for advancing the equine sector and ensuring the sustainability of natural equine populations. Efficient reproduction lies at the core of conserving, enhancing, and developing horse herds. In the wild, horses adapt by developing various breeding strategies to ensure optimal foaling during periods of abundant forage and warm climate (Cilek 2009). However, domestication has had a substantial impact on reproductive performance, as selective pressures on fertility have been limited, resulting in domestic horses having comparatively lower reproductive effi-

ciency, as is the case in other species such as the dromedary and (Eulmi et al. 2023; Gherissi et al. 2020).

The timing of the breeding season varies from one country to another, typically spanning 4–5 months. For instance, the breeding season starts on August 15th in African countries located in the southern hemisphere and February 15th for those in the northern hemisphere (Mota and Regitano 2012). In Morocco, the breeding season officially begins at the start of February and continues until the end of June (SOREC 2020), while generally, in North Africa, it extends from February 15th to June 15th (Aouane et al. 2019). In South Africa, the official mating season for horses commences on August 1st. While Stallions can mate year-round, mares only ovulate during the summer months.

Schulman et al. (2003) conducted a study using 25 years of recorded reproduction data from South African Thoroughbred horses (Schulman et al. 2003). They reported an average annual live foal production rate ranging from 52.3% to 62.0%. The percentages of slips and stillborn foals ranged from 2.5% to 3.9% and 7.5% to 9.4%, respectively. The "barren and no return" category showed a percentage of 29.0% to 35.1% (Schulman et al. 2003). The relatively low fertility rate observed in African horses has been noted across different breeds, countries, and with different breeding purposes (Gómez et al. 2020). Factors contributing to this include hormonal dysfunction, genital infections in mares, parasitic infections, and inadequate management prior to the breeding season (Mota and Regitano 2012; Sullivan et al. 1975). The extended reproductive cycle, combined with a long prepubertal period, extended gestation period, high generation interval and low fertility rate, along with occurrences of genital pathologies, abortions, and neonatal mortality, collectively contribute to the limited numerical productivity of horse herds, particularly in extensive breeding systems. Considering that reproductive traits generally have low estimates of heritability and are selected in horses through indirect methods (Taveira and Mota 2007), achieving genetic improvements in this aspect is neither rapid nor straightforward, especially in species like horses with prolonged intergenerational intervals.

11.6.3 Governmental Conservation Programs

11.6.3.1 Characterization Programs

Characterization serves as a fundamental prerequisite for determining which genetic resources need to be conserved and in what order of priority. It plays a pivotal role in optimizing the utilization of resources, especially in situations of limited availability. A prime example is the extensive study carried out by Kefena et al. (2012) on the morphological and phenotypic characterization of the Ethiopian equine population (Kefena et al. 2012). This study not only established a valuable database containing essential information on the geographical distribution of Ethiopian horses but also laid the groundwork for managing and conserving subsequent generations of the five indigenous horse populations. However, certain challenges, such as the elusive behavior of wild horses, their relatively small numbers, and other factors, impeded the morphological characterization of certain wild horse breeds like Borana, Kundido, and Somali/Wilwal. The Somali/Wilwal breed, for instance, is classified as endangered (FAO DAD-IS 2021).

In this context, the lack of widespread utilization of biotechnologies, including molecular markers and "omics" technologies, in the characterization process across African countries presents a significant hurdle in advancing the conservation of the continent's equine genetic heritage. These advanced biotechnologies have the potential to provide valuable insights into the genetic diversity, population structure, and unique traits of horse breeds, which can be critical for their conservation and sustainable management. Efforts to integrate such biotechnological tools into the conservation strategies can enhance the understanding of equine genetics, aid in making informed conservation decisions, and contribute to the long-term viability of these valuable genetic resources in Africa.

11.6.3.2 Conservation Programs

Issues around conservation of AnGR, including approaches, specific challenges in Africa, and needed actions, are described in Chap. 25. In the realm of conservation of African horse genetic resources, two primary strategies are employed: in situ conservation and ex situ conservation. In situ conservation involves the preservation of species within their natural habitats, allowing for ongoing evolution and adaptation. There is a notable scarcity of conservation initiatives for endangered equine populations across Africa. For example, the Kundido wild horses in Ethiopia faced the challenge of domestication due to poor knowledge of horse management practices, inbreeding, and high market demand for newborn foals. To address this, collaborative efforts between Haramaya University, the Ethiopian Biodiversity Institute, and the Oromia Environment, Forest, and Climate Change Authority (OEFCCA) were initiated. This partnership aims to research the Kundido mountain horse species, design sustainable conservation strategies, including ex situ conservation. It also hopes to develop ecotourism opportunities to generate income from genetic resources. Such collaborations are pivotal in increasing the wild Kundido horse population and boosting tourism income.

In the Namib Naukluft Park, there is an intriguing program that studies wild horses in conjunction with the conservation of plants and the interaction between these wild animals and their environment. Predation by hyenas poses a significant threat to foals, leading to management strategies such as the construction of sanctuaries, managing water and food, as well as maintaining a diverse prey population to deter hyenas. Despite these efforts, challenges remain, including a decline in foal survival rates, possibly leading to reproductive challenges in the future.

Understanding and managing wild horse behavior, their response to human care, and the dynamics of their interactions with their environment are crucial aspects of effective conservation. The complexities in managing wild horses are exemplified by conflicts between scientists, advocates, opponents, and stakeholders. In North America, Boyce et al. (2021) highlighted how scientists conducting research may find themselves caught between various interests and stakeholders, affecting their ability to provide informed decision-making (Boyce et al. 2021).

Ex situ conservation involves preserving genetic resources outside their natural habitat. This can be achieved through cryopreservation, where genetic material is stored at extremely low temperatures. Cryopreservation offers numerous benefits, including cost-effectiveness, long-term conservation, reduced risk of loss, minimal space requirement, and the retention of genetic material for future improvement. However, its systematic use is often limited in developing African countries due to the lack of specialized facilities, unreliable energy supply, and difficulties in obtaining liquid nitrogen. Despite these challenges, efforts are being made to establish cryopreservation practices in countries like Senegal, Morocco, and Algeria. Ultimately, both in situ and ex situ conservation strategies, when properly implemented and collaboratively managed, can play vital roles in preserving equine genetic diversity and ensuring the sustainable future of these valuable genetic resources in Africa.

11.7 Conclusion and Future Perspectives

The chapter reviews the origin, number, qualities, characteristics, and importance of equine livestock in Africa. The quality spectrum ranges from the hardiness exhibited by all indigenous strains and breeds to the disease resistance or tolerance observed in certain populations. It also extends to their adaptation to endemic pathologies. The stamina and saddle ability found in the noblest breeds underscore their significance.

These multifaceted attributes of horses in Africa serve to reinforce the recommendations by the FAO that there is a need to maintain a high degree of genetic diversity within domestic species. For example, given the current era of global warming, it can be envisaged that genes from the African equine populations adapted to the hot environment could in the future be introgressed

into their European horses, although the appropriateness of such action could be in question.

At present, these populations stand as a testament to adaptation to the harsh and challenging environments of their habitats. They represent a valuable asset, contributing significantly to agricultural, cultural, and transport activities. Consequently, they merit thorough investigation, preservation, and enhancement. The following strategies may be implemented for the resilience and sustainability of African horse genetic resources.

11.7.1 Genetic Markers Studies

A good knowledge and understanding of breed-specific markers in African horses is critical. It has helped, for example, in consolidating populations that were previously assumed to be distinct. Genetic markers play a pivotal role in facilitating parentage verification. Construction of phylogenetic tree for breeds within and across continents helps give a clear understanding of breed relationships and origin. This visual representation illuminates the intricate interconnections between breeds and underscores the impact of human migrations on their evolution. The high cost and advanced complexity of such investigation should no longer present barriers, given the increasing accessibility within educational and research establishments and institutions to funds and human resources. The execution of such research endeavors would not only contribute to the objective classification of diverse breeds but also serve to oversee the establishment of comprehensive studbooks.

11.7.2 Biochemical Studies

In Africa, where many countries lack the necessary infrastructure for molecular studies, investigations into erythrocyte markers can have significant utility. The extensive diversity of blood groups among horses affords an accuracy of approximately 98%. Nonetheless, it is worth noting that other biochemical attributes, particularly those associated with mare's milk, also hold promise for insightful exploration and examination.

11.7.3 Morphometric Studies

An accurate description of a population necessitates an extensive array of measurements. Such comprehensive studies facilitate the development of precise and intricate breed standards. Morphometric analyses rely on straightforward and easily manageable tools such as measuring boards, tape measures, and cameras. This renders conducting a morphometric study involving tens or even hundreds of horses a feasible endeavor for students working on their theses. The cumulative effort of numerous student studies would collectively offer an intricate portrayal of the equine population within each African country.

11.7.4 Anthropological Studies

Horses hold a prominent place in rituals and beliefs across cultures, serving as the protagonists of numerous tales and proverbs. Their esteemed symbolism also renders them integral to celebrations and ceremonies. The realm of traditional medicine, primarily rooted in medicinal plants, remains prevalent. The upbringing of young colts receives meticulous attention, evident in practices like bathing foals on their third day of life or engaging in superstitious acts such as splitting an ear during birth to ward off repeated foal mortalities.

Traditional knowledge of physical attributes crucial for horse selection holds significant value and needs to be preserved and passed on to the younger generations. Attributes such as body proportions, the angles of radius bones, or distinctive tufts of hair sometimes constitute an informal standard, or at the very least, merit inclusion within one. Yet, this indigenous empirical knowledge is often disregarded by researchers and stakeholders tasked with establishing standards. The perception that the concept of standards and morphological criteria is absent

contradicts the rich cultural heritage encapsulated within oral traditions.

Morphological criteria, like the width between the jaws, can be used in scientific validation and incorporation into breed standards. If they appear unrelated, they still warrant documentation as a repository of traditional wisdom. This cultural legacy is deserving of rediscovery, scholarly assessment, and preservation to perpetuate the memory of the continent, enrich our understanding of these breeds, and honor the wisdom of indigenous traditions.

Through genetic, biochemical, morphometric, and anthropological studies, opportunities arise to explore rearing methods, dietary practices, equine healthcare, and more. The conservation of traditional harnesses and saddlery not only upholds the identity of equestrian cultures but also safeguards local arts and crafts, potentially offering economic prospects through tourism. Innovations within the technical sphere can distinctly benefit draft horses. For instance, adoption of a modern horse pull collar over the less efficient breast band harness for plowing or cart pulling could considerably diminish power loss and unnecessary energy expenditure. The creation of affordable horse pull collars by local artisans and their gradual popularization could substantially advance the well-being of millions of draft horses and their owners throughout Africa.

Venturing beyond the equestrian realm, mention must be made of the seed drill for direct sowing, a pivotal agricultural tool whose significance aligns with the expansive tracts cultivated by horses, mules, and donkeys in Africa. This ecologically friendly implementation drastically reduces time and physical exertion for both humans and equines. Its dissemination across Africa would serve multiple objectives, including enhancing animal welfare. Exploring local blacksmithing techniques offers potential for improvements without incurring additional costs, utilizing existing methods and tools. This technical enhancement, albeit partial, holds promise for broader implementation, yielding substantial economic gains due to the extensive target population.

11.7.5 Genetic Improvement

Emphasizing the intrinsic strengths of African breeds is crucial in preserving their unique genetic heritage and promoting sustainable breeding practices. Rather than attempting to mold African breeds into unsuitable sports through crossbreeding, focus should be on leveraging their inherent strengths. African breeds excel naturally in disciplines such as endurance riding, TREC, working equitation, and driving. Respecting these strengths safeguards their genetic integrity and ensures their continued relevance in diverse equestrian activities. Principles around breeding goals and strategies, and broad issues/challenges in Africa, as described in Chap. 15 (on breeding goals and strategies).

Breeding programs aimed at enhancing equine traits prioritize performance and utility attributes such as speed, endurance, and temperament. Research indicates the heritability of these traits, suggesting potential improvements through selective breeding practices (McGowan et al. 2002). Moreover, conformation and health play crucial roles in equine welfare and performance, with studies linking certain conformation traits to performance outcomes (Koenen et al. 2004). Additionally, adaptability to diverse environmental conditions is vital for African horse breeds. Studies have identified genomic regions associated with environmental adaptation, indicating opportunities for selective breeding for environmental resilience (Librado et al. 2017). Furthermore, acknowledging the cultural significance of indigenous horse breeds, research on ethnozoology and cultural aspects of horse breeding provides insights into traditional knowledge guiding breeding practices (Madimabe 2016).

Breeding purebred horses in Africa faces numerous challenges, including limited breeding stock, inadequate infrastructure, economic constraints, lack of awareness, and environmental factors. To overcome these obstacles, collaborative efforts are crucial, focusing on investing in education, infrastructure development, genetic conservation, and sustainable breeding practices. By addressing these issues, the success and sustainability of purebred breeding can be ensured,

thereby fostering the growth of the equine industry in Africa.

In the context of preserving genetic diversity and maximizing the utility of equine populations, rethinking crossbreeding approaches is paramount. Rather than viewing crossbreeding as a one-size-fits-all solution, it should be approached as an experimental process, rigorously assessing adaptability and performance improvement. It is imperative to avoid repetitive crossbreeding with European breeds, which can deplete local genetic pools and diminish the hardiness of indigenous breeds. Tailoring crossbreeding for regional needs is essential to develop versatile equine populations that meet specific regional requirements. By exploring crossbreeding between Barb horses and local African breeds, it is possible to combine desirable traits from both parent breeds to benefit agriculture, transportation, cultural practices, and recreational activities.

Drawing from principles surrounding breeding goals and strategies, within-breed selection programs prioritize enhancing performance traits and genetic conservation. Additionally, crossbreeding initiatives seek to introduce desirable traits and enhance genetic diversity. Research on African horses has investigated the impacts of crossbreeding on performance and adaptability, underscoring the importance of managing hybrid vigor and maintaining breed purity. To inform future endeavors, studying successful crossbreeding initiatives, such as those involving Barb horses, provides valuable insights into enhancing versatility and performance across various disciplines. Furthermore, preserving distinct indigenous populations is crucial for maintaining genetic diversity and safeguarding cultural heritage.

Despite progress, several challenges persist. Limited access to veterinary services and breeding technologies hampers systematic breeding efforts in African countries. Indigenous horse breeds are particularly vulnerable to threats to genetic diversity, including inbreeding and population decline, necessitating the implementation of conservation programs. Moreover, economic constraints pose significant barriers, requiring sustainable funding mechanisms and capacity-building initiatives to support breeding programs. Addressing these challenges will be instrumental in advancing the equine industry in Africa and ensuring the preservation of its diverse equine heritage.

Capacity-building initiatives, including training programs for breeders and veterinarians, can enhance breeding skills and improve animal health management (AHST n.d.). Investments in veterinary infrastructure and genetic laboratories are crucial to support breeding programs, with organizations like the African Union's Inter-African Bureau for Animal Resources advocating for infrastructure development to enhance livestock production (AU-IBAR n.d.). Collaboration between governments, research institutions, and breed associations is essential for knowledge sharing and resource mobilization, as demonstrated by initiatives like the African Union's Pan-African Animal Genetic Resource (n.d.).

11.7.6 Development of African Horse Breeding

Formulating a comprehensive development strategy for the equine sector in Africa requires the establishment of regional African horse networks. These networks should be designed to champion the interests of these animals, promote local equine populations, and devise solutions for the diverse local and regional challenges associated with breeding and utilization.

The creation of studbooks for local breeds is a crucial step, with the aim of establishing studbooks at local, national, and transnational levels for African horse breeds. Such an initiative would confer visibility and formalize the identity of these populations. Additionally, it would facilitate the formation of local associations, which play a pivotal role in breed development and recognition by showcasing their contributions to traditional sports, traction, transportation activities, and equitherapy.

An effective valuation strategy for African horses must encompass the promotion of eques-

trian disciplines that align with their inherent strengths. While flat races generate excitement and financial activity, there is a risk that crossbred animals might surpass local breeds, even going so far as to assume their names. Equestrian disciplines like endurance racing, wherein breeds like the Nara horse, the Baguezzan, and the Bahr El Ghazal have the potential to excel, should be a focal point. These breeds exhibit qualities honed over centuries of raids and hunting expeditions. An added advantage of endurance racing is that it requires minimal infrastructure, making organization relatively straightforward. Preserving and enhancing local breeds and equestrian heritage can be achieved through traditional equestrian activities such as fantasia, long-distance races, Mata (a North Moroccan variation of Buzkashi), guugsi, djerid, and more. It is essential to empower practitioners of these disciplines, as they naturally possess the authority for judging competitions or codification due to their intimate connection with tradition.

The establishment of inter-professional groups within the equine sector, alongside awareness programs, is vital. Collaborating with professional equine organizations, these groups should collectively propose medium and long-term development strategies. Priorities must be identified for each equine population according to their aptitudes, within the context of sustainable development programs tailored to each region (traditional activities, tourism, transport, and traditional sport). These organizations should create a comprehensive strategy outlining their missions, objectives, tasks, and contributions to the public. Guided by this strategy, the equine sector should be represented in broader development initiatives of regional, continental, or international significance.

Encouraging investment in horse breeding necessitates the implementation of national aid strategies, including breeding contracts, bonuses for special or endangered breeds, stallion approval incentives, and breeding competitions. Such efforts are instrumental in propelling the equine sector's growth and success.

12 African Water Buffalo Genetic Resources, Diversity, and Unique Features

Sahar S. E. Ahmed, Amal A. M. Hassan, Ibrahim A. H. Barakat, and Hassan M. Al Ashmaoui

Abstract

This chapter presents the buffalo genetic resources in Africa. The first section (Sect. 12.1) discusses the origin and distribution of African buffalo with emphasis on the domestic water buffalo types (swamp and river buffalo). The African water buffalo phylogeny is presented in Sect. 12.2, while the various approaches to mapping the genes of buffalo and genetic diversity characterization are presented in Sects. 12.3 and 12.4, respectively. The production and husbandry systems of African buffalo and genetic resources conservation are discussed in Sects. 12.5 and 12.6. This chapter concludes with a presentation of the challenges facing buffalo production and future perspectives on the development of sustainable genetic resources management for the African buffalo.

Keywords

River buffalo · Gene mapping · Genetic diversity · Biodiversity conservation

Abbreviations

MAS	Marker-assisted selection
QTL	Quantitative trait loci
DNA	Deoxyribonucleic acid
RNA	Ribonucleic acid
rRNA	Ribosomal RNA
mtDNA	Mitochondrial DNA
SNPs	Single-nucleotide polymorphisms
CO1	Cytochrome C oxidase subunit 1
PCR-RAPD	Random amplified polymorphic DNA
BBU1 map	Chromosome 1
LG1	Linkage group 1
LG2	Linkage group 2
RH map	Radiation map
STSs	Sequence-tagged sites
GWAS	Genome-wide association studies
CAPN1	Micromolar calcium-activated neutral protease
LEP	Leptin
PCR	Polymerase chain reaction
RFLP	Restriction fragment length polymorphism
IGF2	Insulin-like growth factor 2

GH	Growth hormone
GHR	Growth hormone receptor
GHRH	Growth hormone releasing hormone
SSCP	Single-strand conformation polymorphism
IGF2	Insulin-like growth factor 2
ADG	Average daily gain
Q	Glutamine
aa	Amino acid
H	Histidine
MY	Milk yield
FY	Milk fat yield
PY	Milk protein yield
FP	Milk fat percentage
PP	Milk protein percentage
LP	Lactose percentage
LY	Lactose yield
ADMYD	Average daily milk yield deviation
LL	Lactation length
k-casein (CSN3)	Kappa-casein
ABCG2	ATP Binding Cassette Subfamily G Member 2
OLR1 or *Ox-LDL* receptor 1 or *LOX1*	Oxidized low-density lipoprotein receptor 1
PPARGC1A or PGC1A	Proliferator-activated receptor gamma, coactivator 1 alpha
SCD1	Stearoyl-CoA desaturase 1
PRL	Prolactin
PRL promoter	Prolactin promoter
PIT-1 or *POU1F1*	Pituitary-specific transcription factor
Text	Microsatellite markers
β-LG	β-Lactoglobulin
FSHR	Follicle-stimulating hormone receptor
IGF-1	Insulin-like growth factor1
IGF-1R	Insulin-like growth factor1- receptor
INHBA	Inhibin beta-A
STAT5A	Signal transducer and activator of transcription5
LHR	Luteinizing hormone receptor
ERα	Estrogen receptor-α
CYP19A1	Cytochrome P450 aromatase
BMP15	Bone Morphogenetic Protein 15
FSHB	FSH beta-subunit
LF	Lactoferrin
LEP	Leptin
GnRHR	Gonadotropin releasing hormone receptor

12.1 Introduction

The buffalo belongs to the Bovidae family (bovids), and two genera are recognized, *Syncerus* and *Bubalus*. The genus *Syncerus* is the wild African buffalo (*Syncerus caffer*) while the genus Bubalus is made up of four species, namely *Bubalus arnee* (water buffalo wild type), *Bubalus bubalis* (water buffalo domestic type), *Bubalus mindorensis* (tamaraw), *Bubalus depressicornis* (lowland anoa), *and Bubalus quarlesi* (mountain anoa) (Huffman 2006; Owak and Paradiso 1983).

The African buffalo wild type is a large animal with large horns for both sexes. Their bodies are covered with thick reddish hair at birth, while by age the mature animals are dark brown or black. According to the chromosomal numbers, Di Berardino and Iannuzzi (1981) divided the African buffalo into two groups: *Syncerus caffer nanus* (2n = 54) and *Syncerus caffer caffer*.

The African buffalo distribution patterns are influenced by season, topography, and herd sizes and are divided into forest buffalo, West African savanna buffalo, Central African buffalo, and southern savanna buffalo (Furstenburg 2007, Fig. 12.1). Some of the African nations with buffalo populations are Ethiopia, Somalia, Zambia, Zimbabwe, Namibia, Botswana, Mozambique, South Africa, Kenya, and Tanzania. African buffalo are formidable fighters and have never been successfully domesticated. Although in the past, the population of African buffalo was in the tens of millions, it now stands at about 900,000, mostly found in the savannas of Eastern Africa. One of the reasons for this decline in numbers is hunting, both for food and for sport. The African buffalo is not considered to be in danger of extinction as long as it remains protected in parks and reserves, although habitat loss continues (Huffman 2006; ICUN 2016). In Asia, dwarf buffalo populations known as mountain anoa (*Bubalus quarlesi*) and lowland anoa (*Bubalus depressicornis*), which are similar in appearance and size (weight 150–300 kg) have been classified as endangered, and the population continues to decrease (ICUN 2016). Both populations are found on the island of Sulawesi in Indonesia and the nearby island of Butung. The tamaraw (*Bubalus mindorensis*) is native to the island of Mindoro in the Philippines. It is believed to have once also thrived on the greater island of Luzon. The tamaraw buffaloes are smaller than other buffaloes, have more hair and are dark brown to grayish black in color. They can be aggressive and have been known to attack humans (Huffman 2006). Tamaraw has been considered highly endangered.

The wild water buffalo (*Bubalus arnee*) is one of the largest members of the Bovidae family in the Indian subcontinent. It was historically distributed across Europe to South and Southeast Asia; they are currently restricted to India, Nepal, Bhutan, Thailand, Cambodia, and Myanmar. With an estimated current global population size of <4000 and a rapidly declining population trend, they are considered as "endangered" by the IUCN (Kaul et al. 2019).

Asiatic buffalo (*Bubalus bubalis*) is a domesticated water buffalo that is assumed to have originated from the wild buffalo (*Bubalus arnee*) that was found in the northeastern region of India (Fahimuddin 1975), and is considered an important animal that affects the agricultural economy. Its worldwide population is approximately 207 million heads (FAO 2019; Rehman et al. 2021). Within the Asian region, approximately 74.80% of buffaloes are found in South Asia, 12.80% in East Asia, and only 8.40% in South-East Asia (Hamid et al. 2017).

There are two types of domestic water buffalo: swamp buffalo, which inhabits Northeast India, Bangladesh, China, and Southeast Asian countries, and river buffalo, which inhabits the Indian subcontinent, South Asia, and the Mediterranean area (Egypt, Italy, and the Balkans). The two buf-

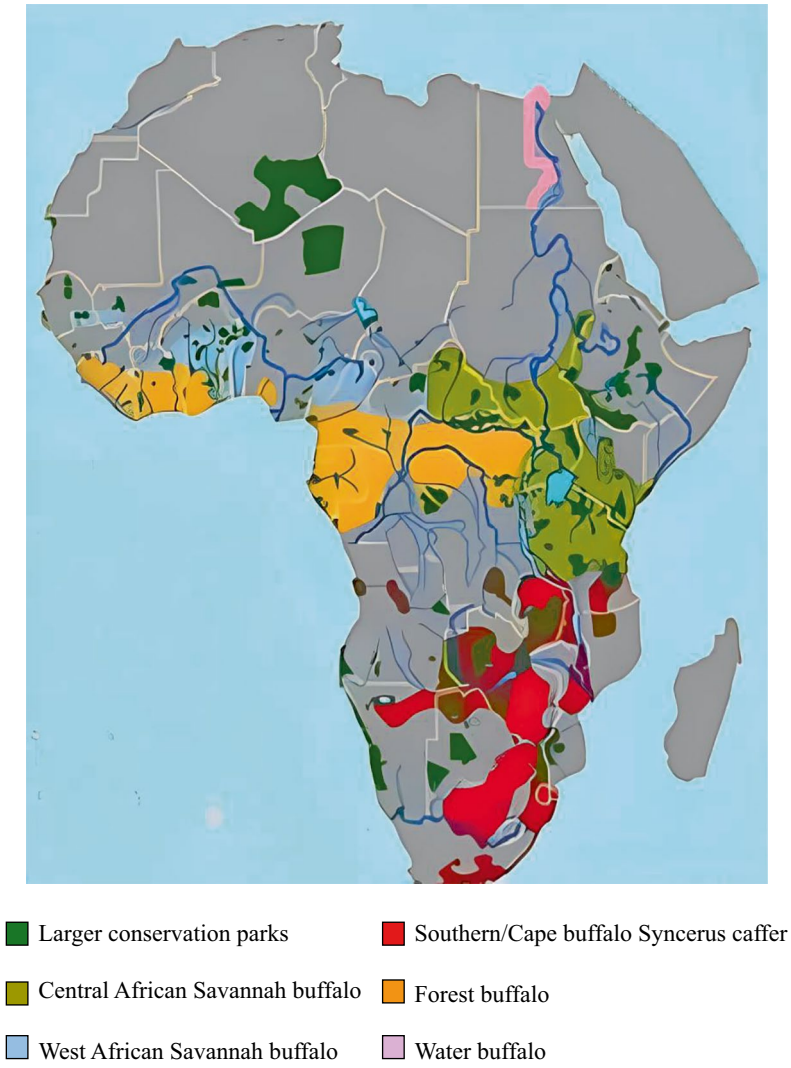

Fig. 12.1 Distribution of wild and domestic water buffalo in Africa. (From Furstenburg (2007), licensed under CC-BY 4.0, modified by adding distribution of water buffalo)

falo types were introduced into South America and Australia (Cockrill 1981).

The river buffalo is black with horns showing a double curvature (at first, they are directed downward and backward, and then curl upward in a spiral) whereas the swamp buffalo is generally dark gray with white chevrons on the throat, white socks, and semi-circular horns that always remain approximately in the same plane as the forehead (Macgregor 1941; Zhang et al. 2020). The river buffalo population constitutes approximately 70% of the world's domestic water buffalo population (FAO 2015). River and swamp buffaloes differ in behavioral traits and purposes with different geographical distributions as well (Cockrill 1974; Borghese 2011). The river buffalo has been selected mainly for milk and meat production with several recognized breeds, while the swamp buffalo has primarily been used for draught power (Borghese 2011; Kierstein et al. 2004; Yindee et al. 2010). The two types also differ in the number of chromosomes; while the river buffalo has 25 pairs of chromosomes (n = 50), the swamp buffalo has 24 chromosome pairs (n = 48) due to a tandem fusion translocation between river buffalo chromosomes 4 and

swamp buffalo chromosome 1. All the chromosomal pairs, including the sex chromosomes, are acrocentric in the two types except for the first five chromosomal pairs, which are bi-armed (Kierstein et al. 2004; Iannuzzi and Di Meo 2009; Michelizzi et al. 2010).

The natural history of domesticated mammals (Clutton-Brock 1996), molecular data, including single-nucleotide polymorphisms (SNPs) and mitochondrial DNA (mtDNA) (Kumar et al. 2007), and archaeological evidence (Colli et al. 2018) have demonstrated the westward migration of the river buffalo from its domestication epicenter to areas as far as the Balkans, Italy, and Egypt. Colli et al. (2018) suggested two independent events of migration that are well matched with population genetic diversity: the first being the proto-Mediterranean gene pool of Italy that came through the Balkans and the second the proto-Middle Eastern gene pool toward the Caspian Sea and Mesopotamia, later extended to Turkey and northern Africa (only in Egypt).

The data of migration routes suggested that the combined effects of multiple migration events which occurred at different stages of the post-domestication history shaped the genetic structure of each water buffalo population in different areas of the world where the buffalo in Italy, Balkan, and Turkey, have unique characteristics that differ from Egyptian water buffalo, which suggests that the Egyptian buffalo is an intermediate breed between the Indian (Eastern) and European (Italian) buffaloes (Michelizzi et al. 2010; Şahin et al. 2014, 2019).

12.2 African Water Buffalo Phylogeny

12.2.1 Maternal Origin

Mitochondrial DNA (mtDNA) polymorphism has a tremendous usage in the study of genetic variation and evolution of various species. This is facilitated by the speed and ease of genotyping a large number of individuals and by the complete absence of genetic recombination in mtDNA, which is inherited through the maternal lineage only. Two of the studies (Ramadan and El-Hefnawi 2008; Hassan et al. 2009) focused on the mitochondrial D-loop region, which is the most variable part of mtDNA due to a higher substitution rate than in the rest of the mitochondrial genome. The results of Hassan et al. (2009) showed the mixed origin of the two Egyptian populations (the Northern and the Southern) and probably indicated the presence of many ancient maternal lineages for the Egyptian buffalo with high diversity in mtDNA sequences. The results also suggested that the Egyptian buffalo did not derive from a unique breed imported from Mesopotamia or India, but rather from multiple migrants. The two studies, however, confirm that the Egyptian buffalo has a common origin with river buffalo in other regions of the world (Hassan et al. 2009; Ramadan and El-Hefnawi 2008).

Because the genetic analysis of the whole mitochondrial genome (mitogenome) of livestock, rather than partial mtDNA sequences, has become an important and indispensable part in breed characterization (Ślaska et al. 2014), mitogenome sequencing was applied in population genetic and taxonomic studies in Egyptian buffalo. Youssef et al. (2021) sequenced and analyzed the mitogenome of 29 Egyptian Northern and Southern river buffalo populations and deposited the mitogenome sequences in the GenBank under the accession numbers: MT237604- MT237632. The authors also made a comparison between the Egyptian buffalo mitogenome and the mitogenome sequences of Bubalus (6 river buffaloes, 112 swamp buffaloes, and the anoa (*Bubalus depressicornis*)) to study their phylogenetic relationships. The phylogenetic analyses supported the paraphyly of the water buffalo species since the anoa (*B. depressicornis*), endemic to Indonesia, was found to be the sister group of the river buffalo, with the swamp buffalo at the outside. This result suggested that river buffalo and swamp buffalo belong to distinct species (Fig. 12.2). With the recent availability of the wild water buffalo (*Bubalus arnee*) mitogenome sequence (Pacha et al. 2021; Hassan et al. 2022), Hassan et al. (2022) reconstructed the phylogenetic relationship between the members of the genus *Bubalus,* including the wild, river, and swamp water buffalo types, and reported close genetic architecture

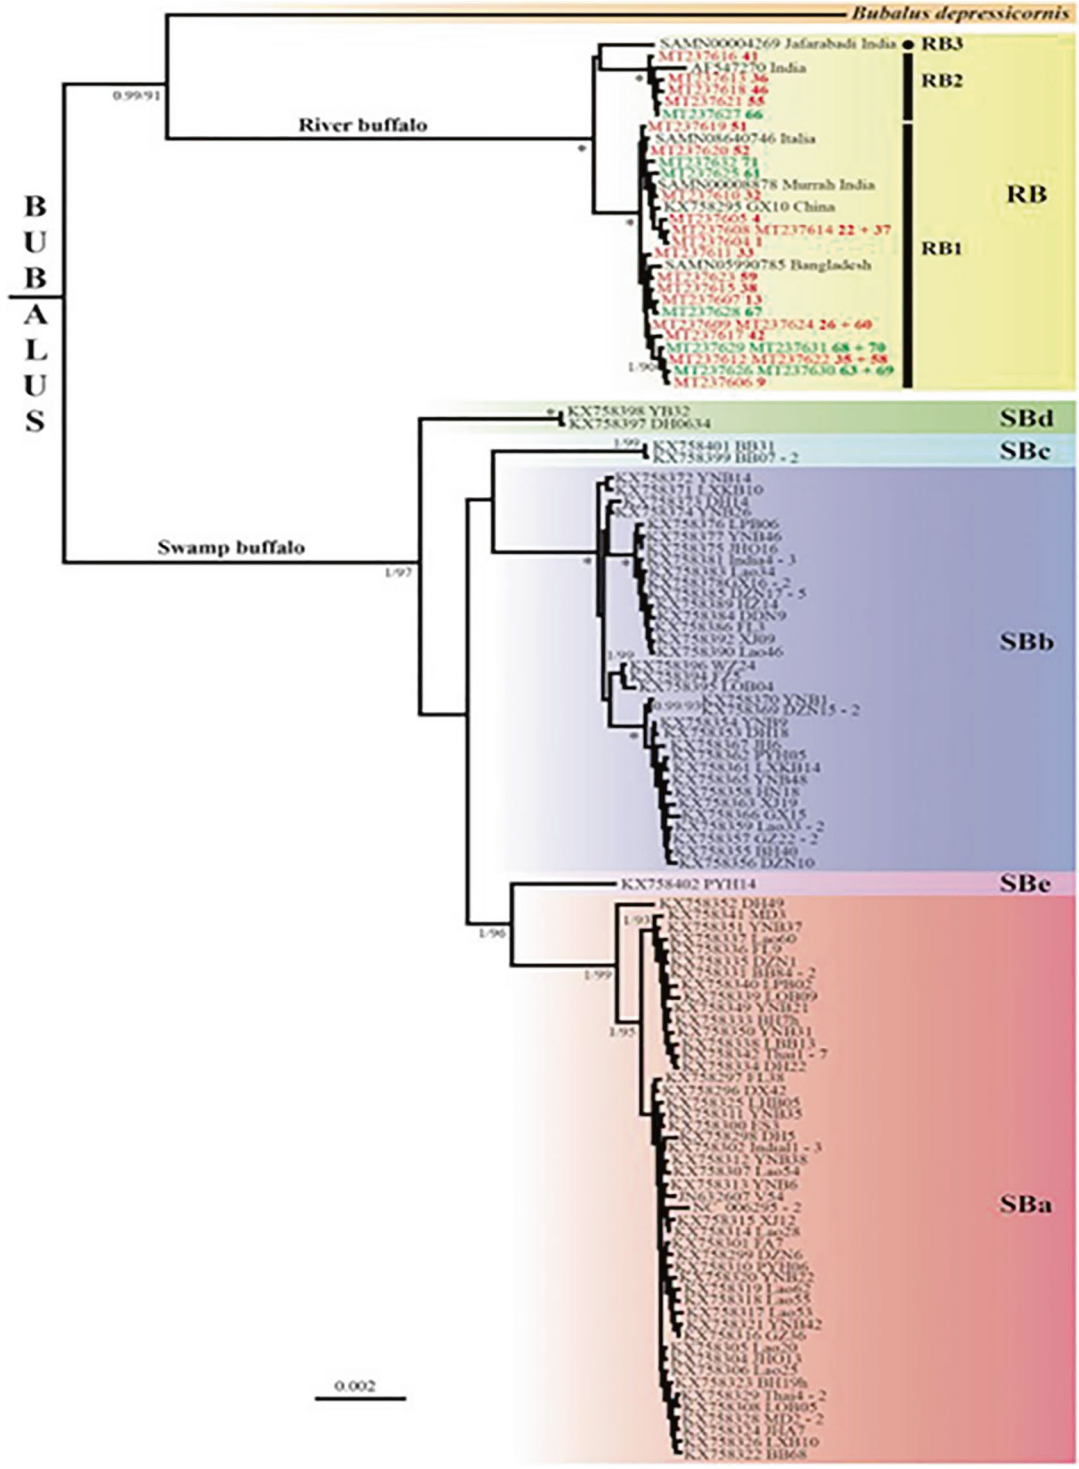

Fig. 12.2 Phylogeny of Bubalus based on complete mitochondrial genomes. The tree was reconstructed with MrBayes software using the 118 mitogenomic haplotypes of Bubalus identified in our alignment of 16,356 nucleotides. The tree was rooted with Syncerus (not shown). Haplogroups showing more than 0.5% of nucleotide divergence are highlighted by different colored rectangles, and those found in the swamp buffalo are named SBa to SBe (the name of the haplotype is followed by a dash and a number when the same haplotype was found in

between the river and wild water buffalo types. The paraphyly of water buffalo species, including *lowland anoa* and *mountain anoa*, river and wild water buffalo, are in a separate clade, leaving swamp buffalo on the outside. The authors confirmed the hypothesis that the river buffalo and the swamp buffalo are two separate species and that the river buffalo is a descendant of wild water buffalo (*Bubalus arnee*) (Fig. 12.3).

12.2.2 DNA Barcoding

DNA barcoding as a genetic tool focuses on the delineation of species rather than their relationships (Hajibabaei et al. 2007). It differs from molecular phylogeny in that the main goal is not to determine classification but to identify an unknown sample in terms of a known classification (Kress et al. 2005). It seeks to assemble a standardized reference library. DNA barcoding is based on the premise that a short standardized sequence can distinguish individuals of a species because genetic variation between species exceeds that within species (Hebert et al. 2003, 2004). The 5′ half (648-bp region) of the mitochondrial cytochrome C oxidase subunit 1 (CO1) gene was proposed as the standard marker for DNA barcoding in animal species (BOLD 2023). Enrichment of barcode databases with COI barcode sequences in different animal taxa has become important for the identification of animal source in food samples to prevent commercial fraud. The 5′ half of the mitochondrial COI gene was used as a DNA barcode for differentiation between different buffalo species and other bovid species, including the Egyptian buffalo. One study differentiated between river buffalo, swamp buffalo, sheep, goat, and cattle (Oraby et al. 2011).

The barcode-based phylogenetic tree assembled using the 5′ half of CO1 gene sequence (650-bp) successfully delineated the investigated species (Fig. 12.4). While another study using the same segment differentiated successfully between the closely related members of the different buffalo species (river buffalo, swamp buffalo, lowland anoa, and African buffalo) (Fig. 12.5) (Hassan et al. 2018).

12.2.3 Genetic Distance Among African Water Buffalo Populations

The Egyptian buffalo population admixture revealed high gene flow between populations, prompting the conclusion that the Egyptian buffaloes belong to one breed (El-Kholy et al. 2007). To detect the genetic variation among Northern and Southern Egyptian buffalo populations, the polymerase chain reaction random amplified polymorphic DNA (PCR-RAPD) and microsatellite markers were used. The results revealed that the populations have the same origin and belong to one breed without significant genetic differences between them (Othman et al. 2012). Other studies used the microsatellite loci to determine the genetic differences between Egyptian buffalo populations from different agroclimatic regions. The results recorded a high level of inbreeding in all populations, a low level of genetic differentiation and reduction of heterozygosity among the different buffalo populations (Abou-Bakr and Attia 2012; Merdan et al. 2020). Although several studies confirmed that the Egyptian buffalo is one breed, it has many local names according to the governorate in which they are raised, such as Al- Buhairi, Al-Menoufi, and Al-Saeedi (Fig. 12.6).

Fig. 12.2 (continued) least two individuals). Among the 29 mitogenomes of Egyptian river buffalo, the 21 samples collected from North are indicated in red, whereas the eight samples collected from South are indicated in green. The four mitogenomes of river Buffalo assembled using SRA data available in GenBank are named with the SAMN accessions. For nodes supported by bootstrap percentage (BP) _ 90 in the RAxML analysis (see details in Material and Methods), the two values correspond to the posterior probability (PP calculated using MrBayes software, left of the slash) and BP (right of the slash). An asterisk is used when both MrBayes and RAxML analyses provided maximal support values, i.e., PP ¼ 1 and BP ¼ 100, respectively. No information was provided for nodes supported by BP <90. (From Youssef et al. (2021), licensed under C-C BY 4.0)

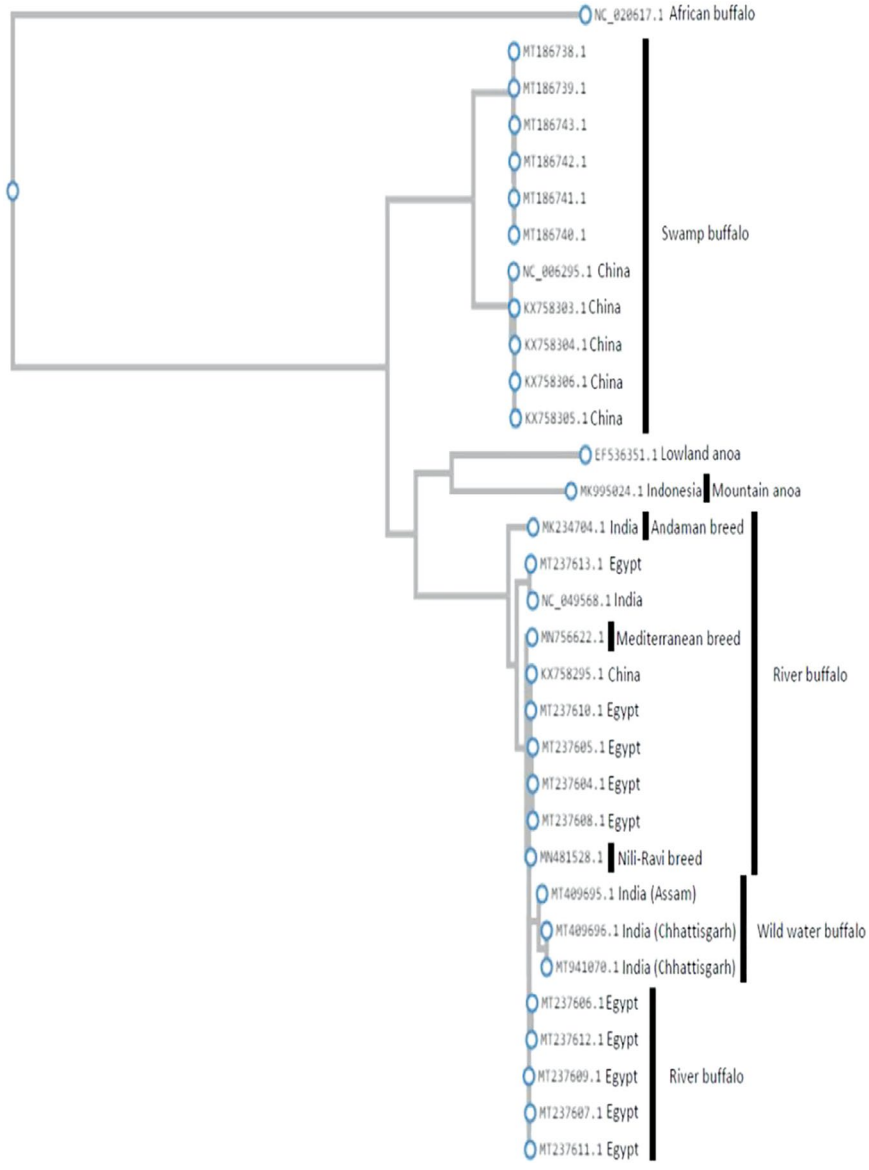

Fig. 12.3 Phylogeny of genus *Bubalus* based on complete mitochondrial genomes. The tree was rooted with African buffalo. (From Hassan et al. (2022), licensed under C-C BY 4.0).

12.3 Buffalo Gene Mapping

Gene mapping is an important tool for mapping disease genes or quantitative trait loci (QTL) used for genetic improvement.

12.3.1 Physical Gene Map

The buffalo genome was established as a first step to identifying loci controlling physiological and quantitative traits. A plethora of research

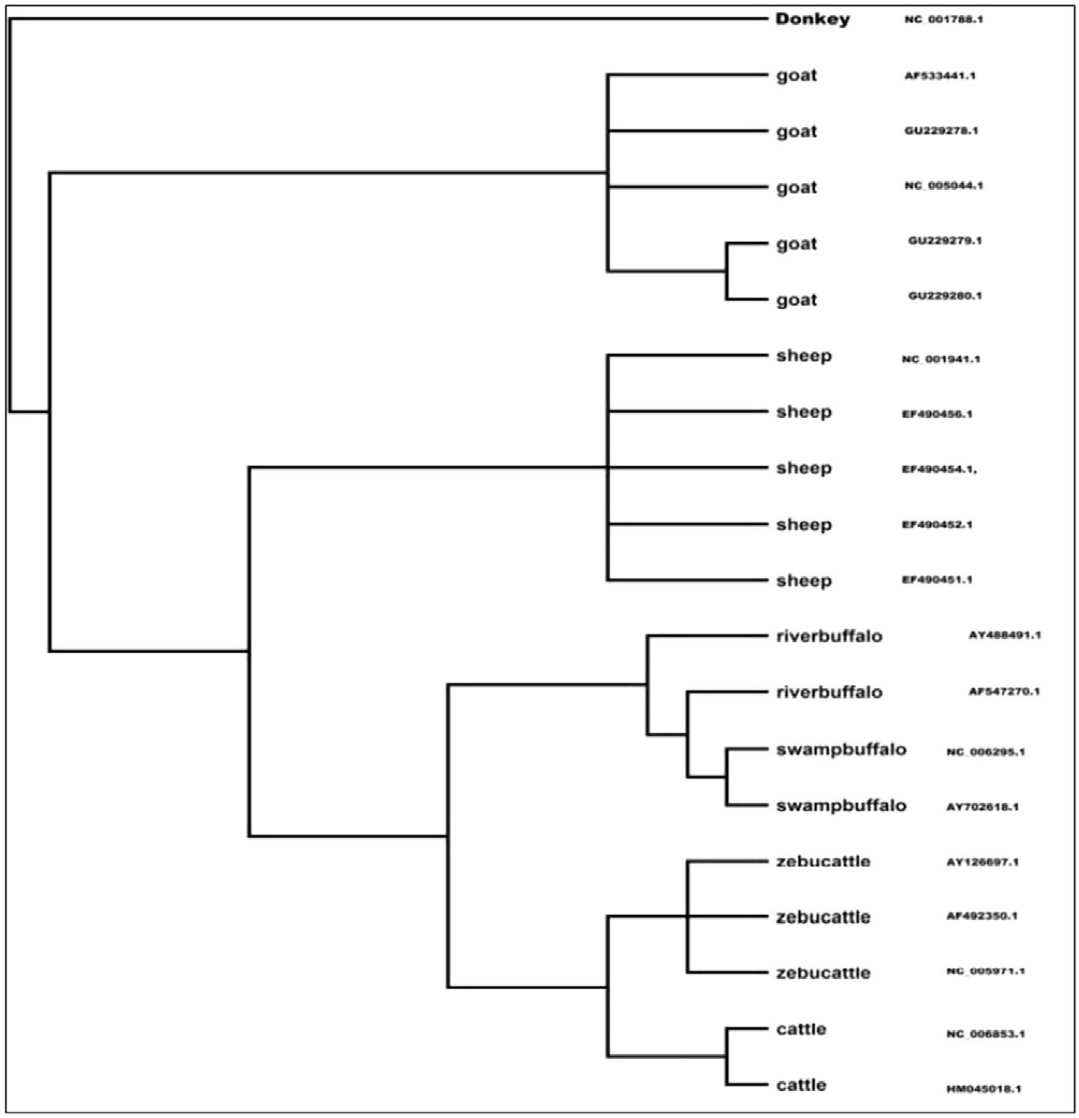

Fig. 12.4 A phylogenetic tree assembled using the 5′ half of CO1 gene sequence (650-bp) in all the investigated species and the donkey sequence as an outgroup. Accession numbers are given to all samples. (From Oraby et al. (2011), licensed under C-C BY 4.0)

studies around the world have investigated and assign genes of buffalo traits on different chromosomes of the Egyptian buffalo (de Hondt et al. 1997; Nahas et al. 1993, 1996, 1997, 1999; El Nahas et al. 1996a, b, 1997, 2001; Hassanane et al. 1993, 1994; Oraby et al. 1998; Othman and Nahas 1999; Ramadan et al. 2000; Mahfouz 2007). The physical cytogenetic buffalo map provided information for 388 gene loci, most of them having homologs mapped in other species (Di Meo et al. 2008) and/also assignment of the genes' syntenic groups to chromosomes (El Nahas et al. 1996a).

12.3.2 Radiation Map

The radiation map (RH map) of river buffalo was established based on cattle-derived markers, with aim to provide a more extensive resource for

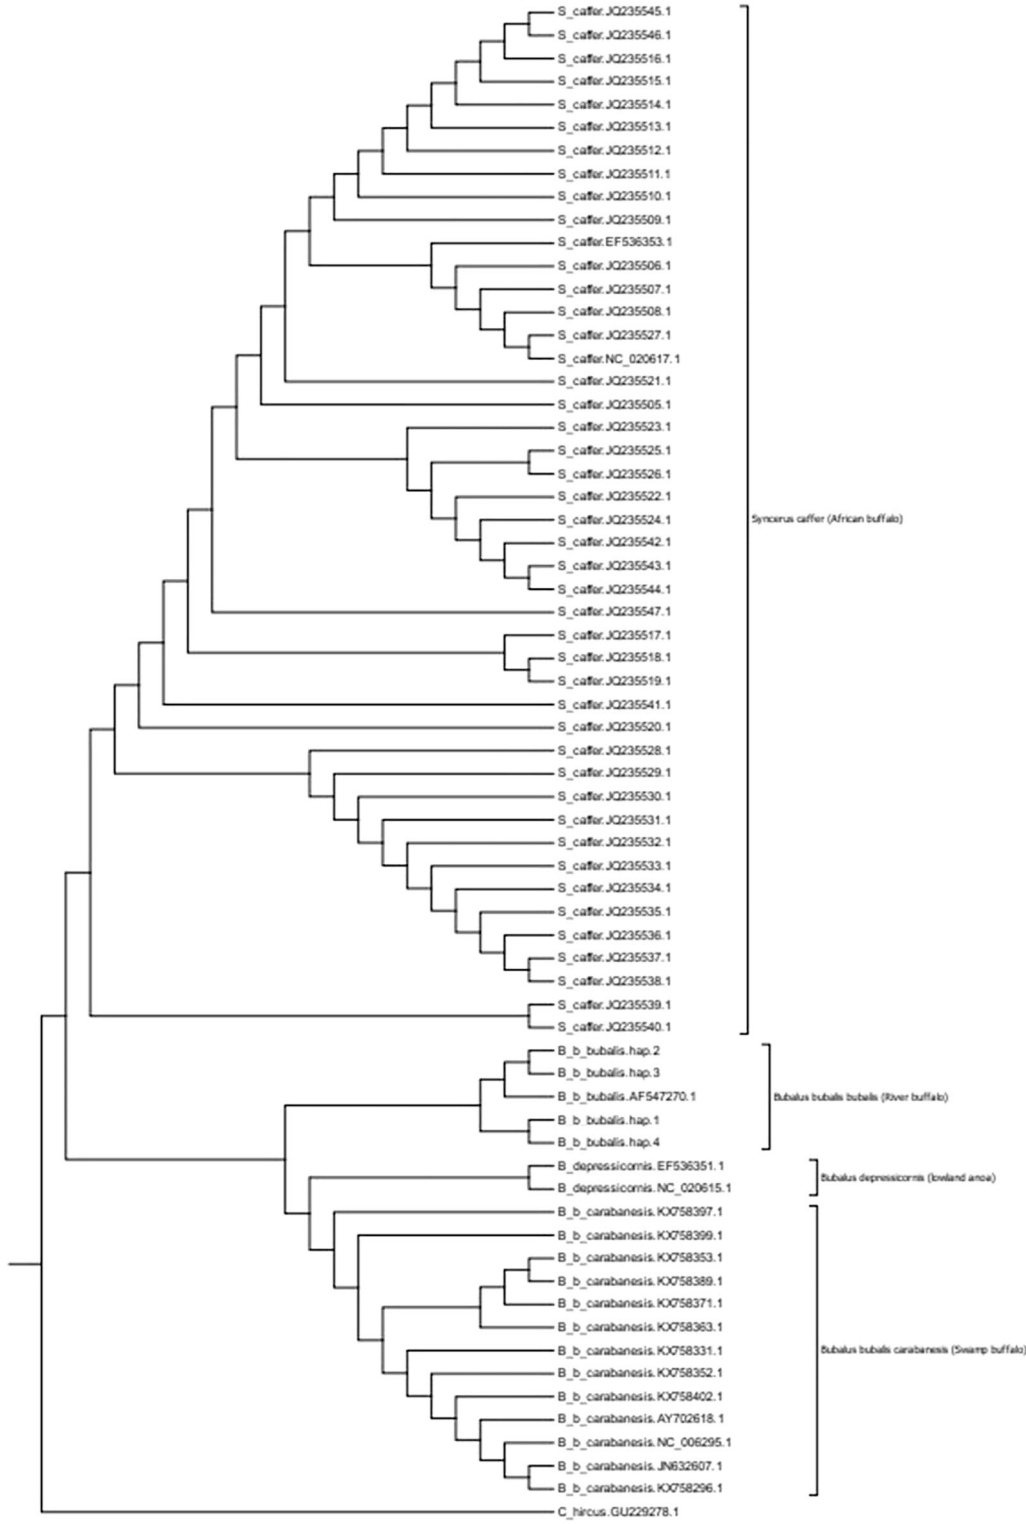

Fig. 12.5 COI (mitochondrial cytochrome C oxidase subunit 1) barcode-based phylogenetic tree constructed using sequences from four buffalo taxa groups and a sequence of goat (*Capra hircus*) as an outgroup. *Hap*. haplotype. (Hassan et al. 2018, licensed under C-C BY 4.0).

Fig. 12.6 Egyptian buffalo types

positional candidate mapping of genes associated with complex traits, obtain information for genome-wide scans and detect chromosomal regions contributing to economically important traits and for large-scale physical mapping of the river buffalo genome. However, despite the important information provided by the RH map, the buffalo RH map is still based on limited studies.

The construction of the RH map for river buffalo chromosome 1 (BBU1 map) presented two linkage groups which included linkage group 1 (LG1; a total of 58 markers (39 coding genes, 15 microsatellites and four ESTs) spanning the entire short arm and extending across much of the long arm, with 47 markers placed as framework and 11 markers placed in bins) and linkage group 2 (LG2; 11 markers (nine coding genes and two microsatellites) covering the remaining portion of the BBU1 long arm with 9 framework markers and two placed in bins) (Miziara et al. 2007). The first-generation whole genome radiation map (RH map) for buffalo was developed by Amaral et al. (2008). The results of their study detected 3990 markers on the BBURH5000 panel, of which 3072 were cattle-derived SNPs. The remaining 918 were classified as cattle sequence tagged site (STS), including coding genes, ESTs, and microsatellites. RH mapping analysis by El Nahas et al. (2014) reported that the BBU7 RH5000 map is composed of 22 RH markers (19 genes and three sequence-tagged sites (STSs). Nine genes (ADRB3, ATP2C1, COPB2, CRYGS, P2RY1, SLC5A3, SLC20A2, SST, and ZDHHC2) and one microsatellite (CSSM043) were added by Stafuzza et al. (2015) to the set of markers previously mapped on BBU1.

12.4 Genetic Diversity in Africa Buffaloes

Advanced molecular technologies such as whole-genome sequencing, genome-wide association study (GWAS), gene expression profiling, next-generation sequencing (RNA and DNA), and genome-wide CHIP-seq scanning are used to detect genetic variants and study gene regulation, gene functioning, and single nucleotide polymorphism (SNP) required to differentiate molecular phenotypes and predict breeding values to screen superior mates to produce improved progeny and sustainable management of genetic resources (See Chap. 20).

12.4.1 Marker-Assisted Selection and Quantitative Trait Loci

Quantitative trait loci (QTL) are specific regions on chromosomes that harbor genes controlling reproduction, production, and disease resistance traits. QTL analysis is an important tool to correlate between two types of information, phenotypic data (trait measurements) and genotypic data (molecular markers) that are used to carry-out marker-assisted selection (MAS) of desirable traits required for inclusion in a breeding program and sustainable management of the animal genetic resources (See Chap. 20).

12.4.1.1 Growth Trait

Growth trait is an important economic trait in farm animals. Studying the genes associated with growth is essential for the identification and inclusion of the desirable genotypes in breeding strategies. However, few studies on growth traits have been conducted on buffalo.

The micromolar calcium-activated neutral protease (*CAPN1*) gene is reported as the primary enzyme in the postmortem tenderization process, and the Leptin (*LEP*) gene is considered a candidate gene for performance, carcass, and meat quality traits in beef cattle. Using the method of polymerase chain reaction (*PCR*)—restriction fragment length polymorphism (*RFLP*), Othman et al. (2011) reported genetic diversity in these genes in the buffalo population, whereby tested buffaloes were genotyped as CC for *CAPN1* and AA for *LEP* gene. Genetic characterization of growth hormone and its receptor genes was studied using the *PCR-RFLP* method. The result showed that all tested buffaloes are genotyped as LL for growth hormone (*GH*) and GG for growth hormone receptor (*GHR*) gene, with GenBank accession numbers JN809916 and JN809917, respectively (Othman et al. 2012). Insulin-like growth factor 2 (*IGF2*) is considered a marker for growth traits in farm animals. *PCR-SSCP* (single-strand conformation polymorphism) results recorded a novel single-nucleotide polymorphism (SNP), C287A in exon 10 of the IGF2 gene, with SSCP frequency patterns of 54% (AA), 32.5% (AC), and 13.5% (CC). Association analyses revealed that the AA individuals had a higher average daily gain (ADG) than individuals of CC and AC genotypes from birth to 9 months of age (Abo-Al-Ela et al. 2014). The hypothalamic hormone, growth hormone-releasing hormone (*GHRH*) and its receptor are candidate genes for growth and milk traits. The *GHRH* acts as a stimulator of pituitary growth hormone (*GH*) synthesis and secretion. It has an influence on increasing milk yield, protein, and fat content. The genetic diversity of buffalo *GHRH* and *GHRHR* genes based on *PCR-RFLP* and sequence alignment revealed that all tested buffalo are of genotype AA (GenBank accession number is KC295414) (Othman et al. 2015).

12.4.1.2 Milk Traits

Genetic characterization and association of genetic variants with milk traits (e.g., milk secretion, protein, and fat) is important in breeding programs for milk production (Togashi et al. 2019). Table 12.1 shows the genetic diversity of candidate milk trait genes of kappa-casein (*k-casein (CSN3)*), ATP Binding Cassette Subfamily G Member 2 (*ABCG2*), oxidized low-density lipoprotein receptor 1 (*OLR1* or *Ox-LDL* receptor 1 or *LOX1*), peroxisome, proliferator-activated receptor gamma, coactivator 1 alpha (*PPARGC1A* or PGC1A), stearoyl-CoA desaturase 1 (*SCD1*), prolactin (*PRL*), prolactin promoter (*PRL* promoter), pituitary-specific

Table 12.1 Genetic diversity of milk traits genes and association with different milk production measures

Gene	Function	Molecular detection method	Genetic diversity	Trait	Accession number	Marker-trait association	Reference
k-CN (*CSN3*)	Casein gene family	PCR-RFLP	Monomorphic	–	–	–	Othman (2005), Othman et al. (2011), Gouda et al. (2013), El Nahas et al. (2013), and Al-Shawa et al. (2020)
		PCR-nucleotide sequencing	Two polymorphic variants in exon IV at codon 135 and 136	–	–	–	
PRL	Role in mammary gland development, lactogenesis, and expression of milk protein genes	PCR-RFLP	Monomorphic	–	–	–	Othman et al. (2011)
PRL promoter		PCR-SSCP and nucleotide sequencing	Two genotypes	MY, FP, PP, LP, and LL	–	no significant association with milk traits production and composition	El-Magd et al. (2015)
PIT-1 (*POU1F1*)	Role in pituitary development and hormone secretion in mammals	PCR-RFLP	Monomorphic	–	–	–	Othman et al. (2011)
Microsatellite markers (BM1706, BMS711, BM143, BM415, BM6438, ETH131, BM1443, ETH2)	Highly reproducible and specific	PCR	Polymorphic	ADMYD, FP, PP, FY, PY	–	BM415 has a significant influence on protein yield	Rushdi et al. (2017)
ABCG2	It plays a protective role	PCR-RFLP	Two polymorphisms	–	–	–	Hassanane et al. (2016)
OLR1	It plays a role in lipid metabolism	PCR-RFLP	Two polymorphisms	–	–	–	Hassanane et al. (2016)
SCD1	Its expression affects the fatty acid composition of membrane phospholipids	PCR-RFLP	Two polymorphisms	–	–	–	Hassanane et al. (2016)

(continued)

Table 12.1 (continued)

Gene	Function	Molecular detection method	Genetic diversity	Trait	Accession number	Marker-trait association	Reference
PPARGC1A (P616L; T19C, A968C)	It regulates a whole range of nuclear hormone receptors and other transcription factors, affecting adipogenesis, adipocyte differentiation, and mitochondrial biogenesis	PCR-RFLP	Two polymorphisms	–	–	–	Hassanane et al. (2016)
β-LG	It is the major whey protein of ruminant species. Is an important source of bioactive peptides	PCR-RFLP	Monomorphic	–	–	–	Al-Shawa et al. (2020)
GHR (4, 5, 6, and 8 exons)	Receptor for pituitary gland growth hormone involved in regulating body growth.	PCR-SSCP and nucleotide sequencing	Two SNPs: 380G>A and 836T>A	MY, PP, and FP	KC107765	Two SNPs were associated with higher performance of MY, FP, and PP for AA haplotype	El-Komy et al. (2020)

transcription factor (*PIT-1* or *POU1F1*), microsatellite markers, β-Lactoglobulin (*β-LG*), and growth hormone receptor (*GHR*) in Egyptian buffalo.

12.4.1.3 Fertility Traits

Fertility may be considered as two traits, which are inherent fertility and expressed fertility. Inherent fertility is referred to as the genetic potential for reproduction performance and is not directly measurable (Ahmed et al. 2011). Candidate genes were investigated to detect the molecular characteristics of genes associated with fertility traits in buffalo. PCR-RFLP, SSCP, and sequencing techniques were used to detect the genetic variations in candidate genes of reproduction traits. The fertility measures were calving interval, ovarian activity, repeat breeder, anestrus, and semen traits. Table 12.2 shows the genetic variations of the candidate fertility traits genes follicle-stimulating hormone receptor (*FSHR*), insulin-like growth factor1 (*IGF-1*), insulin-like growth factor1-receptor (*IGF-1R*), inhibin beta-A (*INHBA*), signal transducer and activator of transcription5 (*STAT5A*), luteinizing hormone receptor (*LHR*), estrogen receptor-α (*ERα*), cytochrome P450 aromatase (*CYP19A1*) gene, bone morphogenetic protein 15 (*BMP15*), FSH beta-subunit (*FSHB*) lactoferrin (*LF*) and leptin (*LEP*). For semen traits, the genes are gonadotropin-releasing hormone receptor (*GnRHR*) gene and pituitary-specific transcription factor (*PIT-1or POU1F1)* gene.

12.4.1.4 Immune Traits

The immune system is regulated by several thousand genes (8–9% of the genome), indicating its high genetic priority as a critical fitness characteristic that supports species survival. Identifying and raising livestock with an inherent ability to produce superior immune responses can reduce disease incidence, improve milk quality, and increase farm profitability. However, few studies have been conducted on Egyptian buffalo immune traits.

The *BoLA-DRB3* gene is one of the major histocompatibility complex (*MHC*) subclass IIα genes. Due to its role in the development of an immune response and its highly polymorphic nature, it is considered the most important candidate gene in disease resistance. Genetic characterization of *BoLA-DRB3* exon 2 by *PCR-RFLP* method (284-bp product) revealed five genotypes, including three homozygous genotypes AA (6%), BB (34%) and DD (4%), and two heterozygous genotypes AB (36%) and BD (20%) in tested animals (Othman and Ahmed 2010). Another study correlated the polymorphism of the *BoLA-DRB3* gene (exon 2) with foot and mouth disease (*FMD*) resistance. Specifically, the genotype AA may be associated with *FMD*-resistance, especially *FMDV* serotype O, compared to the AC genotype (Othman et al. 2018).

Mastitis is an infectious disease of the mammary gland that leads to reduced milk production and changes in milk composition. The interleukin 8 receptor gene (*IL8RB*) is a genetic marker in inflammatory responses during mastitis, while complement component (C3) plays a major role as a central molecule of the complement cascade involved in the killing of microorganisms, either directly or in cooperation with phagocytic cells. The CXCR2 sequence of IL8RB 124-bp covering a part of intron 1, exon 2 and a part of 3'UTR (Genbank accession #KY399457.1) was analyzed to detect the genetic structure associated with mastitis. The result indicated a potential association between SNP C/A at c.127 and mastitis (El Nahas et al. 2017). Six novel SNPs were detected in buffalo C3 cDNA sequences, and the C>A substitution (ss: 1752816097) in exon 27, together with the milk somatic cell score, are considered indicators of mastitis (El-Halawany et al. 2017a).

12.4.2 Whole-Genome Sequencing and Characterization

Whole-genome sequencing and genome-wide association studies (GWAS) provide an opportunity for the analysis of genotype–phenotype relationships in livestock and identification of selective sweeps associated with performance traits and adaptation. A total of five annotated buffalo genome assemblies have been deposited

Table 12.2 Genetic diversity of fertility traits genes associated with different fertility measures

Gene	Function	Genetic diversity	Trait	Accession number	Marker-trait association	Reference
FSHR	It is the binding receptors for FSH hormone, expressed by granulose cells and during the luteal phase in the secretory endometrium of the uterus	Three polymorphic patterns in exon 10	Calving interval	–	Pattern 2 was recorded with high fertility	Ahmed et al. (2011)
			Repeat breeder		The genotype GG recorded with repeat breeder animals	Fouda et al. (2021)
IGF-1	Necessary for the process of follicular development and ovulation	Two polymorphic patterns	Calving interval	–	Does not affect fertility	Ahmed et al. (2011)
IGF-1R	Critical for the normal development of the mammary gland tissue during pregnancy and lactation	Four polymorphic patterns	Calving interval	–	Does not affect fertility	Ahmed et al. (2011)
INHBA	Involved in the recruitment and development of ovarian follicles during folliculogenesis	Monomorphic	Calving interval	–	Does not affect fertility	Ahmed et al. (2011)
STAT5A	Responsible for the initiation and maintenance of pregnancy in ruminants	Three polymorphic patterns	Calving interval	–	Pattern 2 was recorded with high fertility	Ahmed et al. (2011)
LHR	Regulates gonadal function, including steroidogenesis and gametogenesis	Monomorphic in exon 11	–	JQ885687	Not detected	Othman and Abdel-Samad (2013) and Sosa et al. (2016)
ERα	Estrogen receptors play important roles in reproduction, development of the mammary gland, growth and differentiation of cells	Two polymorphic alleles in exon C	–	JQ308795 JQ308796	Not detected	Othman and Abdel-Samad (2013)
Cyp19	Key enzyme in estrogen biosynthesis	Three polymorphic patterns in exon 2	ovarian activity	KJ551928 KJ551929	The substitution of nucleotide T by C at position 72 in exon 2 of Cyp19	Othman et al. (2014)

CYP19A1	Regulates estrogen biosynthesis	Four single nucleotide polymorphisms (SNPs) in exon 10 and 2 SNPs in exon 5	Anestrus		SNP-anestrus association analyses revealed that genotypes (CC, AA and GG) and alleles (C, A and G) of the −135T>C, c.559G>A and c.1394A>G SNPs respectively were high risk for anestrus	El-Bayomi et al. (2018)
BMP 15.1 *BMP 15.2*	Play crucial roles in ovarian follicular development and ovulation rate.	Monomorphic—in 5UTR & exon 1	repeat breeders	KU043381	Does not affect fertility	El-Bayomi et al. (2016)
FSHB	Essential for regulation of gametogenesis and follicular growth	Two polymorphic patterns		M83753.1		Sosa et al. (2017)
LF	Has wide biological roles	Two polymorphic alleles in intron 6	- Repeat breeder - Anoestrum	KX228134 KX228137 KX228135 KX228136		Eldebaky et al. (2020)
LEP	Involved in the metabolism and growth of animals and plays a role in regulation of the reproductive hormones GnRH/LH	Two polymorphisms in intron 2	Normal and abnormal ovary and uterus	AH013754.2	Does not affect fertility	El-Debaky et al. (2020)
GnRHR	Stimulate the synthesis and release of both follicle-stimulating hormone and luteinizing hormone	Two polymorphic patterns. Two SNPs as a transversion base substitution mutation at positions 20 (T/A) and 193 (A/T)	Semen trait	EU621854.1	Pattern I was seen in good motility, with incidence of 100%. Pattern II appeared only in poor semen motility.	Mahmoud et al. (2021)
		Three polymorphic patterns with 5 single nucleotide polymorphisms including one nucleotide insertion, one nucleotide deletion and 3 nucleotide substitutions between the three patterns	Repeat Breeder Anoestrum	NM_001290857.1	Pattern III reported infertile animals showed insertion was at position 4, deletion was at position 189, and the 3 nucleotides substitutions were at positions 204 (T/G), and 207 (A/T)	Sosa et al. (2016)
PIT-1 (POU1F1)	Stimulate expression of growth hormone, prolactin, thyroid, hormone (TSH) β-subunit and gonadotropin-releasing hormone receptor genes	Monomorphic	Semen traits	–	Does not affect fertility	Hasanain et al. (2016)

in the National Center for Biotechnology Information (NCBI) database. The nucleotide sequences submitted to GenBank include 538 microsatellites, 490 minisatellites, 503 satellite sequences, and 273,061 whole-genome sequences. A total of 1,921,573 nucleotide and 34,831 water buffalo gene sequences, including 471 mitochondrial sequences, have been deposited in the GenBank database (Hassan et al. 2022).

The GWAS detected and annotated 436 SNPs along with 34 indels in 38 fertility-related candidate genes in Murrah buffaloes (Surya et al. 2019). For buffalo milk production traits, four GWASs have been conducted so far, including two studies performed on 1018 individual Italian Mediterranean buffaloes (de Camargo et al. 2015; Liu et al. 2018) and two on Egyptian and Brazilian buffaloes (de Camargo et al. 2015; El-Halawany et al. 2017b).

A partial genome assembly of the Egyptian water buffalo has been achieved by El-Khishin et al. (2020). A total of 21,128 genes were identified in the partial assembly including milk virgin-related genes; milk pregnancy-related genes, milk lactation related genes, milk involution-related genes and milk mastitis-related genes.

Recently, the mitogenome of 29 buffaloes from the North and South of Egypt has been sequenced and analyzed by Youssef et al. (2021). The mitogenome of the Egyptian buffalo is a circular double-stranded DNA sequence that is 16,357–16,359 base pairs in length. Similar to other mammalian mitogenomes, the two strands of buffalo mtDNA are a heavy strand (H) rich in guanines and a light strand (L) rich in adenines. The overall base composition of the mitogenome is A: 33.1%, C: 26.6%, G: 13.9%, and T: 26.4%. The genome contains 37 genes in addition to a non-coding control region (D-loop), which is the only region that has different lengths in the 29 investigated buffalo mitogenomes (926–928 bp). The 37 genes comprise 22 transfer RNA (tRNA) genes, 2 ribosomal RNA (rRNA) genes and 13 protein-coding genes. The 22 tRNA genes are tRNA-Phe, tRNA-Val, tRNA-Leu1, tRNA-Ile, tRNA-Gln, tRNA-Met, tRNA-Trp, tRNA-Ala, tRNA-Asn, tRNA-Cys, tRNA-Tyr, tRNA-Ser1, tRNA-Asp, tRNA-Lys, tRNA-Gly, tRNA-Arg, tRNA-His, tRNA-Ser2, tRNA-Leu2, tRNA-Glu, tRNA-Thr, and tRNA-Pro. The two rRNA genes encode for 12S and 16S rRNAs. The 13 protein-coding genes (PCGs) are composed of seven genes: ND1, 2, 3, 4, 4L, 5, and 6 that code for 7 reduced nicotinamide adenine dinucleotide (NADH) dehydrogenase subunits, 3 genes: COX1, 2, and 3 that code for 3 cytochrome c oxidase subunits, 2 genes: ATP 6 and 8 that code for 2 adenosine triphosphate (ATP) synthetase subunits, and a cytochrome b gene (CYTB) that encodes one subunit of cytochrome c reductase. Twenty-eight genes are located on the mitochondrial DNA heavy strand and 9 genes (ND6, tRNA-Gln, tRNA-Ala, tRNA-Ans, tRNA-Cys, tRNA-Try, tRNA-Ser1, tRNA-Glu, and tRNA-Pro) are located on the light strand. The gene arrangement in the Egyptian river buffalo mitogenome is conserved with other mammalian species. All protein-coding genes of the mtDNA have the start codon ATR (ATG or ATA), except ND4L (GTG) and ND2 (ATW = ATT or ATA). Further investigations revealed that eight of the PCGs (ND1, COX1, COX2, ATP8, ATP6, ND4L, ND5, ND6) use the TAA stop codon, whereas ND2 and CYTB use the TGA and AGA stop codons, respectively. However, the stop codons are incomplete in Cox3, ND3, and ND4. The authors detected 78 nucleotide variations along the whole mitochondrial sequence. Forty-four out of the 78 nucleotide variations were detected in the PCGs while the rest of the variations (34 nucleotide variations) were distributed as follows: 3 in the tRNA genes, 2 in the rRNA genes, and 29 in the D-loop region.

12.5 Production Systems, Husbandry Practices, and Production Characteristics

Domesticated water buffalo is an important animal for many countries throughout the world, as it contributes to human food security and social and cultural aspects (Desta 2012; Mohammed 2018). In developing countries, they play a major

part in agricultural economies as important sources of milk, meat and meat products, and skin (El-Debaky et al. 2020). After dairy cattle, the water buffalo is the second most important species in terms of milk production in the world (Coroian et al. 2013). Buffalo milk has a higher content of protein, fat, lactose, and calories than cattle milk (Hamid et al. 2017). However, it only accounts for 13% of global milk consumption due to their small animal population (Liu et al. 2018). Buffalo meat is lean with lower cholesterol and fat contents and with comparatively better taste than beef (Hassan et al. 2022). Furthermore, when compared to cows, buffaloes are better at transferring low-quality forages with low digestible characteristics to milk or meat (Ibrahim 2012; El-Debaky et al. 2020; Li et al. 2020) and have a high ability to adapt and survive in a variety of habitats with varying topography, climate, and vegetation (Li et al. 2020). Buffalo also contributes a significant amount of leather to the global market (FAOSTAT 2014). Its manure is utilized as a fuel and heating source, as well as a fertilizer to enrich the soil and reduce the usage of chemical fertilizers (El-Debaky et al. 2020).

With all these distinctive qualities, buffaloes in Egypt occupy a prominent place in the life of Egyptian farmers as an important source of red meat, milk, and a long productive life (Attia et al. 2014; El-Magd 2015; FAO 2019). The Egyptian customer prefers buffalo milk because of its white color, great quality (in rural areas where unpasteurized milk is consumed), and high fat percentage (El-Magd 2015; Al-Hosary et al. 2015). The Egyptian buffalo population is around 3.5 million heads (FAO 2019; Di Stasio and Brugiapaglia 2021). The production of buffalo accounts for 44% and 36% of Egypt's total milk and meat production, respectively (FAO 2019).

Buffalo breeding management in Egypt is mainly two systems: smallholder and pri-urban production systems (See Chap. 2). The smallholder production system is traditional, characterized by one to five heads of buffalo, and consists of keeping buffaloes indoors at night and confined in fenced areas during the day. The input and output are relatively low. Buffalo milk from this system is used either for family consumption or sold to neighbors. The peri-urban production system is usually near cities and with an average herd size of nine heads per household. The system is characterized by higher milk production, longer lactation length, and better feeding. Almost all buffaloes are traditionally managed, hand milked and naturally bred. Intensive meat and milk production systems characterized by having more than 50 heads of buffaloes per farm and with better management and mechanical milking systems occur at a limited scale (Arefaine and Kashwa 2015).

The average annual red meat production of the Egyptian buffalo reached 495,000 tons, contributing 45% to overall meat produced; the average slaughter weight is 500 kg, at the age of 18–24 months; carcass yield is 51% and overall growth rate is 700 g/day (Ibrahim 2012). The birth weight of calves ranged from 22 to 36 Kg, while the weight after puberty is 200–250 Kg (Perera et al. 2005). The total milk yield is between 1266 ± 229 and 2607 ± 500, milk/Kg 6.5 ± 1.2 and 10.2 ± 1.62, lactation period/day 198.11 ± 37.8 and 258.1 ± 37.51 (Abdel-Salam and Fahim 2018).

Buffaloes are polyestrous, meaning they can breed at any time of the year. The Egyptian buffalo reproductive features are distinguished by the first calving age at 31.98 ± 4.1 to 32.5 ± 3.8 (month), calving interval at 391.9 ± 44.9 to 404.5 ± 55.7 (day), estrus cycle length 17–26 (day), length of gestation averaged 310 days, while the period from calving to the first service ranged from 49.1 ± 23.7 to 59.6 ± 29.1 (day) (Perera et al. 2005; Abdel-Salam and Fahim 2018).

12.6 Genetic Resources Conservation

Advanced biotechnology techniques, molecular genetic tools, ex situ and in situ conservation tools are used to achieve the goals of sustainable livestock management strategies (Baruselli et al. 2013).

12.6.1 Biotechnology Tools

Biotechnology is widely acknowledged as having a role to play in resolving the production restrictions of small-scale or resource-poor farmers, who account for over 70% of food production in developing countries. A wide range of assisted reproductive technologies (ARTs), from artificial insemination to advanced transgenesis and genome editing, have been effectively employed to improve livestock productivity and value. Recent advancements like recombinant DNA technology and associated procedures, monoclonal antibody techniques, embryo manipulation technologies (Baruselli et al. 2007; Hoshino et al. 2009; Selokar et al. 2014) have been introduced as well. Also, artificial insemination (AI), in vitro embryo production, sex preselection, and stem cell technology are examples of revolutionary ARTs that have boosted the production potential of domesticated animals (See Chap. 20).

Artificial insemination (AI) is the only ART tool used for improving the Egyptian buffalo. It is however only used in 1% of the medium to large herds farms. There are six AI stations owned by the government and one by the university, which house a total of 70 bulls. Artificial insemination is still performed at the research level; usually only one semen dose is offered at each estrus, conception at the first estrus being 30% (Abdel-Salam and Fahim 2018; Mohammed 2018).

12.6.2 In Situ and Ex Situ Conservation

Conservation of genetic resources is based on keeping the genetic variation as gene combinations in a reversible form and keeping specific genes of interest. In situ conservation is the maintenance of the breed within the livestock production system and its environment through the enhancement of its production characteristics. This approach needs extensive infrastructure and management, which involves the maintenance of the genetic variation through continued use by livestock keepers. Successful in situ conservation usually requires a performance recording and development of breeding programs with special emphasis on maintaining the genetic diversity within the breed by the livestock keepers, along with the willingness to invest in technologies that improve productivity, such as AI, veterinary services, or supplemental feeding (FAO 2013) (See Chap. 25).

Ex situ in vitro conservation is the preservation of genetic material in haploid form (semen and oocytes), diploid (embryos), or DNA sequences. The Convention on Biological Diversity recommended that ex situ conservation be complementary to in situ conservation for farm animal genetic resources (Prentice and Anzar 2011). Few studies have been reported for cryopreservation of semen, oocytes, and embryos to optimize the methodology in vitro. Successful cryopreservation of Egyptian buffalo ovaries using in situ oocyte cryopreservation was achieved by Abd-Allah (2009). Another study by El-Sayed et al. (El-sayed et al. 2017) proved that the cryotop is an effective tool for cryopreservation of in vitro produced Egyptian buffalo blastocysts.

12.7 Challenges of Buffalo Production and Opportunities

The improvement of the productivity of the Egyptian buffalo, preservation of its genetic resources and its sustainable management face many problems that include poor nutrition, inadequate housing, lack of appropriate veterinary care, and poor management and breeding methods. Additionally, AI, milk recording, genetic screening, and milk marketing systems are not available. Furthermore, most buffaloes at smallholder farmers are bred spontaneously with untested bulls, i.e., bulls that have not been selected for improved production and have not had their reproductive disorders investigated. Furthermore, there are no connections between recording, genetic assessment, and AI institutions, therefore, there are no buffalo genetic enhancement initiatives in Egypt. Despite a major objective to retain and protect native breed genetic materials, the risky use of imported fro-

zen semen without awareness and measures could impair the genetic efficiency of native buffalo breeds.

12.8 Implications and the Way Forward

Advancements of biotechnology and molecular genetics combined with improved breeding programs should help advance improvements in production, environmental adaptation, and disease resistance for this economically important livestock. Therefore, future development plans for the water buffalo should focus upon:

1. Use advanced biotechnologies in buffalo breeding programs, as well as select and use superior males and females in breeding programs.
2. Create banks for oocytes, sperms, and embryos produced in vitro from animals with superior genetic traits in order to preserve the buffaloes' genetic material.
3. Focus on research data that correlates the phenotype (trait measurements) and genotype (molecular markers).
4. Develop MAS of desirable traits in breeding programs.
5. Sustainable management of the buffalo genetic resources.
6. Develop community-based breeding programs for buffalo breeders.
7. Increase efforts by state departments and scientific and research institutions on improving buffalo production in Egypt.
8. Create animal production projects and enact supporting laws and legislations that prevent the slaughter of genetically superior animals from the buffalo population.

13 Nonconventional Animal Genetic Resources, Diversity, and Unique Features

Kingsley A. Etchu, Abdelkader Ameur Ameur, M. Chahbar, Félix Meutchieye, Annick N. Enangue Njembele, Gerald C. Tasse Taboue, and Semir B. S. Gaouar

Abstract

The African continent abounds in rich faunal diversity, which should contribute significantly to human nutrition. Before the introduction and establishment of conventional livestock and farming systems, Africans fed on animals found in their environment. Here is a non-exhaustive list of some edible animals: gastropods (marine or terrestrial snails), amphibians, small mammals (grasscutters, porcupines, rabbits, etc.), and insects and their larvae (caterpillars, grasshoppers, palm weevil larvae, etc.).The development of conventional animal husbandry systems has resulted in the reduction or even the abandonment of the consumption of certain types of animals now called nonconventional livestock. However, the conventional livestock system struggles to meet the animal protein needs of the African population. In order to fill this shortage in animal proteins, Africans have turned to and are relearning to consume abandoned traditional animal resources. In this chapter, four species, namely the frog, land snail, rabbit, and honeybee, are highlighted.

13.1 Introduction

Conventional livestock are animals raised in an agricultural system in order to produce meat, eggs, milk, and other products used for human consumption. Therefore, animals that do not follow the above definition are called nonconventional livestock. Animal protein consumption in Africa is below the WHO recommendation. The conventional livestock system continues to endeavor to meet the animal protein needs of the African population. Africans have turned to or are relearning to consume abandoned traditional animal resources. In this chapter, four species are highlighted: frog, land snail, rabbit, and honeybee.

13.2 Frog in Africa: The Goliath Frog

13.2.1 Introduction

Amphibians are known for their dual lifestyles, living in water and on dry land. They have medicinal properties and are used in cultural settings (Gonwouo and Rödel 2008; Mohneke et al. 2010; Efenakpo et al. 2016). Amphibians constitute a source of protein and other nutrients in human and livestock diets (Gonwouo and Rödel 2008; Karamoko et al. 2011; Oduntan et al. 2012). Amphibians also have cultural values, and their use in cultural rites such as weddings has been documented (Gonwouo and Rödel 2008). They have been used to cure human infertility by the Bakossi people of Cameroon (Gonwouo and Rödel 2008). In sub-Saharan Africa, various amphibians are consumed by humans. These are directly harvested from the field. The rate at which they are naturally harvested has led to consideration of captive breeding. Some markets are dedicated to frogs in West Africa, where they are sold as dried or smoked stock (Mohneke et al. 2010). In Central Africa, for instance, frogs are harvested for home consumption and either sold on the roadsides or on market days.

The Goliath frog (*Conraua goliath*), known as the largest living frog on earth, is commonly called the giant slippery frog or the goliath bullfrog. It is a species of frog in the family Conrauidae.

The population of Goliath frogs in the wild in Cameroon is decreasing because of accelerated habitat loss caused by deforestation, hunting, and overharvesting from the wild for the pet trade and consumption. Despite its protected status in Cameroon (class A species: not allowed for hunting (MINFOF 2020)), this frog is systematically collected from the field mainly for consumption. An adult Goliath frog has an average snout–vent length of 22–32 cm for males with an average weight ranging from 1.5–2.7 kg and 15–32 cm snout–vent length for females with an average weight of 0.6–3.3 kg (Krüger 1912; Sabater-Pi 1985; Channing and Rödel 2019).

Adult *Conraua goliath* has no tail, and the head is large and flat with a mouth capable of opening widely. The body is massive with long and muscular hind limbs that extend accordingly to provide the necessary force during jumping. The body is arranged in order to provide the necessary power for saltatory locomotion. There is a strong pectoral girdle and a vertebral column arranged for the forelimbs to absorb the shock of landing (see Fig. 13.1).

13.2.2 Semi-domestic Frog Genetic Resources

Goliath frogs are indigenous to Cameroon and mainland Equatorial Guinea. This species belongs to the genus *Conraua*, which has eight species, namely, *Conraua goliath, C. robusta crassipes, C. beccarii, C. alleni, C. derooi, C. sagyimase, and C. kamancamarai*. The genus *Conraua* is the sole member of the Conrauaidae family, considered as a sister family of the Petropedidae. Genetic diversity of the Goliath frog in Cameroon, highlighted from a study of two mitochondrial genes (Cytochrome Oxidase subunit 1 (COI) and 16S ribosomal RNA gene (16S)), revealed a demarcation between populations, potentially due to geographic distance (Nguiffo et al. 2019a). This species is facing threats from overhunting, climate change, conversion of its natural habitat for agriculture, and construction of large infrastructures such as dams. It is, therefore, important to consider captive breeding in order to save this species.

13.2.3 Housing and Environmental Adaptation

The following must be considered when caring for amphibians, especially the Goliath frogs: (1) enclosures, (2) water (sources and quality), (3) environmental conditions (light, temperature, and humidity), (4) food, and (5) veterinary care.

Goliath frog lifecycle stages require different-sized enclosures. Tadpoles can easily be kept in a plastic box of 40 cm × 50 cm × 30 cm. However,

Fig. 13.1 An adult Goliath Frog

juvenile and adult frogs need extra space. Very small enclosures might lead to various traumas such as scoured rostrums, lethargy (due to lack of exercise), and sometimes death. The core idea for making a tank for frog keeping is to use materials made from glass or plastic that are easy to clean and disinfect. The frog tank should be cleaned, disinfected, dried, and fresh water added before receiving any animal.

Water remains one of the most important considerations for amphibian husbandry. Amphibians rely on water to keep their skin moist and permeable for respiration. Water is vital for amphibian reproduction, for eggs and tadpoles to dwell. Water quality is, therefore, essential for amphibian husbandry, and its temperature, pH, ammonia, and nitrite should be tested and maintained to ensure suitable conditions for all lifecycle stages (Odum and Zippel 2008; Wright and Whitaker 2001; Browne et al. 2007).

13.2.4 Reproduction

Female amphibians release eggs that are then fertilized by the male. Goliath frogs are known to build nests for reproduction, and to date, three different types have been documented (Schäfer et al. 2019). Nests (See Fig. 13.2) are known to harbor various cohorts of tadpoles at different ages. Goliath frogs are known to breed during the dry season when the water level is low (Sabater-Pi 1985; Schäfer et al. 2019). Locals have pointed out that a drop in water level in water bodies harboring the Goliath frog during the dry season acts as a signal for reproduction. However, chemical signals are associated with reproduction, like water parameters required for mating.

13.2.5 Health and Care

Goliath frogs are known to harbor parasites such as helminths and microfilariae. Three major groups of helminths have been documented (Nematoda, Trematoda, and Pentastomids) compared to a single microfilaria (Nguiffo et al. 2015, 2019b). The deadly fungus, *Batrachochytrium dendrobatidis,* responsible for the collapse of several populations of amphibians worldwide, is known to be present across the geographical distribution of the Goliath frog (Miller et al. 2018). However, there is no report on the mortality of the Goliath frog due to this fungus. To avoid the escape and movement of populations into the colony that might potentially spread pathogens into the farm, biosecurity and restrictions would be needed, and this may include homemade or natural barriers. Additionally, a limitation of visits to a single colony per outing is encouraged.

Fig. 13.2 Nest of Goliath frog

13.2.6 Core Challenges and Perspectives

Amphibians have been used for various purposes. Their population is also experiencing a decline in Africa due to disease and overexploitation. Captive breeding programs might be the solution to provide sustainable use of this resource. However, due to a loathing of amphibians in several ethnic and economic constraints, sustainable breeding of amphibians has not been a priority. There is an absence of coordination of action as frog hunters are essentially isolated and have no major interest in frog keeping. Additionally, land issues remain a challenge, especially for captive breeding programs involving large amphibians such as the Goliath frog. The lack of funding remains a major problem in frog farming. This is exacerbated by the lack of economic attractiveness of the practice. There is still a long way to go for amphibian husbandry efforts in Central Africa. Indeed, to be effective in addressing the numerous challenges in amphibian husbandry, the development of multidisciplinary research programs in combination with increasing awareness of local communities is necessary. Through education, the development of better management tools for key iconic species like Goliath frogs is needed to fully integrate the needs of local populations. Enhancing local expertise to handle amphibian husbandry efforts and increase awareness is of vital importance. Combined with these, long-term monitoring programs are needed for wild amphibian populations to document the status and trends in these populations and relate trends to threats and the need for action. Actions need to be informed by scientific data on population structure, movement of individuals, health, and climate change. Such information will serve as a basis for current and future actions. These might range from potential translocation efforts to the prioritization of areas with high biological and genetic diversity. The engagement of various stakeholders would ultimately serve as a medium for the exchange of ideas, boost collaboration, encourage in-country students and researchers to conduct research in order to improve the husbandry approaches, and propose specific models and site management plans. Public engagement (brochures, posters) and the involvement of media in publicity campaigns in conservation education programs targeting schools and local communities at the national level should be considered.

13.3 Snails

13.3.1 Introduction

The phylum of mollusks, by the number of its species (more than one hundred thousand), is second only to arthropods and is, therefore, one of the most important and most varied groups. A mollusk is an invertebrate of a large phylum that includes snails, slugs, mussels, and octopuses. Mollusks are triploblastic metazoans with fundamentally bilateral symmetry. They live in aquatic or damp habitats, and most of them have an external calcareous shell. Their body is soft, unsegmented, and consists of three fundamental parts: a head, a foot, and a visceral mass (Maissiat et al. 2011). Meglitsch (1974)reports that mollusks have seven classes, namely: Monoplacophores, Aplacophores, Polyplacophores, Scaphopods, Lamellibranchs (Bivalves), Gastropods, and Cephalopods. Gastropods account for about 80% of mollusk species: they represent the major part of the seven existing classes (Belanger 2009). During their organogenesis, these mollusks undergo very profound anatomical modifications, which upset the anatomical relationships of their organs; these are mainly flexion and torsion movements, to which is added a winding (Maissiat et al. 2011). Originally, all gastropods have a shell and gills, and are aquatic. During their evolution, some species have lost all or part of these characters. Species that have lost their shells are called "slugs" (Kerney et al. 1999), while species with shells, such as the snail, are gastropod mollusks. There are 103,000 species of gastropods; the oldest known fossils date back to the Cambrian, 510 million years old (Lecointre and Le Guyader 2001). Despite their great biodiversity, their evolutionary, geological, ecological, and economic values, terrestrial gastropods are not well known, both from a point of view of biology and of the distribution of species, and most of the data comes from old studies (Karas 2009).

13.3.2 Systematic Position of the Snails

The systematic position of the snail is as follows:
Kingdom: Animalia
Phylum: Mollusca
Class: Gastropoda
Subclass: Pulmonata
Order: Stylomatophora
Superfamily: Helicacea
Family: Helicidae
Subfamily: *Helicina*
Genus: *Helix*
Species*: Aspersa* (and many other species)

13.3.3 Common Snail Species in Africa

Among the species widely sampled in North Africa, from the West of Morocco to the East of Tunisia, and to explain the historical processes influencing their current distribution, the land snail, *Cornu aspersum* or *Helix aspersa*, provides an excellent biological model to understand phylogeographic patterns across North Africa and the surrounding regions of the Western Mediterranean basin. This species is a model for evaluating hypotheses leading to population differentiation.

This land snail, formerly known as *Helix aspersa* (Müller, 1774), is native to the Mediterranean countries. It includes a set of forms and subspecies endemic to North Africa that were described at the beginning of the twentieth century on the basis of the characteristics of the shells (Taylor 1913). The most common, *Cornu aspersa. Aspersum* (syn. *Helix aspersa. aspersa*) has become very abundant in all habitats disturbed by humans in regions with Mediterranean, temperate, and even subtropical climates. To reconstruct the biogeographic history of this invasive form in the Western Mediterranean, the variation in the spatial patterns of shellfish, genital, and molecular charac-

ters was previously estimated by investigating more than a hundred populations representative of the distribution area of the *aspersum* (Western Mediterranean and European coasts).

Regardless of the set of populations and/or markers used, the combination of all the different types of data leads to a clear picture of the geographic structure. Indeed, (i) two groups of anatomically and biochemically divergent populations are in the West and East, and the separation that occurs in Kabylia (Algeria) is invariably observed throughout the North African coastal region; (ii) almost all European populations are grouped with those of the Western part of North Africa, with genetic distances smaller than those between the Western and Eastern parts of North Africa (Guiller and Madec 2010) (see Fig. 13.3).

In Africa, generally, the information about snail species (geographical distribution, inventory, characterization, etc.) is scant. Three studies have examined the African snail species through inventory and characterization. According to Oke and Alohan (2006), 46 taxa are recorded from Okomu National Park, Southwestern Nigeria, of which 23 could be identified to species level, while 23 taxa seem to be of unclear status or may be new species. The molluscan fauna is dominated by two families, the *Streptaxidae* (15 species) and the *Subulinidae* (12 species), constituting over 50% of the total number of species. The *Streptaxidae* was the most dominant family, constituting 33% of the total number of species collected and 35% of the total number of individuals. Two common species, namely *Archachatina marginata* and *Achatina fulica,* are listed in Cameroon (Tsayo et al. 2020). In Algeria, the common species are *Otala punctata*, *Helix aspersa, aperta,* and *pomatia* (Bouchiba et al. 2021; Mezouar et al. 2021; Skendraoui 2015). Moreover, these are the same dominant species in neighboring countries like Tunisia and Morocco (MAPM 2017). The genus *Eremina (Helicidae)* comprises a few species of land

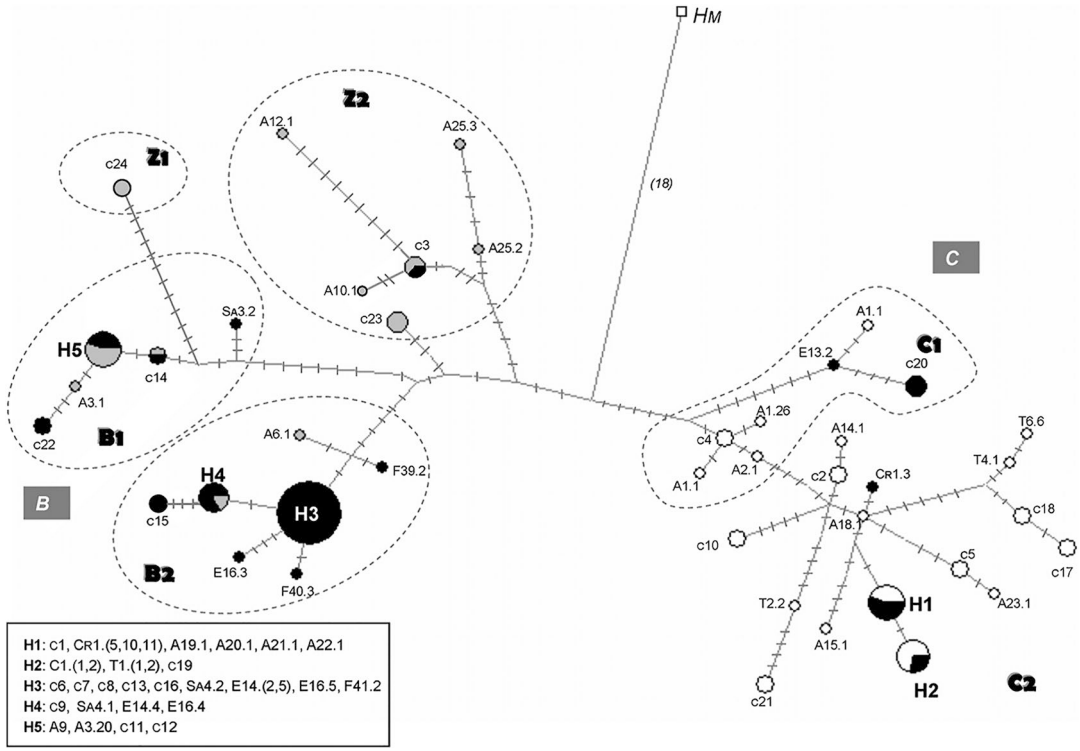

Fig. 13.3 Median-joining network for the cyt b mtDNA haplotypes of *C. aspersum*. (Guiller and Madec 2010)

snails living mainly in desert or semidesert habitats of North Africa and the Near East. Four Moroccan species are recognized as *E. dillwyniana, E. vermiculosa, E. duroi,* and *E. inexspectata*. The two taxa of the land snails, *Eremina d. desertorum* and *Eremina desertorum irregularis,* are differentiated by shell size and shape and are separated by a narrow hybrid zone west of Alexandria, Egypt (Ali et al. 2016).

13.3.4 Geographical Distribution of Common Snail Species in Africa

13.3.4.1 Snails of North Africa

Prevalent Species in North Africa

Fourteen species of land snails in Algeria show high phenotypic diversity of the shell (Fig. 13.4) (Bouchiba et al. 2021; Mezouar et al. 2021). These studies, conducted in 27 regions in Algeria and including 1090 snails, indicated that the district of El Tarf presents more species variability compared to other districts. The species found in El Tarf include *Helix pomatia, Helix aspersa, Pseudotachea splendida, Gllandia annularis, Cryptomphalus aspersus, Cepea hortensis, Cepeanemoralis, Helicellaitemorala,* and *Cepea sylvatica*. The rest of the districts presented few varieties such as Constantine (*Helix aspersa, Arianta arbustrum, Helix pomatia*), Algiers (*Otala punctata, Theba pisana*), Tlemcen (*Theba pisana, Helix pomatia, Pseudotachea splendida, Otala punctata*), Mila, Annaba and Setif (*Helix aperta*), Oran, Sidi Bel Abbès, Ain Témouchent, Saida, Mostaganem, Mascara (*Otala punctata*), and Naama (*Sphincterochila boissieri*).

In Tunisia, out of 400 species of snails reported, only six are the object of significant commercial interest: the Bourgogne snail (*Helix pomatia*), the small gray snail *(Helix aspersa aspersa or muller*), the big gray snail (*Helix Aspersa Maxima*), the tapado or Attupatelli snail (*Helix aperta*), the mourguette (*Eobania vermiculata*), and the Turkish snail (*Helix lucorum*). Breeding is carried out either outdoors, indoors, or both indoors and outdoors (See: Sect. 13.2.6. Snail production systems).

Also, land snails represent an important natural resource for Morocco through their diversity, productivity, and marketability. In Morocco, the

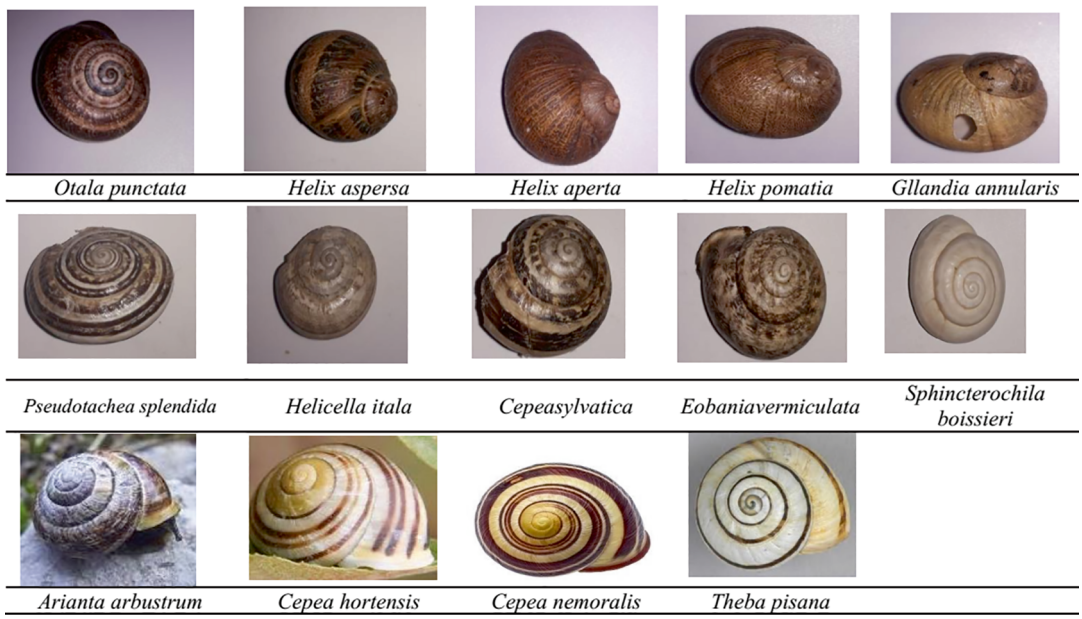

Fig. 13.4 The most common snail varieties in northern Algeria. (Adapted from Bouchiba et al. 2021 and Mezouar et al. 2021)

main species exploited are *Helix aspersa aspersa, Helix aspersa maxima, Otala lactea, Eobania vermiculata,* and *Euparipha pisana*. However, the national specialty is the big gray, which is only found in Morocco and Algeria (MAPM 2017). Finally, in Egypt, the land snails are widespread in the Northern Governorate, Alexandria, El-Beheira, Kafr El-Shikh, and Domietta (Eshra 2013). Nine terrestrial snail species in the Upper Egypt region have been identified by the Assiut Governorate. All the species recorded belong to the order *Pulmonata* from eight families. Two species of land snails are recorded: *Monacha obstracta* (Montagu) and *Eobania vermiculata* (Muller) in the Sohag Governorate, in Egypt (Desoky et al. 2015).

External Morphology

Four characteristics are selected (shell "height, length, width, and body weight") to define the body measurements of the Algerian land snail populations. In fact, there is a remarkable variation in the weight of the land snail between the 15 species (Table 13.1). A small species, such as *Cepea sylvatica* and *Helicella itala*, with a weight that does not exceed 2.5 g, was found. On the other hand, *Otala punctata* and *Helix pomatia* are relatively heavy species with an average weight of around 10 g. The rest of the species have average weights that are sometimes similar (Table 13.1). Nevertheless, the shell morphology measurement in the species shows a very homogeneous variation between them, except *Otala punctata,* which shows quite some variability. Hence, the height, length, and width of the shell present a highly significant difference between the studied species with an overall average of 1.99 ± 0.56 cm, 3.35 ± 0.93 cm, and 2.67 ± 0.68 cm, respectively (Table 13.1).

Regarding the qualitative traits, two characters were taken into consideration, which dominate the phenotype (the flesh and the shell color). The results of shell and flesh color show that the Algerian land snail exhibits five different flesh colors: White, brown, yellow, black, and beige, either united or mixed (Bouchiba et al. 2021; Mezouar et al. 2021). The results also show that the El Tarf district has more shell color variability than the other districts, with seven and six shell phenotypes. Then, Constantine and Annaba with four colors, followed by Algiers and Mila, which include three shell colors. In parallel, the other districts are characterized by a single shell color (brown and white) like Naama, Setif, Oran, Sidi

Table 13.1 Descriptive analysis of body measurements (height, length, and width of shell and body weight) between different species in Algeria (Bouchiba et al. 2021)

		Height shell	Length shell	Width shell	body weight (g)
Species	N	Mean ± SE	Mean ± SE	Mean ± SE	Mean ± SE
Helix aperta	116	1.56 ± 0.27	2.46 ± 0.32	1.94 ± 0.53	4.33 ± 1.60
Helix pomatia	55	2.47 ± 0.91	3.52 ± 0.86	2.61 ± 0.56	9.34 ± 3.46
Helix aspersa	51	1.89 ± 0.40	2.76 ± 0.56	2.19 ± 0.50	7.07 ± 2.69
Arianta arbustrum	10	1.73 ± 0.24	2.68 ± 0.37	1.95 ± 0.24	7.40 ± 2.63
Otala punctata	292	2.13 ± 0.40	4.25 ± 0.45	3.34 ± 0.31	10.37 ± 3.11
Theba pisana	109	1.75 ± 0.57	2.60 ± 0.52	2.16 ± 0.41	3.99 ± 1.10
Pseudotachia splendida	35	1.67 ± 0.32	2.72 ± 0.33	2.28 ± 0.25	5.56 ± 2.69
Helicella itala	16	1.57 ± 0.27	2.35 ± 0.15	2.14 ± 0.27	2.35 ± 0.25
Eobania vermiculata	3	1.88 ± 0.11	2.95 ± 0.32	2.68 ± 0.16	3.26 ± 0.15
Cepea sylvatica	4	1.49 ± 0.09	2.32 ± 0.04	2.12 ± 0.15	2.12 ± 0.09
Cepea nemoralis	1	/	/	/	/
Cepea hortensis	1	/	/	/	/
Cryptomphalus aspersus	17	2.85 ± 0.33	3.41 ± 0.39	2.90 ± 0.31	5.58 ± 2.29
Gllandia annularis	8	3.02 ± 0.62	3.59 ± 0.86	2.88 ± 0.46	5.37 ± 3.99
Sphincterochila boissieri	33	2.33 ± 0.36	2.85 ± 0.11	2.50 ± 0.59	5.57 ± 1.52
Total	751	1.99 ± 0.56	3.35 ± 0.93	2.67 ± 0.68	7.34 ± 3.82

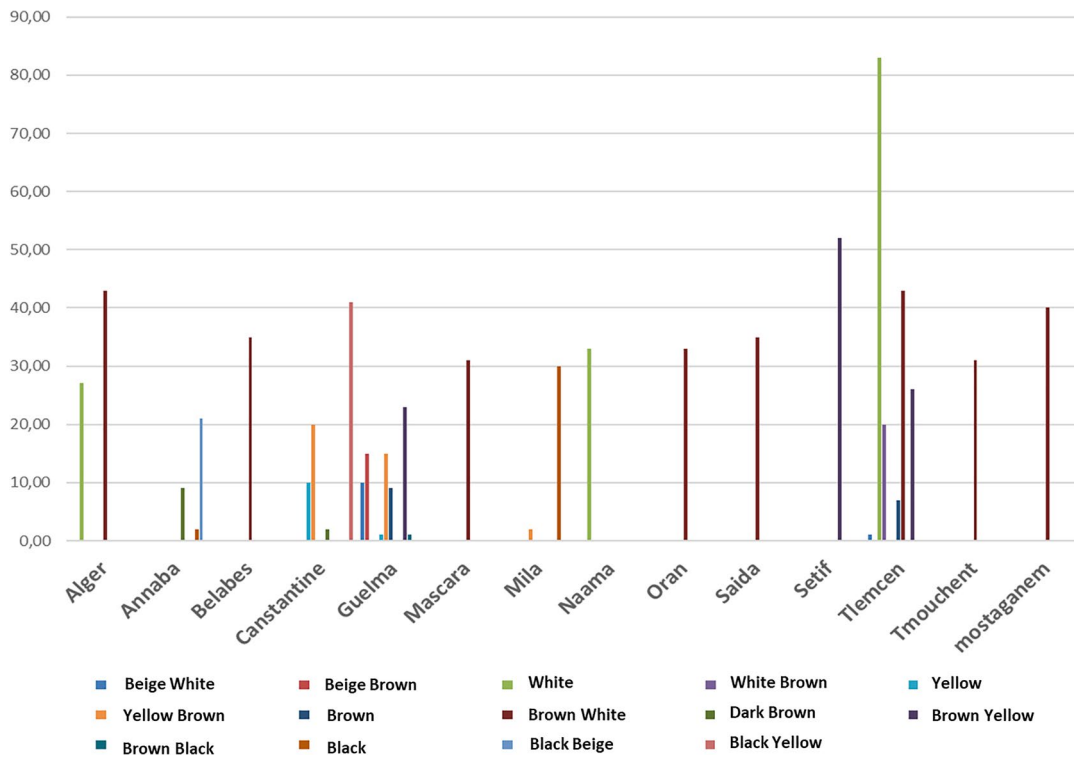

Fig. 13.5 Distribution of snails according to shell color in Northern Algeria

Bel Abbès, Mascara, Saida, Timouchent, and Mostaganem (Fig. 13.5). Generally, the presence of the majority of species at the El Tarf district and their different morphologies may be due to the geographical position; effectively, this part of Algeria is the most humid and is part of a humid climate stage. In addition, the sociocultural state of the citizens of El Tarf is different compared to the other districts visited; they are not interested in snails, neither for national marketing nor for self-consumption, which explains the presence of several species.

13.3.4.2 Snails of Central and West Africa

Prevalent Species: The Giant African Snail

Giant African snail is one of the largest land snails in the world, reaching up to 19 cm in length (Peterson 1957). In part because of its polyphagous diet, it has been recognized as one of the world's most damaging pests and is considered one of the top 100 invasive species by the World Conservation Union, IUCN (ISSG 2003).

According to Tsayo et al. (2020), only two predominant species, namely *Archachatina marginata* and *Achatina fulica,* were identified out of a total of 693 adult giant land snails studied in six localities (Odza, Mbankolo, Biyem-assi, Nyom, Nkolbisson, and Simbok) in the Mfoundi Division of Cameroon. These two species are the most widely harvested edible snails in the Central and West African forest zones.

External Morphology of the African Giant Snail

According to Tsayo et al. (2020), the diverse colors of the shell opening observed in the edible snail populations of the equatorial region indicate that there is genetic variability. The colors are influenced by many factors, including genetics, the action of the environmental conditions and diet, and the different interactions between them. In fact, the African land snail in Cameroon shows

a black coloration with yellowish stripes and a red tip, observed in *Archachatina marginata,* in contrast to other observations made by Nkwedem et al. (2019) in Moungo (Cameroon) and those of Mbetid-Bessane (2006) in the Central African Republic, which had shown that the black color with whitish stripes was the most observed. Nevertheless, the brown color with white stripes and white tip observed in *Achatina fulica* is also mentioned by Nkwedem et al. (2019) in Moungo (Cameroon), Hana et al. (2016) in Nigeria, and Mbetid-Bessane (2006) in the Central African Republic.

Furthermore, the results obtained by Okon et al. (2012) about a comparative study between two species of giant land snail, *Archachatina marginata* and *Achatina fulica,* revealed that there are significant correlations between shell length and shell "mouth" width and between shell "mouth" length and shell "mouth" width for *A. fulica* snails. Thus, these quantitative or phenotypic traits of the two species could be chosen to differentiate as well as characterize growing snails in the Niger Delta region of Nigeria (Fig. 13.6).

13.3.4.3 Snails in South Africa

Origin and Distribution

Herbert (2010) examined in detail the exotic terrestrial mollusk fauna of South Africa: 34 species were considered to have been introduced into the country, of which 28 became established and 13 invasive. The author concluded that the introductions continue at a rate of about two species every 10 years, with no signs of stabilizing. He also highlighted that the agricultural and horticultural industries are the main contributors to the introduction and spread of exotic species. The composition of this exotic fauna shows considerable similarity to that known from Southern Australia, reflecting the regions' similar colonial history and climatic correspondence with the regions of origin in Western Europe and the Mediterranean. Each species was discussed based on its distinctive characteristics, habitat preferences, date of introduction and first record, native range and global distribution, distribution in Southern Africa, pest status, and similarity to native species. In addition, some attention has been paid to potentially harmful species whose occurrence in South Africa is not yet known but which represent a significant risk of future introduction. The author also reports the presence for the first time in South Africa of the species: *Discus rotundatus, Hawaiia minuscula, Vitrea contracta, and Aegopinella nitidula* (Fig. 13.7).

Characteristics of Prevalent snail Populations in South Africa

Perera et al. (2021) analyzed the zoogeography of the terrestrial malacofauna of Southeast Africa (SEA), proposing the first digital regionalization based on mollusks for the area. They also dis-

a *Achatina fulica* b *Archachatina marginata*

Eobania vermiculata (Müller, 1774), South End cemetery, Port Elizabeth (NMSA V8627 [2000]).

Cochlicella barbara (Linnaeus, 1758), Constantia, Cape Peninsula (NMSA V8326 [2000]).

Cornu aspersum (Müller, 1774), scalariform freak, Cape Town, W. Cape (NMSA V7391 [1999]).

Oxychilus draparnaudi (Beck, 1837), Kirstenbosch, Cape Peninsula (NMSA W5705 [2007]).

Theba pisana (Müller, 1774), crawling animal, Cape Agulhas (NMSA V7750 [2000]).

Fig. 13.7 Some species of land snail in South Africa. (Herbert 2010)

cussed the models and centers of endemism of terrestrial snails, thus assessing the importance and delineation of the Maputaland-Pondoland-Albany (MPA) biodiversity hotspot for their conservation. An incidence matrix compiled for relatively well-collected lines of terrestrial snails and slugs (73 taxa in twelve genera) in 40 *a priori* operational geographic units was subjected to (a) a phenetic agglomerated hierarchical clustering using the method of groups of unweighted pairs

with arithmetic means (UPGMA), and (b) endemicity parsimony analysis (PAE) and biotic element analysis (BEA). Responding to the primary objective of the study, the UPGMA dendrogram provided hierarchical regionalization and identified five centers of mollusk endemism for SEA, while the PAE confirmed six areas of endemism, also supported by the BEA. The regionalization covers a zoogeographic province similar to the MPA hotspot, but with a notable extension westward to Knysna (toward Cape Town). The MPA province, centers, and areas of endemism, biotic elements, as well as spatial patterns of species richness and endemism, support the MPA hotspot but suggest further extensions resulting in greater land snail endemism. The MPA region (also with a northward extension in Sky Islands, Southpansberg, and Wolkberg) is similar to that observed for vertebrates. The large MPA region provides a more robustly defined region of conservation concern, with centers of endemism serving as local conservation priorities.

13.3.5 Importance of Snails

13.3.5.1 Snails as a Dietary Resource

The snail constitutes food that is highly appreciated for its tasty, tender flesh and is very rich in amino acids, mineral salts, and particularly iron. Snail is an important alternative source of animal protein in rural communities. The strong pressure to collect snails due to the growing demand as a food source, as well as the destruction of their biotope by humans and natural predators, is a factor that contributes to a reduction in snail stocks in the natural environment. Faced with this situation, snail breeding, as an activity, appears necessary to compensate for the seasonal shortages of snails and to ensure the sustainability of the species (Bouchiba et al. 2021; Karamoko et al. 2011).

13.3.5.2 Soil Mineral Source

In agronomy and pedology, mineralization is the decomposition of the organic part of a soil material, which also contains a mineral part. The snail contributes to the mineralization of organic substances and the formation of humus, which benefits cultures and is the first link in the chain of decomposition of organic matter (Stiévenart et al. 1990).

13.3.5.3 Use in Traditional Medicine

Edible snails are widely used in traditional medicine. These snails are generally farmed and have no toxicity, like inedible and wild snails. In fact, for the treatment of respiratory infections, it is recommended to use a mixture prepared with thyme and snail, which are cooked inside argan oil. This mixture is left to cool and then filtered; thereafter, it is administered in drops orally (Radi 2003). In Ghana, the bluish liquid remaining in the shell after the flesh has been extracted is recommended to combat ulcers and asthma. Also, a recent study showed that the glandular substances present in the flesh of edible snails caused the clumping of certain bacteria, a phenomenon that can help fight a variety of diseases, including whooping cough (Cobbinah et al. 2008).

13.3.5.4 Ecotoxicological Interest

Ecotoxicology is the study of the interactions between the various chemical products widespread in the environment and the biotope. Hence, it is essential to assess the quality of biomass and the ecosystem. The snail *Helix aspersa* was shown to be a powerful bioindicator and bioaccumulator, since it was used to monitor the ecotoxicity of the environment (Cobbinah et al. 2008).

As a result of their permanent contact with the soil surface, land snails are more exposed to several pollutants found in the soil. These contaminants could be absorbed through various routes, such as respiratory, digestive, and transcutaneous (Gomot-de Vaufleury and Pihan 2000). It was shown that *Helix aspersa* snails can accumulate heavy metals such as lead in their shells (Beeby and Richmond 2011). The reproduction and growth of snails are indicators to evaluate the soil pollution by pesticides (Russell et al. 1981). The *genus Helix*, raised under favorable conditions, can be used as a bioindicator of terrestrial pollution, or it can also be used as a test organism for the toxicity of metals (Russell et al. 1981). It is an

element capable of transferring pollutants from the soil to plants and predators (Beeby 1985).

13.3.6 Snail Production Systems

Different systems of snail production have been experimented with over the years. Three snail production systems are currently in use:

13.3.6.1 Outside Farming

Outside, snail farming is conducted completely outdoors, such as open parks, where the snails are located in areas surrounded by snail-proof fences. The enclosures contain the vegetation chosen for its aptitude for feeding snails. Snails are left to breed, reproduce, and grow almost unattended until harvest. This system was adopted by the Italians, and almost all snails produced for the market are bred in this way. Italian snail farms designated very large areas for this system (2.5 hectares or more). The amount of labor and material is reduced to a minimum, and this is more advantageous than other types of snail farming described below. Unfortunately, snails are only collected during the few months of the growing season, and so, the amount of product available on the market is limited (Murphy 2001).

13.3.6.2 Indoor Farming

This system integrates air-conditioned buildings in which the snails spend their time under defined parameters to facilitate the optimal environment for snail reproduction and feeding: all the nutritional needs necessary for each stage of snail development are furnished. This level requires a high initial capital investment. It needs to be constantly monitored by requiring the presence of human supervision seven days a week. The indoor method has been the subject of much research in France for 20 years. This type of snail farming is the result of winters in the Northern Hemisphere that can be quite severe and could curtail snail production. Growing snails indoors has enabled the farmer to produce snails year-round and, therefore, supply markets with fresh produce on demand (Murphy 2001).

13.3.6.3 Mixed (Indoor and Outdoor) Farming

This system incorporates particular management practices of the two types of snail farming above. Reproduction and the nursery environment use the indoor method, while the growth phase takes place outdoors. This system allows the snail farmer to cultivate and produce snails year-round and, therefore, has the product available to the market at all times. This type of snail farming is now widely preserved in France and has been practiced for some time. The indoor/outdoor method is suitable for Australia as the climate along the southern end of the coast is quite mild, and extreme temperatures are not of great concern as they are in Europe. The breeding greenhouse allows snail growers to control the environment to such an extent that the temperature of the outside air does not interfere with the breeding program. The same goes for the nursery greenhouse, where young snails can feed and develop without the overall conditions interrupting the desired growth rate. The growing area is completely covered with a shade cloth that protects the snails from the sun, wind, and hail. The method of raising and managing snails indoors and outdoors gives the Australian grower the best of both systems developed and proven overseas for many years (Murphy 2001).

13.3.7 Genetic Resources of Snails

The first studies in the field of mollusk cytology were carried out at the end of the nineteenth century. Due to inferior optical equipment and methods, many of the first reports were found to be inaccurate (Patterson and Burch 1978).

13.3.7.1 Karyotype

The karyotypes of 76 species from eight archeogastropod families were studied using the hot dry chromosome method of Kligerman and Bloom (1977) and a computer-assisted analysis system (Burch 1968). The number of haploid chromosomes (N) varies from 9 to 21 in the 76 gastropod species. The Patellidae (5 species, N = 9), *Acmaeidae* (15 species, N = 10), and *Neritidae*

(21 species, N = 12; 1 species, N = 9, 10; and 1 species, N = 11, 12 and 14) have a relatively small number of chromosomes, while the *Trochidae* (13 species), *Turbinidae* (3 species), *Stomatellidae* (1 species), and *Helicinidae* (3 species) have a greater number of chromosomes (N = 18), and a *trochid Granatalyrata* (N = 20 or 21). Chromosomal morphologies have been studied in 42 species. More than half of the karyotypic complements are meta- and/or sub-metacentric in each of them, while no family is characterized by complements consisting only of meta and/or sub-metacentrics. The lengths of the chromosomes at the mitotic metaphase are mainly 1–4 micrometers. The total length of diploid chromosomes was measured for 34 species and shows an increase as the number of chromosomes increases (Nakamura 1986). Until now, the systematics of lower taxonomic categories have remained an enigma, both from the practical point of view of identifying specimens and of understanding the mechanisms of speciation and evolution (Burch 1968).

13.3.7.2 Shell Polymorphism in the Hedge Snail (*Cepaea nemoralis*)

On the same site, it is common to observe snails of similar sizes and shapes but differing in the characteristics of their shells. Their colors, as well as the bands that adorn them, can vary widely. *Cepaea nemoralis* is a species that includes individuals whose shell is yellow (it can sometimes be very dark and brown) and others whose shell is pink (likely to drift to purple). Schematically, the color of the shell is controlled by a gene exhibiting two alleles, denoted j and j +, j + being dominant and j recessive. Individuals with two j (j / j) alleles have a yellow shell, individuals with two j+ + (j+/j +) alleles or one j allele and one j+(j +/ j) allele have a pink shell.

Some shells are devoid of bands, while others are decorated with longitudinal brown bands. The absence or presence of bands is determined by a gene with two alleles, b and b+. The b+ allele is responsible for the absence of bands and is dominant over the b allele responsible for the presence of bands. Individuals without bands have two b + (b + / b +) alleles or one b + allele and one b (b + / b) allele, and individuals with five bands have two b (b / b) alleles. Taking into account the color on the one hand and the presence of stripes on the other hand, there are 32 combinations, of which some are common and others are very rare. The possibilities are more numerous, the bands adorning the shell sometimes being fused, discontinuous, or weakly pigmented. The populations of hedge snails, therefore, appear to be polymorphic, with various morphological types coexisting on the same site. In fact, from one observation site to another, the proportions of the different phenotypes are variable, suggesting variations in allele frequencies.

13.3.7.3 Genetics of Body Color Variation of Land Snails

The main factor in variability in color is the amount, density, and distribution of melanin pigmentation. Melanin is dark brown/purple/black in color, which is intensified by dense compaction of melanin granules in the cells of the upper layers of the skin. A mutation in the tyrosine enzyme gene produces a protein with reduced functionality, thereby resulting in reduced melanin production. When the color of the pigments is apparent, the DNA sequence is read (translated into RNA) and translated into the color pigments (protein). At this time, several elements can appear in different ways: The gene code for the color of the pigments can be completely or partially deleted. The gene may be inactive because the regulatory sequences are missing or dysfunctional. If a snail has two copies of an active color gene, the snail is called a wild-type homozygote for the color gene. If a snail has two non-active copies of a color gene, the snail is called a color gene knockout homozygote. If a snail has an active gene copy and a nonfunctional copy, the snail is heterozygous for that color gene. The color variations in the snail are the result of mutations in several genes responsible for the pigmentation of the shell and the body. A major black pigment determines whether the body is dark or albino (colorless). Snails that are not lacking in pigment still vary in the amount of pigment they have. Many genes influence the expression of the major genes, so the intensity of expression can vary, even for normal traits (Afiane 2019).

13.3.7.4 Genetic Structure of Land Snail Populations

The results obtained by Woogeng et al. (2017), where they used mtDNA as a genetic marker, show that the isolation by distance plays a significant role in determining the genetic structure of extant indigenous land snails in Cameroon, in line with the limited ability for dispersal in this species. The *Archachatina marginata* population, nevertheless, displays a diverse gene pool despite its exploitation in recent years. In contrast, *Achatina fulica* shows much less diversity and structure, which is most likely the signature of a bottleneck and weak genome dynamism.

In China, Zhou et al. (2007) proposed a study of the species *Camaena cicatricosa*, which is an important and harmful land snail found in Southern China. It not only damages crops, leading to reductions in yield and quality, but also spreads a zoonotic food-borne parasitic disease and causes substantial damage to human and animal health (Zhou et al. 2007). Based on mitochondrial gene (COI and 16srRNA, mtDNA) and internal transcribed spacer sequences (ITS2), the results of the study revealed significant fixation indices of genetic differentiation and high gene flows between most populations. Furthermore, the phylogenetic trees of haplotypes indicated nonobvious genetic structure. Similar results were obtained based on the synonymous and non-synonymous sites of 347 sequences of the COI gene studied.

Powelliphanta lignaria, a genus of large carnivorous land snail, is endemic to New Zealand and displays phenotypic variation within comparatively small geographic distances. Daly et al. (2019) used information from the data combination of mitochondrial sequence and other microsatellite loci to study the genetic structure of *Powelliphanta lignaria.* The level and structure of genetic diversity provided a picture of a naturally fragmented lineage restricted to a particular ecological zone.

- *Microsatellite*

Jaksch et al. (2017) developed microsatellite markers in the *Clausiliidae* family of snails. The *Clausiliidae* family, known under the name "door" snails, are gastropods with a very high diversity in shell morphology. For the best genetic diversity approach, 13 microsatellite loci with a tetranucleotide repeat were isolated and tested in three geographically close Montenegrina populations.

Furthermore, the study of Shweiger et al. (2004) suggests that the metapopulation structure of such species in fragmented landscapes depends on both the landscape features and the shape of the dispersal function. In fact, four trinucleotide and one tetranucleotide microsatellite loci previously published were analyzed (Davison 1999). The loci Cne1, Cne11, Cne15, and Cne6 were developed in a multiplex PCR to investigate the impact of habitat fragmentation on the spatial genetic structure of an organism with limited dispersal ability of the land snail, *Cepaea nemoralis* (L.). The findings of both genetic and morphological patterns showed spatial structuring at two scales. At the local scale, a deme-structured subdivision of a continuous subpopulation corresponded to the limited active dispersal ability. At the mesoscale, rare dispersal events, most likely driven by passive displacement, were suggested to lead to metapopulation persistence in a fragmented landscape.

- *DNA Sequencing*

The giant African snail, *Achatina fulica* (NCBI:txid 6530), is a gastropod species originating from East Africa. It is the largest terrestrial mollusk, with a voracious appetite, strong environmental adaptability, and a high growth and reproduction rate (Schreurs 1963). The chromosome sequence of *Achatina fulica* will provide the research community with a valuable resource for population genetics and environmental adaptation studies for the species.

13.3.8 African Giant Snails

Snails' consumption by humans has been going on for centuries. In Africa, particularly in West Africa, the consumption of snail meat is part of the culture. Several nutritional benefits were conferred to snail meat compared to the meat of

conventional livestock. However, their breeding is not yet widespread and is still done in the traditional way, which is collection in forests and fields.

13.3.8.1 Snails' Genetic Resources

Snails are invertebrate animals belonging to the group of mollusks due to their shell. They are classified in the group called gastropods since they have one shell. The shell covers and protects the soft part of the body (Stiévenart et al. 1990). The body consists of three parts that are not well defined:

- *The head* has two pairs of retractable tentacles, the longer pair of the tentacles possesses the eyes at their top and the shorter pair has a sensitive function and a mouth located below the head.
- *A long, muscular foot,* whose separation is not clear enough from the head (cephalopod), allows the animal to move.
- *A bumpy visceral mass* is hidden under the shell and composed of its vital organs, important in the functions of digestion, reproduction, and respiration.

In sub-Saharan Africa, particularly in the humid forest areas, the well-known and consumed snails are from the Achatinidae family. Commonly named African giant snails because of their weight, which can reach 250 g as adults for some species. A group of giant land snails native to Western, Eastern, and Southern parts of Africa possess lungs (*Pulmonate*) with a long conical shell. The *Achatinadae* group is also subdivided into 14 subgroups, including the Achatina and Archachatina subgroups.

A description of the differences between the *Achatina* and *Archachatina* subgroups was made by Hodasi in 1984 (Stiévenart et al. 1990). According to their general characterization, the *Achatina achatina* group has a relatively oval shell with a regular spiral and a narrow top, while the *Acharchatina marginata* group has **a** wide-topped shell in a dome shape (see Fig. 13.8).

13.3.8.2 Housing, Environmental, and Adaptation Factors

Heat and humidity are the two main factors important for the survival of *Achatinadea* snails. This explains their geographical distribution in humid regions. Therefore, they can be found in a wide variety of environments such as agricultural land, coastlines, forests, and peri-urban areas. *Achatinadae* snails are animals whose metabolism varies with their environment (poikilotherms). They are very active in humid climatic conditions and are observed generally during the rainy season. During the dry season, when the temperatures are usually high, *Achatinadae* snails live reclusively in their shells that they close with a thin white calcium layer. They are predominantly nocturnal animals, but could have limited activities during the day.

13.3.8.3 Nutrition, Feeds, and Feeding

African giant snails are mostly vegetarians (see Fig. 13.9). However, empty snail shells can be observed inside their cages, suggesting that they may be preying on dying animals. In general, they consume leaves, fruits, and roots (Cobbinah et al. 2008; Agbogidi and Okonta 2011). Based on field observation, mature adults are mostly found around the flowers and leaves of fruit trees (oil palms and plantains). The young are found inside fallen fruits (papaya, tomato). According to snail collectors, snails seem to be affectionate to rotting cassava roots, and are used as bait for them. For breeding needs, many plant species have been identified for their palatability or feed efficiency (Cobbinah et al. 2008). Also, calcium is required for the proper development of their shell, which is obtained in the soil in their natural habitats. In captive breeding, calcium is usually sourced from eggshells or chalk (Cobbinah et al. 2008). A good source of minerals, especially phosphorus, is necessary for shell development (Aktaş et al. 2019).

13.3.8.4 Reproduction, Management, and Breeding Strategies

There are differences in the reproductive tract between *Achatina achatina* and *Archachatina marginata*. For *Achatina achatina,* the

a *Achatina fulica* b *Archachatina marginata*

c. Snail eating watermelon in a husbandry

Fig. 13.9 Snail nutrition

reproductive system comprises an elongated tubular vagina and a short sperm duct (Abiona et al. 2012). For *Archachatina marginata,* the reproductive system comprises a short tubular vagina and a very long and tapered sperm duct (Abiona et al. 2012). There are also differences in reproduction between the two species. According to Hodasi (1979), *Achatina achatina* is self-fertilizing. He concluded based on his observations that there is almost no mating between two snails, even if they can be seen very close to each other (Abiona et al. 2012). This species lays eggs during the rainy season. Laying of 30–300 eggs takes place in holes previously dug by the animal of about 4 cm deep, during the night. The eggs are likely oval and have a yellow color. They are small, 8–9 mm long and 6–7 mm wide. Eggs hatch about two to three weeks after laying (Cobbinah et al. 2008). The eggs of *Achatina* snails are very fragile. As a result, the neonatal

mortality rate is high (Hardouin et al. 1995). The juvenile phase is 1–2 months after hatching until the stage of sexual maturity (14–20 months), which corresponds for this species to the adult phase. An adult can live on average 5–6 years. However, some can live up to 9–10 years (Cobbinah et al. 2008; Hodasi 1979).

For *Acharchatina marginata*, cross-fertilization is required for eggs to be viable (Cobbinah et al. 2008) (see Fig. 13.10). The eggs are relatively large, from 12 mm in length to 7 mm in width, and their average weight at breeding is 4.8 g. Similar to *Achatina achatina,* their eggs are yellow (see Fig. 13.10). The number of eggs per laying is about 4–18. Eggs are laid in the soil at a depth of 10 cm (Radi 2003; Hodasi 1979; Hardouin et al. 1995). Hatching of eggs occurs about four weeks after laying (see Fig. 13.10). The juvenile period is about 15 months. The period during which the shell will thicken and grow. *Archachatina* snails reach sexual maturity around 10–12 months, when they reach 100–125 g (Cobbinah et al. 2008). They can live beyond 10 years (Stiévenart et al. 1990).

13.3.8.5 Health, Production Systems, and Value Chains

The giant snail farming system in Africa was inspired by the major snail-consuming countries of Nigeria, Ghana, and Cote d'Ivoire. Indeed, three production systems are applicable: extensive, intensive, and semi-intensive (Stiévenart et al. 1990; Cobbinah et al. 2008; Hardouin et al. 1995).

- *Extensive System*: the animals are placed outdoors in an environment similar to their natural environment. A vegetable garden with plants eaten by the snails is chosen (papaya, plantain, sweet potato, etc.). Then that area is demarcated with a fence to prevent them from escaping.
- *Semi-Intensive System*: the animals are put in a place similar to the extensive system, but their food is controlled, and snails are supplemented with industrial food that can increase their growth. In addition, the eggs are separated from the adults. They are left to hatch and grow for 2 months before reintroducing them.

a Mating of snails

b Eggs

c Hatching of eggs

Fig. 13.10 Reproduction of *Archachatina marginata* snails

- *Intensive System*: is a completely closed system where the environment is controlled. The enclosures can be pits constructed with bricks and covered on top with wire mesh to prevent animals from escaping. A pen can also be a pit on the ground covered with a wire mesh. Wooden boxes can be used as well as old car tires superimposed together, or even old basins.

Regardless of the type of system chosen by the breeder, to optimize the growth of animals and have a better yield, the following conditions are expected to provide optimal productivity: flat land, shady, humid (above 85%), loamy soil rich in organic material, and moderate environmental temperature (25–28 °C).

Snails have several predators such as rodents (mice, rats and shrews), frogs and toads, birds (crows, ducks, and turkeys), reptiles (lizards, snakes), insects (beetles, millepedes, and centipedes), and slug (Cobbinah et al. 2008; Nyameasem and Borketey-La 2014). Snails are susceptible to fungal diseases mainly caused by *Fusarium spp*., also known as pink egg disease. The eggs turn red-reddish brown when affected by the disease. This disease is mainly due to poor maintenance of pens and rotten food that is not removed (Cobbinah et al. 2008; Aktaş et al. 2019). Parasites such as *Alluaudihella Flavicornis* and *Angiostoma aspersae* are disease vectors for snails in their wild and farming environments. Both parasites lay their eggs on the snail, which hatch into worms that cause death (Aktaş et al. 2019). Bacterial diseases caused by *Pseudomonas* spp. Mostly, *Pseudomonas aeruginosa* causes intestinal infections in snails, which disrupts their growth (Aktaş et al. 2019).

The snail business involves several actors that include field gatherers, breeders, dealers, cleaners, and traders of cooked meats (Mbétid-Bessane 2006; Nzouankeu 2015). Snail farmers have two ways of marketing their animals. The new producers use them as breeders to begin their breeding, which is eventually sold to resellers in the markets. Snails of the dealers are intended for the catering of households. The consumption of snail meat that was once reserved for certain ethnic groups, especially in the South-West region (Kaldjob et al. 2019) in Cameroon, is increasing in the major cities of Cameroon (Nzouankeu 2015). Indeed, most of the snail meat is sold by itinerant traders in grilled form, ready to be consumed. It will also be found in restaurants prepared in various local sauces or simply in the family. Snail meat is certainly valued because of its many proven nutritional qualities (low in fat, high in protein, high in essential amino acids, and rich in vitamins and minerals) when compared to meat from conventional farm animals (beef, chicken, and pork) (Babalola and Akinsoyinu 2009; Eneji et al. 2008; Fagbuaro et al. 2006; Malik et al. 2011; Srilatha et al. 2013). Indeed, snail slime is very popular in cosmetics and pharmacology. According to some studies, it has, among other things, healing, anti-inflammatory, and moisturizing properties (Castro et al. 2007; Chinaka et al. 2021; Laneri et al. 2019). The shell is used in animal feed, particularly in the diet of laying hens (Houndonougbo et al. 2012).

13.3.9 Core Challenges and Perspectives

The diverse use of snails shows that traditional collection in the field can no longer cope with the growing demand (Joshi and Pandey 2019). Breeding would then be an ideal solution to overcome this problem. Indeed, there are several advantages to embarking on snail farming. There is a growing demand for snails because of their several advantages. First, snail meat has several nutritional benefits. Second, snails have other applications, especially in other sectors such as pharmacology, cosmetics, and animal feed. Snail farming is less expensive than conventional farming because the breeding and animal feeding do not require much effort. Furthermore, the snail business is an economic source of income for several actors in the sector. However, breeders encounter problems in getting this sector of activity going. This situation could be explained by several factors. First, there is a lack of funding and training to support farmers. Snail breeding is climate dependent; production is reduced in the

dry season since animals either enter aestivation or die. In addition, snails' reproduction is not yet very well controlled, and the percentage of eggs hatching is very low compared to the number of eggs laid. Finally, there is also a problem of predator invasion that reduces snail production (Woogeng et al. 2017; Baruwa 2012; Ndah et al. 2017). To solve these problems, government and private investors should provide more financing to the sector in order to enhance its potential and to allow breeders to be well-trained. The outcomes will be more snails for the local demand and for the export of byproducts of this mollusk. Indeed, snail slime could be supplied to the pharmaceutical and cosmetic industries. Snail meat could be exported to other countries where snails are consumed as well.

13.4 Rabbit

13.4.1 Origin and Domestication of Rabbit

Historically, the rabbit is a mammal that is native to Southern Europe and North Africa. It may have been discovered by the Phoenicians when they came into contact with the Spanish around the year 1000 BC (Lebas 2002). The oldest fossils of the genus are dated around six million years ago and were found in Andalusia. It is the only domesticated mammal whose paleontological origin is the *Oryctolagus cuniculus* and is located in Western Europe (Lebas 2002).

The rabbit has truly entered the era of genomics with the sequencing of its genome, which has paved the way for work to better understand the evolutionary history of this species (Garreau and Gunia 2018). Indeed, studies have shown the existence of two strongly divergent lineages, called A and B, which are partly related to the subspecies *O. c. algirus* and *O. c. cuniculus* (Rogel-Gaillard et al. 2009). These two lineages share a common ancestor dating back two million years. The two lineages are still geographically separated today: the wild populations of the southwest of the Iberian Peninsula belong to group A, while those of Northern Spain, France, and Tunisia are in group B, as all are domestic breeds. The Pyrenees range seems to have constituted an important genetic barrier since migration from the north of Spain to the north of the Pyrenees resulted in a loss of variability of around 12% (Carneiro et al. 2011). The most recent genetic study confirmed that all domestic rabbit breeds originated from the domestication of wild rabbits of the subspecies *O. c. cuniculus* that were present in France in the Middle Ages. Although the genetic variability of rabbit breeds remains high compared to other domestic mammals, the process of domestication and breed creation has been accompanied by a further genetic depletion of around 21% (Carneiro et al. 2011).

13.4.2 Rabbit Genetic Resources in Africa

13.4.2.1 North African Rabbit Breeds

Algeria Rabbit Breeds

Rabbit farming has existed in Algeria for a very long time (Ait Tahar and Fettal 1990). But according to Berchiche and Kadi (2002), in Algeria, there was no study on indigenous rabbit populations before 1990. In the nineteenth century, the invasion and the arrival of European populations led to the development of rational units in the Maghreb, but this sector did not appear in Algeria until the early 1980s (Colin and Lebas 1996). Three indigenous rabbit breeds exist in Algeria, namely: *Kabyle breed*, Synthetic breed, and White population.

Kabyle Rabbit Breed

Belonging to the local population from the Tizi Ouzou region (Fig. 13.11), this breed is characterized by an average adult weight of 2.8 kg. This value classifies this population in the group of light breeds (Zerrouki et al. 2001, 2004), a body of medium length (arched type), descending in a gradual curve from the base of the ears to the base of the tail, and of good height, carried on limbs of medium length. Its posterior part is well developed with well-filled loins; the tail is straight. The head is convex with erect ears. Its

Fig. 13.11 The Kabyle rabbit phenotypes. (Carneiro et al. 2011)

Fig. 13.12 Phenotypes of the white breed. (Gacem et al. 2008)

coat is soft, presenting several color phenotypes, a consequence of the contribution of imported breeds such as Fauve de Bourgogne, White New Zealand, and Californian (Berchiche and Kadi 2002). This breed has a good adaptation to local climatic conditions and is used mainly in meat production, but its prolificacy and adult weight are too low to be used as such in meat-producing farms. The numerical productivity recorded in the females of this population is of the order of 25–30 weaned rabbits/female/year (Berchiche and Kadi 2002; Zerrouki et al. 2005).

The White Breed

It is a population of "commercial strains" (See Fig. 13.12), which was imported from France by Algeria (1985–1986), characterized by a dominant albino phenotype and produced by a state cooperative. According to Zerrouki et al. (2004), young individuals are weaned at 30–35 days old with an average litter size at birth of 7.1 ± 2.4, of which 6.7 ± 2.8 are born alive; litter size at weaning is 5.8 ± 2.4; stillbirth proportion is 7.3% of total kits born, and birth to weaning mortality is 15.8% of kits born alive; prolificacy is similar to that observed for the indigenous population, but kit's mortality is lower; the average live weight at mating is 15% higher than the indigenous population (3.34 vs. 2.9 kg).

The Synthetic Population

The synthetic population is called "ITELV 2006" (Fig. 13.13), created in 2003 by a cross between the females of the indigenous population and the males of the strain INRA 2666, to improve the potential of rabbits intended for meat production in Algeria. It is of medium size but heavier and more productive; its coat is characterized by several color phenotypes: brown, white, black, gray, and sometimes mixed (spotted) (Gacem and Bolet 2005; Gacem et al. 2008; Bolet et al. 2012).

Moroccan Rabbit Breeds

Rabbit activity in Morocco is relatively recent. The main objective of rabbit breeding by Moroccan breeders is the production of meat for 99.85% of them. Due to the traditional and secondary nature of breeding, 91.1% do not practice any registration. Most animals used on farms (87.7% of cases) consist of purebred rabbits or indigenous populations.

Tadla Rabbit Breed (See Fig. 13.14)

The Tadla breed is of small size and raised for meat production. Tadla rabbits are of medium body length. Chest circumference is relatively similar to that of Zemmouri rabbits, but the loin appears to be relatively narrow in width, which may impair meat production. The hips are strong,

Fig. 13.13 Phenotypes of the synthetic breed

Fig. 13.14 Tadla breed

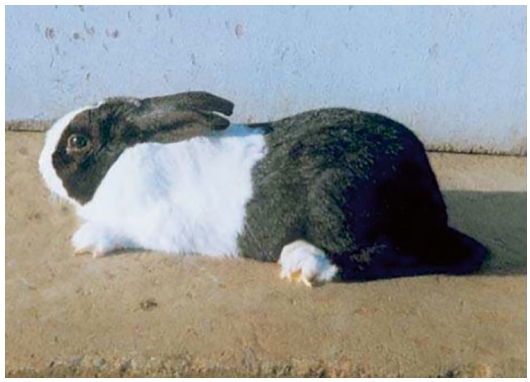

Fig. 13.15 Zemmouri breed

with a convex head, gray eyes, and erect ears. In addition, the length of the feet and legs is about 22.5 and 12.8 cm, respectively, and the tail is curly. Furthermore, the Tadla rabbits are well adapted to hot weather (40 °C in summer). They have resistance to some diseases (fungal infections) but are more sensitive to viral hemorrhagic disease (VHD) than other breeds.

Zemmouri Rabbits Breed (Fig. 13.15)

At the beginning of the invasion of Morocco by France and Spain (1912), some exotic rabbit breeds were brought by the European religious people. These rabbits were naturally mated to the native stock of the indigenous population in Azrou (Middle Atlas Mountains) and Temara (Rabat region). After several generations, the resulting populations were adapted to local environmental conditions. Then, the inter-mating of the populations of both areas probably gave origin to the Zemmouri population, which is now quite stable regarding phenotypical traits. The Zemmouri breed is of medium size and raised for meat production, the skin being used for traditional manufacture. Regarding its large body length, Zemmouri rabbits seem to have a good ability for meat production; the hips are quite strong; the loin, which is quite large, carries a good amount of meat; the chest circumference balances in good shape with the rest of the body with a convex head, maroon eyes and erect ears, feet and legs: medium in length and a straight tail. Regarding sexual maturity, Zemmouri rabbits seem to be sexually mature earlier than the exotic breeds known in Morocco. This trait needs to be further studied. However, the body weight at first mating for both sexes is within the normal range (80–85% of their expected adult weight). Further, the conception rate in Zemmouri rabbits is relatively lower than that seen in exotic improved breeds (Californian and New Zealand White). Also, the litter sizes at birth and at weaning, and the litter weights at birth and at weaning are still low in comparison to improved breeds.

Fig. 13.16 Bauscat breed. (El Raffa et al. 2002)

Fig. 13.17 Giza White Breed. (El Raffa et al. 2002)

Fig. 13.18 Chinchilla breed. (Bolet et al. 2012)

Egyptian Rabbit Breeds

- The Bauscat Rabbits (Fig. 13.16)

This breed is a medium-sized breed and is used mainly for meat production. This breed has well-rounded hips with a well-filled loin. The ribs are carried forward to combine with the shoulders, which balance with the rest of the body. The shoulders blend smoothly into the midsection, and the midsection smoothly extends into the hindquarters. The body is of medium length with good depth. The top bodyline rises in a gradual curve from the base of the ears to the center of the hips and then falls in a smooth curve downward to the base of the tail. The sides taper slightly from the hindquarters toward the shoulders. The back is markedly convex ventrally without being potbellied. The skin is smooth (El Raffa et al. 2002).

- The Giza White Rabbits (Fig. 13.17)

In 1932, a native stock of rabbits (Baladi rabbits) was bred by the Animal Breeding Department, Cairo University, Giza, Egypt, in an attempt to form a breed of uniform characteristics, El-Khishin. These rabbits were of different colors and sizes. Colors were isolated, and black and albino colors were segregating. In 1937, systematic breeding took place with the objective of obtaining an albino type of rabbit with a faster rate of growth and a larger litter size, which is presently known as the Giza White breed. Closed breeding in the albino population was performed for several years. This is a medium-sized breed and is used mainly for meat production. The body is of medium length with good depth and soft, silky fur. In addition, the top bodyline rises in a gradual curve from the base of the ears to the center of the hips and then falls in a smooth curve downward to the base of the tail. The sides taper slightly from the hindquarters toward the shoulders. The back is markedly convex ventrally without being potbellied. The skin is smooth. Giza White rabbits are late in their sexual maturity, and the conception rate of Giza White rabbits is relatively higher than that of standard breeds raised in Egypt.

- Chinchilla Breed (Fig. 13.18)

This is a medium-sized breed and is used mainly for meat production. In fact, the real Chinchilla has a dark slate blue undercolor at base; the intermediate portion is pearl—and should be as light as possible. The top edge has a very narrow black band, above this is a very light

Fig. 13.19 Baladi Breed. (El Raffa et al. 2002)

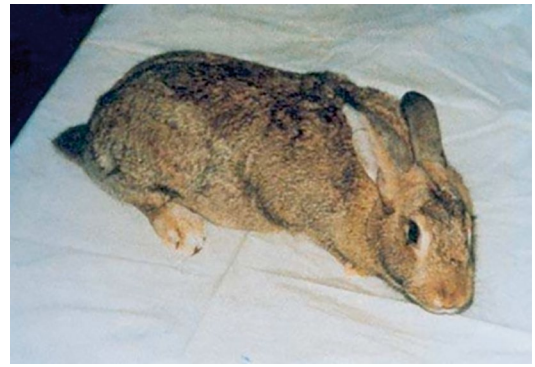

Fig. 13.20 Gabali Breed

band brightly ticked with black hairs, either wavy or even ticked to make the beautiful chinchilla surface color. The body of this breed has well-rounded hips with a well-fitted loin and hips. The body is of medium length, with a rather compact and chubby body. The top bodyline rises in a gradual curve from the base of the ears to the center of the hips and then falls in a smooth curve downward to the base of the tail. The back has a slight, gradual arch starting at the ear base. The skin is smooth (El Raffa et al. 2002).

- Baladi Breed (Fig. 13.19)

The origin of the Baladi breed is a result of several crossbreedings practiced between indigenous (native) rabbits and Flemish Giant (G) in stations of the Poultry Breeding Section, Ministry of Agriculture (Galal and Khalil 1994). The breeding plan is used for producing three native strains of Baladi Red (R), Baladi White (W), and Baladi Black (B). This is a medium-sized breed and is used mainly for meat production. The body of the three strains of Baladi rabbit has well-rounded hips with a well-filled loin. The ribs are carried forward to combine with the shoulders, which balance with the rest of the body. The shoulders blend smoothly into the midsection, and the midsection smoothly extends into the hindquarters. The body is of medium length with good depth. The top bodyline rises in a gradual curve from the base of the ears to the center of the hips and then falls in a smooth curve downward to the base of the tail. The sides taper slightly from the hindquarters toward the shoulders. The back is markedly convex ventrally without being potbellied. The skin is smooth. The Baladi breed has a medium to high conception rate since this rate ranges from 42% to 85% (El Raffa et al. 2002).

- Gabali Breed (Fig. 13.20)

This breed is from Sinai and the Eastern and Western (in the north coast belt) deserts of Egypt. They are raised by the Bedouins for their food. They were also raised in some western Giza Governorate areas by individual persons. It is a medium-sized breed and is used mainly for meat. The color is yellowish-brown with black hairs spread all over the body, with soft fur. Black hairs are intense on the tail, the body has well-rounded hips and well-fitted loins and ribs, extending forward to combine with the shoulders. The shoulders blend smoothly into the midsection, which extends into the hindquarters, with medium body length and a good depth. The top bodyline shows a gradual curve to the base of the tail. The sides taper slightly from the hindquarters to the shoulders, and the back is markedly ventrally convex. The animals are not potbellied. The skin is smooth. Regarding reproductive performance, the average age at first kindling in Gabali rabbits is about 7 months, which is later than 6.2 and 6.3 months reported by El Raffa et al. (2002) on New Zealand White and Californian rabbits, respectively. Moreover, the average performance of Gabali rabbits for litter size traits is within the average range (8–12 rabbits) (El Raffa et al. 2002).

In the following regions of Africa, it is rare to find breeders who use an indigenous rabbit breed for production, except for South Africa, where breeders use exotic breeds and an indigenous breed called Phendula, and Sudan, where a breed called Baladi Sudan is used. In the other regions, the indigenous breeds are generally referred to as local breeds, with heterogeneous characteristics and no standardization approach (Fig. 13.21).

13.4.2.2 Central and West African Rabbit Breeds

In Central and West Africa, the rabbit breeds kept are exclusively exotic breeds such as: Dutch rabbit, New Zealand White, Cottontail rabbit, Hyla rabbit, Chinchilla rabbit, California rabbit, Giant Flemish rabbit, Rex rabbit, and Satin rabbit.

13.4.2.3 East African Rabbit Breeds

In many countries in East Africa, French Ear Lop, California White, Flemish Giant, New Zealand White, and some local crossbreeds (crosses between indigenous and exotic rabbit breeds) are kept.

(a) Sudan

Sudan Baladi is an indigenous breed of Sudan (El Raffa et al. 2002). Researchers compared feedlot performance, carcass and non-carcass traits of a temperate rabbit breed, New Zealand white (NZW), and Sudan Baladi (SB). Thirteen individuals of each breed were used. The results revealed that breeds significantly ($P < 0.05$) affected final live weight and weight gain. The traits recorded 1.8 vs. 1.4 kg for live weight and 17.4 vs. 10.7 g/day for weight gain for NZW and SB, respectively. For carcass traits, slaughter weight, hot carcass weight, cold carcass weight, and one-side carcass weight showed significant ($P < 0.05$) breed differences. They estimated 1672 vs. 1375 g for slaughter weight, 940 vs. 749 g for hot carcass weight, 882 vs. 693 g for cold carcass weight, and 413 vs. 324 g for one-sided carcass weight, respectively, for NZW and SB breeds. The meat/ bone ratio was significantly ($P < 0.05$) higher in SB (5.5%) than in NZW (4.4%). Most of the non-carcass traits studied showed no significant breed differences. It was, therefore, concluded that the temperate breed was superior to the local breed in meat yield and weight gain.

(b) Kenya

Mailu et al. reported that the common rabbit breeds used for commercial production in Kenya include the French Ear Lop, California White, Flemish Giant, New Zealand White, and some local crossbreeds (Mailu et al. 2013).

Fig. 13.21 Phendula

13.4.2.4 Southern African Rabbit Breeds

Most countries of Southern Africa use imported rabbit breeds. These breeds generally include Flemish Giant, Grey Giant Rabbit, Soviet Chinchilla Rabbit, New Zealand White Rabbit, New Zealand Black Rabbit, California Rabbit, and Dutch and Angora Rabbits.

13.4.2.5 South Africa

In South Africa, the rabbit breeds are used for meat and skin production (Steenkamp 2021). The majority of breeders used exotic breeds, as well as a local breed called Phendula. The Phendula is a local landrace breed developed in 2002 and was recognized officially by the South African Rabbit Judges Council in 2014. The Phendula was selected with the objective of producing a hardy, adaptable breed that is suited to the South African climate and that incorporated genetics from Chinchilla Giganta, Flemish Giant, New Zealand

Red, and New Zealand Black rabbits (recognized breeds in South Africa), as well as those from hardy, nondescript rabbits in the area.

13.4.3 Breeding System

The rabbit rearing system is a system whose productivity depends mainly on the reproductive performance of the doe (fertility and prolificacy) and on the growth and health of the rabbits (Castellini et al. 2003). Rabbit meat is obtained under four farming systems. Thus, Colin and Lebas (1996) have described three types of rabbit farming: traditional, intermediate, and commercial. Another so-called organic production system has appeared in recent years to meet consumer demands (Lebas-Fraczak 2009).

13.4.3.1 Traditional Cuniculture

Composed of small farms that keep about 8–20 females. Located in rural areas or on the outskirts of towns (Saidj et al. 2013), the animals used are indigenous breeds; they are housed in old, recovered premises and sometimes in traditional buildings specially designed for this breeding. The diet is almost exclusively based on grass and domestic byproducts (plants and table scraps), sometimes supplemented with bran (Berchiche and Kadi 2002), which is common to several regions in the world (Finzi 2011). This system provides a significant protein intake for the local human population. In addition, it can recover a large amount of household waste and unusable byproducts. Rabbits from traditional farms are characterized by modest zootechnical performance. These animals are increasingly rare on the market due to the disappearance of traditional breeding (Lebas 2002).

13.4.3.2 Intermediate Rabbit Culture

Composed of medium-sized farms (8–100 females) for both food and commercial purposes, using semi-intensive methods. The diet is farm-type, supplemented with products bought off the farm, and a large proportion of rabbits are produced and marketed. This type of farming is found in peri-urban as well as urban areas (Lebas 2002).

13.4.3.3 Rational Cuniculture

Made up of large farms (more than 100 females) using rational marketing-oriented techniques, the promotion of this breeding is initiated by the exploitation of hybrid breeders of the Hyplus type, introduced from France or Belgium (Berchiche et al. 2000), but their adaptation has often proven difficult due to climatic conditions and local diet (Berchiche 1992).

Rabbits are housed in cages inside closed, lighted, and ventilated buildings; they are heated in winter and cooled in summer (Lebas 2000). These farms are grouped into cooperatives, themselves supervised by various technical institutes (Colin and Lebas 1995).

13.4.3.4 Organic Cuniculture

Currently, consumers in Europe are increasingly demanding meat from an organic production method (impact on the environment and on health). Thus, the organic meat market has grown (Lebas 2008). The organic rabbit production system implements most of the agroecological principles. Rabbits, generally of rustic breed, are reared in the open air in mobile cages on unfertilized multispecies meadows. The cages are moved every day to provide fresh grass to the animals, which limits contact with their droppings and thus reduces parasite infestation (coccidia). In addition to pasture, the animal feed is mainly composed of dry fodder and a mixture of cereals and protein crops grown in combination, possibly supplemented by commercial organic whole granulated feed. This type of rabbit production system is generally small in size (around 40–60 breeding females) and driven by an extensive reproductive rate (80–90 days between kindling); this makes the system much less productive (20 rabbits/female/year); consequently, its economic viability is only allowed by a higher wind price (Lebas 2000; Fortun-Lamothe et al. 2013).

13.4.4 Genetic Characterization of African Rabbits

Generally, genetic variability can be defined, at a given locus, as the diversity of alleles encountered. For a set of loci, it is defined as the diversity of alleles and their combinations. In absolute terms, genetic variability can be defined over the entire genome, but in the absence of a large number of loci easily studied on large numbers. There are different approaches for defining genetic variability: phenotypic (morphologic), biochemical (isoenzyme, blood groups, and karyotype), and molecular (mtDNA, SNP, SSR, ARFL, and RABD) information, which gives access to this or that part of the genetic variability.

Chromosomes are the support of the genes that carry genetic information. According to cytological studies, the rabbit genome consists of two sex chromosomes, XX (for a female) and XY (for a male), and 21 pairs of autosomes (2n = 42). The rabbit karyotype was first described in 1926 by T.S. Painter. Mapping genes and markers involves determining their position along the chromosomes. A comparative chromosome map between humans and rabbits has been published by Korstanje (Korstanje 2000), this map is based on the results of reciprocal chromosome painting. The rabbit karyotype was refined in 2002 (Hayes et al. 2002), which resulted in the fine localization of 250 new genes distributed on all chromosomes (Rogel-Gaillard et al. 2009). A chromosomal map of microsatellite markers was also produced (Chantry-Darmon et al. 2005), which made it possible to construct a genetic map with all of the linking groups between markers positioned and oriented on the chromosomes (Chantry-Darmon et al. 2005).

Genetic markers must have at least four qualities for genetic mapping methods to be optimal: be polymorphic, codominant, neutral, and homogeneously distributed on the genome (Falconer and Mackay 1996).

In rabbits, as in mice and rats, the size of the animal as well as the ease and speed of reproducing made it possible to easily position morphological and biochemical markers on the first linkage groups. In 2000, the rabbit linkage map was made up of 37 loci including 13 morphological markers, 17 immunological markers and seven biochemical markers, forming nine linking groups, of which four are assigned: linkage group I to chromosome OCU1, the group of linkage VII to chromosome OCU12, linker group VIII to chromosome OCU2, and linker group IX to chromosome OCU17 (Korstanje 2000). Ebegbulem (2012) studied in humid tropical southern Nigeria the bodyweight (BWT) and linear body measurements (LBM) of 21 growers and 21 breeders, crossbreed rabbits. The LBMs were: head length (HL), body length (BL), heart girth (HG), ear length (EL), and tail length (TL). The breeders showed significantly higher mean values in BWT and all LBMs than the growers, except in TL. Sex, however, did not have any significant influence on BWT and LBMs between the two groups of rabbits, though the bucks showed slightly higher numerical values than the does. The correlation matrix showed high, positive, and significant values among most of the traits studied ($p < 0.01$). The highest coefficient was between BWT and HG ($r = 0.848$). Results of the regression coefficients showed that HG was the best predictor of BWT, contributing 93% of the total variability. In their study, North et al. examined the meat production of the New Zealand White (NZW) and Phendula rabbit breeds (North et al. 2019). The live weights (LW) and average daily gains (ADG) of 80 (44 males, 36 females) NZW and 40 (22 males, 18 females) Phendula rabbits, housed in single-sex groups of three, were recorded from weaning (5 weeks) until slaughter (11 weeks). The slaughter weight, carcass, organ, and carcass portion weights were recorded for 10 male rabbits and 10 females of each breed, and the physical and proximate chemical quality of the loin meat was determined. The breeds differed for the reference carcass (RC) yield (NZW: 85.3 ± 0.14%; Phendula: 84.9 ± 0.24%) and the proportions of the low-value fore (NZW: 38.6 ± 0.26%; Phendula: 37.6 ± 0.28%) and high-value intermediate (NZW: 19.6 ± 0.16%; Phendula: 20.4 ± 0.28%) parts. Females had greater LW and ADG at 11 weeks old and reduced dressing percentages but greater RC yields owing to lighter heads and red offal. Females also had

smaller proportions of the fore part. Meat quality did not differ between the breeds or sexes. All breeds are defined according to the international standards based on external appearance. Quantitative traits were measured on 70 rabbits belonging to different agroecological localities (Steppic, Mountainous, and Saharan). A comparison was carried out in order to identify differences and similarities between males and females. The barometric characterization revealed a significant phenotypic diversity in the population studied. Multiple correspondence factor analysis (MCA) and ascending hierarchical classification (CAH) identified three distinguished classes. In general, the local rabbit has an average weight of 1.97 kg, an average body length of 28.8 cm, and a chest measurement of 26.1 cm. Identification of the local rabbit population in western Algeria is ongoing, specifically in the two wilayas of Tlemcen and Sidi Bel Abbès. This study is based on a phenotypic approach via morphometric tools using 15 quantitative characters, including (lt, LT, lo, Lo, Do, Dy, Pc, lp1, lp2, lc, ltc, lQ, lD, LD, TP) measured on 93 rabbits belonging to the following breeds: Synthetic, local, Half-Giant, Giant, White Population, Berber, Butterfly, Havana Butterfly, and Lion's Head. Moreover, eight qualitative characters (Cp, Cy, CT, Cn, Co, CQ, Cm1, Cm2) were also assessed. The findings between sexes were discussed, of which the barometric characterization revealed a clear phenotypic diversity between the breeds studied, with very highly significant differences ($p < 0.001$) for most of the body measurements used. On the other hand, the biometric measurements of the rabbit breeds studied did not vary with sex; the results showed that there were no significant differences at $p < 0.001$ between males and females for all the characteristics studied. Multiple correspondence factor analysis and the ascending hierarchical classification (CAH) identified four classes in the studied population.

Van Haerigen et al. constructed a genetic map, comprising 103 AFLP markers distributed in 12 linkage groups and covering 583 cm (van Haeringen et al. 2002). This AFLP map was subsequently enriched and includes 400 markers distributed over 24 linkage groups, 14 of which are assigned to rabbit chromosomes. However, even if this map allowed the detection of QTL of interest for the study of atherosclerosis (Hayes et al. 2002), it cannot be used for the identification of candidate genes, because the AFLP markers do not allow an integration of genetic and cytogenetic maps and do not provide comparative mapping information.

Ragoju et al. used RAPD markers to assess the genetic variability among three rabbit breeds: Soviet Chinchilla, White Giant, and Grey Giant. They reported no significant genetic variability among and within these three rabbit breeds (Rangoju et al. 2007).

Before 2001, only 31 microsatellites were characterized in rabbits, as few laboratories were interested in the subject. The British group of G. Hewitt developed nine microsatellites by screening a genomic DNA plasmid library with radioactive probes (Surridge et al. 1997). A French team from the CNRS, interested in the genetic diversity of wild rabbit populations, has published nine microsatellites: six isolated from a plasmid library of genomic DNA (Sat5, Sat7, Sat8, Sat12, Sat13, and Sat16) and three provided through the EMBL database (Sat2, Sat3 and Sat4) (Mougel et al. 1997). The Dutch group from Utrecht identified 184 microsatellite sequences in the EMBL database and determined primers for 13 of them (Van Haeringen et al. 1996).

In Tunisia, the genetic status of 12 Tunisian indigenous rabbit populations has been tested by using 36 microsatellite loci. A total of 264 rabbits from the villages of the Tozeur and Kebili regions were studied. This study is the first detailed analysis of the genetic diversity of Tunisian indigenous rabbit populations, and the data generated provides valuable information about the genetic structure and the priorities for their conservation (Ben Larbi et al. 2014).

In Egypt, three native rabbit breeds—Gabali, Baladi Red, and Baladi Black—in addition to the New Zealand White, were genotyped using 12 microsatellite markers. The results of this study confirmed the applicability and efficiency of this microsatellite panel for assessing genetic diver-

sity and setting the conservation priorities for Egyptian local rabbits (Badr et al. 2019). Furthermore, the selected cytochrome c oxidase subunit I (COX1) gene and four microsatellite markers were used to investigate the population genetic structure of Red Baladi (RB) and Sinai Gabali (SG) rabbits as the Egyptian native rabbit breeds. Both microsatellite and the COI gene as a DNA barcode proved to be exceedingly successful in distinguishing between breeds under investigation (Fortun-Lamothe et al. 2013).

In Nigeria, seven microsatellite markers were used to determine genetic variation amongst the rabbit breeds (New Zealand White, New Zealand Red, Californian White, and Chinchilla). The genetic characterization, as revealed by these microsatellite markers, showed that the four rabbit breeds have more within-breed variation than between-breed variation. Also, the low values of genetic differentiation regarding the inbreeding estimates indicated a relatively high outbreeding among the four rabbit breeds.

In Kenya, Owuor et al. (2019) evaluated the population structure of domesticated rabbits by using 263 base pairs of the mtDNA D-loop region. The rabbit population analyzed in this research was from the Western region (Kakamega, Vihiga, and Bungoma), the Central region (Laikipia and Nyandarua), and the Eastern region (Kitui, Machakos, and Makueni). In this study, the researchers found five unique haplotypes in the mtDNA D-loop region. The results suggested that the Kenyan domesticated rabbits may have originated from Europe. The integration of exotic breeds into breeding programs could have contributed to the low genetic diversity.

Due to its position in the phylogenetic tree of mammals and for its role as a model species in biomedical research, the rabbit was selected for the “Mammalian Genome Project” (Lindblad-Toh et al. 2011). This project aims to identify sequences conserved between species in order to improve the annotation of the human genome and to produce a complete atlas of functional DNA sequences. So, for the first time, the genome of a New Zealand rabbit was completely sequenced at low density (OryCun1.0) by the "Broad Institute" (Boston, USA). Many laboratories at the international level working on rabbits joined forces to write a "white paper," which called for deeper sequencing. The rabbit genome was then sequenced a second time, more densely (OryCun2.0) (Carneiro et al. 2014), and included the sequencing of clones of large DNA fragments (BAC) provided by INRA (France). Annotation of the genome, that is, the location and description of the biological function of genes, was carried out by the Ensembl genomic platform using in particular the sequencing of RNA strands (RNA-Seq) of tissues of rabbits provided by INRA and the human orthologous annotation (similar genes shared by the two species) (http://www.ensembl.org/Oryctolagus_cuniculus/Info/Annotation).

Genome annotation identified 19,203 protein-coding genes, 3375 noncoding genes, and a total of 24,964 transcripts. The University of Uppsala (Sweden) and the University of Porto (Portugal) have sequenced six breeds and wild French and Spanish rabbits, belonging to the two subspecies *O. c. algirus* and *O. c. cuniculus* (Carneiro et al. 2014). This sequencing made it possible to identify 51 million markers of the single nucleotide polymorphism (SNP) type, that is to say, regions of the genome that present differences between individuals for a single DNA base, as well as 5.6 million insertion/deletion polymorphisms were detected. SNPs represent the most abundant source of variation in the genome. Genotyping is the discipline that aims to determine the nature of the alleles (variations) of the markers of each individual. The standardization and mechanization of genotyping techniques now make it possible to quickly know the sequence of several tens or hundreds of thousands of SNP markers. As part of the European project “A Collaborative European Network on Rabbit Genome Biology – RGBNet,” a commercial A y metrix chip, supporting 200,000 SNP markers, has been developed, thus offering the possibility of carrying out high-throughput genotyping of rabbits. It was released on the market in 2016.

The goal of genetic association and linkage studies is to identify chromosomal regions (QTL for "Quantitative Trait Loci") involved in the expression of traits of interest. They are based on the statistical demonstration of a link between the genotype of certain markers and the phenotypic

value of the characters. The search for QTL is one of the stages in the search for causal mutations. Only one QTL research study has been published to date for rabbits (Ben Larbi et al. 2014). The most significant QTLs were identified on chromosome 7 for growth traits, on chromosome 9 for bone weight, and on chromosome 12 for water loss on wiping. Due to the small number of markers used, the regions of the genome highlighted were too large to be able to precisely identify the genes involved in the development of these characters.

The candidate gene approach consists of studying the association between the alleles of certain genes chosen, on the basis of prior knowledge, and the expression of phenotypes (color, growth, reproduction, feed efficiency, resistance to disease). A variation in the gene can indeed affect one of the key physiological functions in the development of the phenotype. The first step in this approach is to select a list of genes whose biological functions are known from studies carried out in the target species or other species. The second step is to identify variations in the DNA sequence of these genes. These variations are identified by genome sequencing. The third step is based on association studies, which will make it possible to statistically verify the link between variations in the gene and the phenotype in the populations studied. This strategy has the advantage of finding potentially interesting polymorphisms (variations in genes) very quickly and inexpensively. Its drawback is that it is limited to genes for which we know a priori neither the value of their effect on the characters of interest nor their variability in the population studied. Numerous candidate gene studies have been conducted in rabbits (Miller et al. 2014). They can be divided into three categories corresponding to the groups of traits studied: i) growth and meat production traits, ii) female reproductive traits, and iii) disease resistance traits.

13.4.4.1 Growth and Carcass Traits of African Rabbits

Due to the economic importance of growth and meat production, most studies of candidate genes in rabbits have focused on this group of traits (Owuor et al. 2019; Lindblad-Toh et al. 2011; Carneiro et al. 2014; Sternstein et al. 2015; Miller et al. 2014). They investigated the most commonly recorded and selected growth trait in commercial meat production populations, 70-day weight. Other authors (Fontanesi et al. 2011) have studied growth, carcass, and meat quality traits measured at different ages. The myostatin gene (MSTN) has been extensively studied in rabbits because of the well-known effects of mutations in this gene on the development of muscle tissue. The effects of hypermuscularity linked to variations in this gene, MSTN, have so far been found in rabbits in the breeds and lines studied (Peng et al. 2013).

The genes involved in the functioning of the somatotropic axis, and in particular the gene for growth hormone (GH1), growth hormone receptor (GHR), insulin-like growth factor (IGF2), and the melanocortin receptor gene, can have significant effects on growth or production traits. These effects have been described in rabbits (Fontanesi et al. 2012a, 2013; Fontanesi 2016). Most of these studies showed that the most favorable allele of these genes is also the most common in the commercial populations studied. This observation demonstrates the effect of selection, which tends to increase the frequency of favorable alleles by selecting at each generation the best animals (carriers of favorable genes) to reproduce them and constitute the following generations.

Reproductive Traits

The candidate gene studies for reproductive traits are all based on a single experimental divergent population selected for uterine capacity (maximum number of fetuses that a rabbit can carry when ovulation rate is not a limiting factor) for ten generations (Fontanesi et al. 2012b). An association between the polymorphism of three genes (OVGP1, PGR, and TIMP1) and some reproductive characteristics, including embryonic implantation and litter size, has been demonstrated in this experimental population (Peiró et al. 2008).

Disease Resistance Traits

Candidate gene studies have been carried out by Chinese teams from the Sichuan Agricultural University in Chengdu on various local and

imported breeds for traits of resistance to digestive disorders. These teams have demonstrated the involvement of various genes encoding receptors participating in the recognition of pathogens: “Toll like receptor 4” (Zhang 2011) (TLR4), “Nucleotide-binding oligomerization domain 2” (Zhang et al. 2013) (NOD2), and “Dendritic-cell associated C-type lectin 1” (Peng et al. 2013) (Dectin-1). They also identified the following genes: "Myeloid differentiating factor 88" (MyD88) encodes a protein that has a central role in the activation of innate and adaptive immunity (Chen et al. 2013); NLR Family Pyrin Domain Containing 12 (NLRP12), which plays a role in the regulation of inflammation; Janus kinase (JAK1)–an intracellular signaling molecule, “Signal transducer and activator of transcription 3” (STAT3)–a factor for transcription and differentiation of immune cells, and Chemokine receptor 6 (CCR6)–a receptor controlling the movement of leukocytes.

13.5 The Honeybee in Africa

The bee is an important insect that has been exploited for its honey, wax, royal jelly, pollen, propolis, and even venom. Bee products are known not only for their economic importance but also for their beneficial properties on human health. Bees pollinate (fertilization, production of fruits and seeds) and, thus, maintain the sustainability of the plants and the ecosystem. Beekeeping is a lucrative activity that provides a sustainable source of employment and additional income for beekeepers and artisans making beehives (Fotso et al. 2021). A multitude of subspecies and ecotypes of honeybees are reported. Beekeepers used mostly traditional methods, that is, fire, to harvest honey produced by wild colonies. Fire could be a threat to honeybees as the beehives and colonies are often destroyed (Tchoumboue et al. 2001). The deforestation, breeding, urbanization, the use of chemicals by farmers, and locust control are also factors that are reducing the number and diversity of these insects.

13.5.1 Generality on the Honeybee

13.5.1.1 The Bee Species of the Genus *Apis*

The bee is an eusocial flying insect, belonging to the animal kingdom, the phylum Arthropoda, the insect class, and the order Hymenoptera (Peiró et al. 2008). It has been around for over 70 million years (Linksvayer et al. 2012). There are about ten recognized bee species belonging to the genus *Apis* (Engel 1999; Arias and Sheppard 2005). All of these species are represented by three distinct groups according to phylogenetic analyses of nuclear DNA and mitochondrial (Arias and Sheppard 2005). The species of the first group are dwarf bees (*Apis florea* and *Apis andreniformis*), the second group species are giant bees (*Apis dorsata, Apis laboriosa, Apis bingham,* and *Apis nigrocincta*), and those of the third group are nesting bees (*Apis mellifera, Apis cerana, Apis koschevnikovi,* and *Apis nulensis*) (Arias and Sheppard 2005; Raffiudin and Crozier 2007). Of all bee species in the genus *Apis*, only two species, namely *Apis mellifera* (in Africa and Europe) and *Apis cerana* (in Asia), are domesticated by humans (Koeniger 1976). According to Ruttner et al. *(*Ruttner and Volprecht 1983*)*, *Apis mellifera* and *Apis cerana* are in the first stages of speciation.

13.5.1.2 The Origins of the Honeybee *Apis mellifera*

Apis mellifera is native to Africa, Europe, and the Middle East. It was introduced by humans to America, Australia, and other countries around the world (Gupta et al. 2014). Three hypotheses (Fig. 13.22) are proposed regarding the origin of the honeybee *Apis mellifera* (Gupta et al. 2014). The first hypothesis (i), based on morphometric analyses, suggests an expansion from the Middle East, involving the colonization of Europe, toward two trajectories, one Eastern and another Western (Mogga and Ruttner 1988). The second hypothesis (ii), based on a molecular study of mitochondrial DNA, suggests an expansion from the Middle East, which does not involve Western colonization of Europe (Garnery et al. 1992). The third hypothesis (iii) suggests an expansion from

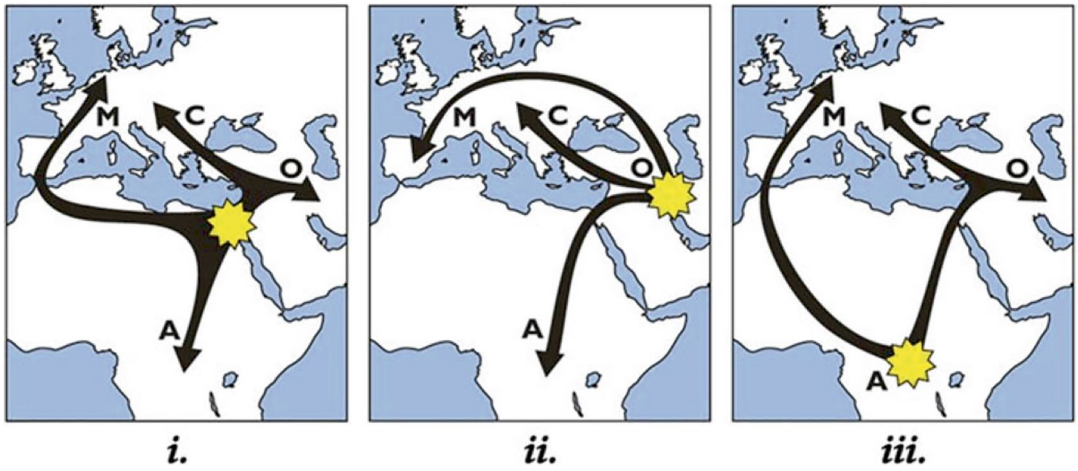

Fig. 13.22 The origin of the honeybee, *Apis mellifera,* according to three hypotheses. (Gupta et al. 2014)

Africa toward both trajectories, east and west (Wilson 1971), which was confirmed by the analyses of 1136 SNPs (Sinha et al. 2006).

13.5.1.3 The Subspecies of *Apis mellifera* in the World

The subspecies of *Apis mellifera* in the world are grouped at the level of five evolutionary branches (A (African), C (Carnica), M (Mellifera), O (Oriental), and Y (Yemenetica) (Garnery et al. 1992; Ruttner et al. 1978). Several studies have characterized the subspecies of *Apis mellifera* based on their morphological and genetic differences (Ruttner et al. 1978; Miguel et al. 2007; Miguel et al. 2011).

13.5.1.4 Geographical distribution of *Apis mellifera* in Africa

The honeybee *Apis mellifera* is found in all African countries (Mogga and Ruttner 1988; Chahbar et al. 2016; Haddad et al. 2015). According to Ruttner et al. (Ruttner et al. 1978), all individuals of the *Apis mellifera* species draw a very clear, lying "Y" (Fig. 13.22i). In the three branches of the "Y," the studied samples are arranged in a characteristic order; in the trunk of the "Y" are the races of Africa south of the Sahara, in one branch the races from the eastern part of the Mediterranean region, and in the other those from the western part (branches A, C, and M). These data are justified by mitochondrial DNA analysis (Garnery et al. 1992; Cornuet and Garnery 1991; Meixner et al. 2011). Specialists distinguish at least 29 subspecies of *Apis mellifera* in Africa (Ruttner et al. 1978; Meixner et al. 2011).

The most dominant races are *Apis mellifera scutellata* and *Apis mellifera adansonii*. For *Apis mellifera scutellata*, they are found in Eastern Africa from Ethiopia to Southern Africa, passing through Burundi, Kenya, Tanzania, and Zimbabwe (Gupta et al. 2014; Hepburn and Radloff 1998). As for *Apis mellifera adansonii*, it covers Benin, Cameroon, Chad, Congo Basin, Nigeria, and Senegal (Ruttner 2013; Amakpe 2010). The two subspecies, *Apis mellifera scutellata* and *Apis mellifera adansonii*, in the presence of the third race *Apis mellifera capensis,* are recorded in South Africa and Namibia (Hepburn and Radloff 1998; Radloff and Hepburn 1997). In Southeast Africa, Mozambique, Zambia, and Zimbabwe, members of honeybee populations of three subspecies, those of *Apis mellifera litorea*, *Apis mellifera scutellata,* and *Apis mellifera adansonii* (Hepburn and Radloff 1998). For the North African regions, five subspecies of *Apis mellifera* are exploited, namely *Apis mellifera intermissa, Apis mellifera sahariensis, Apis mellifera major, Apis mellifera lamarckii* (formerly called *fasciata*), and *Apis mellifera iberica* (Koudjil 1990; Garnery et al. 1993, 1995). The tellian bee, *Apis mellifera intermissa*, is found in

the north of Libya to Morocco, passing through Tunisia and Algeria (Hepburn and Radloff 1998). *Apis mellifera sahariensis* is exploited in the desert of Algeria, particularly in the southwest of Morocco (Chahbar et al. 2016; Haccour 1960). In Egypt, the race *Apis mellifera lamarckii* (Sheppard et al. 1996) was introduced in the nineteenth century (Schiff and Sheppard 1993; Schiff and Sheppard 1995). In Northeast Africa, *A. m. jemenitica* is being identified from Mali to Sudan (Amakpe 2010). In the same way, in Somalia, Franck et al. (Franck et al. 2001) mentioned the presence of the *A. m. litorea* species. Contrarily, there are no native *Apis mellifera* in the Pacific and Caribbean regions where the European lineage bees have been imported (Paterson 2006).

13.5.1.5 The Influence of Environmental Factors on the Geographical Distribution of Races and Bee Characteristics

The high variability between the different African races of *Apis mellifera* is mainly due to climatic factors (Hepburn and Radloff 1998). Therefore, the biogeographic distribution of the races of *Apis mellifera* varied depending on the ecosystem (El-Niweiri and Moritz 2008). All the colonies in the regions of Burundi, Kenya, Malawi, and Tanzania belong to localities that are associated with a mountain system, and they are considered members of the same race, *Apis mellifera monticola* (Hepburn and Radloff 1998). Following the Mogga and Ruttner (Mogga and Ruttner 1988) classification system, the low-altitude bees are members of the race *Apis mellifera scutellata*, and those at high altitudes are members of *Apis mellifera monticola*. According to Ruttner (2013), the bee populations from high altitudes differ from those of low altitudes in size and pigmentation. For example, within the same breed, *Apis mellifera monticola*, two colors of pigmentation can be observed. In Kenya and Tanzania, the race *Apis mellifera monticola* is black in color; meanwhile, it is yellow in Malawi (Miguel et al. 2007). A significant correlation was found between the altitude and the size of bees, as well as their pigmentation. It was reported that for each increase in altitude, the bees become larger with a lighter color. On the contrary, a decrease in altitude results in the bees becoming small and darker in color (Radloff and Hepburn 2000). A strong correlation has been found between some adaptive traits and environmental factors in bee races of tropical Africa (Gupta et al. 2014). According to Paterson (Paterson 2006), strong colonies are generally in hot climates and are more aggressive, while the weak colonies tend to be quite mild in cool climates. Also, anthropogenic factors play a key role in this character. In areas where inhabitants search for honey, bee colonies have become more aggressive, as the milder ones are destroyed by these inhabitants (Paterson 2006).

13.5.2 Importance of Beekeeping

13.5.2.1 Ecological and Economic Importance of the Honeybee

The pollination of flowering plants is carried out by several animals and insects, such as birds and bats. Among these pollinators, insects and honeybees, *Apis mellifera* (Allsopp 1993), are the most important. *Apis mellifera* is considered one of the most important pollinating animals (Morse and Calderon 2000). Its role is essential for plants and crops in agriculture (Mouton 2011), forestry, and other ecosystems (Allsopp 1993). In 2005, the total economic value of pollination worldwide was estimated at 153 billion euros. But it is almost impossible to give any real monetary value to the pollination service because there are non-entomophilic plants, which do not need pollinators to produce fruits; however, they benefit from the visits by the pollinators, which ensure the production of larger, more symmetrical, and sweeter fruits. In Algeria, it has been shown that the pollination of bean (Benachour et al. 2007), cucumber (Benachour and Louadi 2011), and other plants belonging to different natural ecosystems (Bendifallah et al. 2012) by a large diversity of wild and domestic bees (e.g., *Apis mellifera intermissa*) greatly enhances their productivity. In Southern Africa, the two bee species,

Apis mellifera scutellata and *Apis mellifera capensis,* play a very important role in the pollination service of forests, as well as urban (Masehela 2017) and agricultural plants, such as industrial apples (Mouton 2011). In other African countries, the evidence by researchers of the pollination of flowering plants via the honeybee *Apis mellifera* has been well established, notably in some African countries. However, the supply and demand of honeybee *Apis mellifera* colonies for crop pollination is a very responsive service in several countries, however, this is not the case in the majority of African countries (Masehela 2017). On the contrary, in several African countries, beekeepers pay farmers to allow them to place the hives on their farms during the honey season.

13.5.2.2 Bee Relationship—Bioindication of the Environment

Bees also serve as biological indicators (Skorbiłowicz et al. 2018; Goretti et al. 2020). In fact, bees signal the presence of chemical degradation in the environment in which they live through two indicators: the high degree of mortality and the residues that can be found on the bodies of bees or in bee products (phytosanitary substances used in agriculture, antiparasitics and pollutants such as heavy metals and radionuclides) (Calatayud-Vernich et al. 2016).

In addition, many ethological and morphological characteristics also make bees a good ecological indicator. Indeed, most of their bodies are covered with hairs that capture the substances they encounter in flight. It is, therefore, highly sensitive to most antiparasitics, which may be present in the environment (Sabatini 2005). But it is especially at the level of bee products that the presence of toxic products (especially phytosanitary) is felt most and are, therefore, bioindicators of choice compared to environmental pollution (Skorbiłowicz et al. 2018; van der Steen 2016). Losfeld et al. (2014) showed that the rates of environmental contamination by heavy metals are higher in bee products than those detected in the body of the bee because this insect is capable of filtering and purifying nectar containing these pollutants during the honey production (Conti et al. 2018; Borsuk et al. 2021).

13.5.2.3 Beehive Products and Their Uses

Other bee-related products are jelly, wax, propolis, and venom, which are of economic importance (Oyerinde et al. 2012; Abou-Shaara 2014). Moreover, it is important to note that many communities consume the insect itself (especially the larvae) as a source of animal protein (Bamidele et al. 2021). The ancient Egyptians and Romans consumed bees for over 70 million years (Linksvayer et al. 2012).

In Africa, beekeepers do not have the same beekeeping production goals, but honey remains the top priority in animal husbandry. For example, in Algeria, beekeepers do not produce enough beeswax, and the state remains dependent on the importation of wax mixed with paraffin (Mayazine 2019). All Cameroonian beekeepers (100%) collect honey, (69.9%) wax (see Fig. 13.23), (44.2%) propolis, (15.9%) pollen, and only (3.5%) harvest royal jelly (Meutchieye et al. 2016). In Senegal and Rwanda, beekeepers do not know the production of wax; unfortunately, a very large part of the wax is discarded because it is considered waste on the one hand, and on the other, the method of extracting honey consists of burning the wax (Mayazine 2019).

Honey is a highly prized natural product because of its nutritional properties and therapeutic applications. Two types of honey are produced naturally, depending on their origins: that of flower nectar and the other of honeydew (Bogdanov 2016). Honey is used by humans for two reasons: nutritional and medicinal (Oyerinde et al. 2012). Honey of jujube, *Ziziphus lotus*, is part of the popular traditional food and medicinal practices of the inhabitants of the greater Maghreb, but its exploitation is recent and dates from the 1990s (Mayazine 2019). The pH of this type of honey varies between 6 and 7, which provides an environment that promotes the activity of diastase, an enzyme beneficial to human health. It has an interesting microbial activity, which is due to its richness in polyphenols, flavonoids, tannins, and alkaloids, which are

Fig. 13.23 Harvesting of wax by African beekeepers. (Mayazine 2019)

molecules with medicinal properties (Mayazine 2019).

The study of Benlacheheb et al. in Algeria showed that wax has a very interesting anti-inflammatory effect, especially when mixed with plant extracts (Benlacheheb Ahmed and Benchiko 2021). More, wax is used by Senegalese craftsmen and traditional healers (traditional doctors) to plug holes as well as to make seeders, basins, earrings, and medicinal balms (Mayazine 2019).

Another bee product, royal jelly, which is rarely produced by African beekeepers (Conti et al. 2018), is very beneficial for human health and has been reported to have favorable outcomes with people suffering from Alzheimer's disease (Antonelli and Donell 2019).

Propolis has shown a beneficial effect on human and animal health (Rahman et al. 2010). All breeds of bees collect plant resins from their environment and deposit them in their hives as propolis, although some colonies deposit relatively little compared to others. Propolis has significant antimicrobial activity, but may be higher if multiple resin sources are available, where one resin can compensate for a lack of function in another, "functional balance" resin. Functional redundancy and functional balance have been demonstrated during resin collection in wild bees. This implies that the composition of propolis varies depending on the botanical origin of the resin. Generally, it is composed of a resinous substance at 50%, wax at 30%, aromatic substances at 10%, pollen at 5%, and other substances at 5% (Aygun et al. 2012). Propolis also contains active substances, namely enzymes, phenolic compounds, and flavonoids (Meutchieye et al. 2016; Bogdanov 2016). For human health, propolis can be used to fight diseases caused by *Escherichia coli*, Salmonella, and *Staphylococcus aureus* (Mayazine 2019). Propolis has very effective effects against diseases and enemies of the honeybee *Apis mellifera*, such as American foulbrood and ascospherosis (Wilson et al. 2015). Therefore, propolis has also been used to develop the performance of laying hens at a rate of 30 g / l of water or 5 g / kg of feed (Aygun et al. 2012). This dose can also stimulate the immune system of the laying hen (Çetin et al. 2010).

13.5.3 The Types of Beehives Used in Africa

13.5.3.1 Traditional Beehives (See Fig. 13.24a)

Multiple types of beehives are used in Africa (Mayazine 2019; Shenkute et al. 2012); some are modern and others are traditional (Berkani 2007a; Gratzer et al. 2021). But in most African countries, traditional beehives are the most commonly used (Akinwande and Badejo 2009). However, traditional beehives do not allow beekeepers to visit their bee colonies regularly. Traditional beekeeping is transmitted from one generation to another only through contact with parents and neighbors, and vocational training in bee breeding institutions is totally absent (Paterson 2006; Betayene 2008). For the

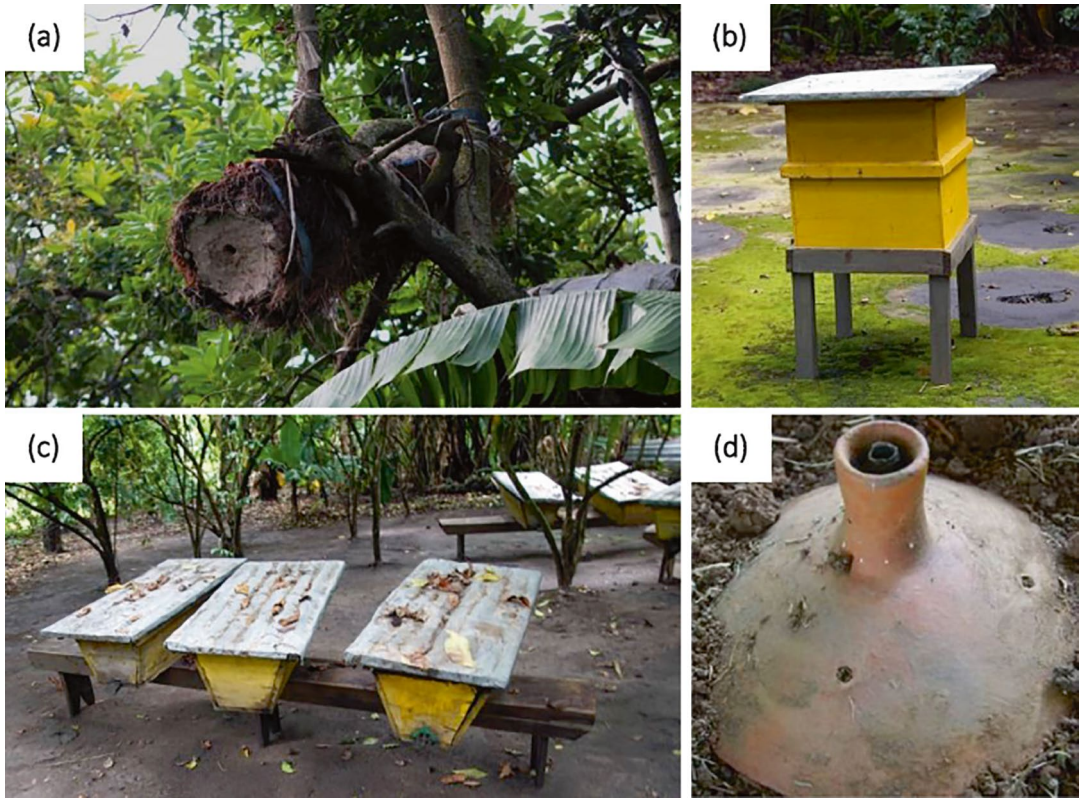

Fig. 13.24 a. Traditional log hive for *A. mellifera* bees; b. modern hive; c. transitional Kenyan top bar hive; d. clay pot hive for stingless bees. (Leven et al. 2005)

construction of beehives, traditional beekeepers use natural materials (Fischer 2013). Most often, beehives are created from tree trunks, cork, clay, or straw (Malaka and Fasasi 2002). The traditional beehive most used in Africa is the hive with bars, which is also called the top bar hive (Paterson 2006; Lonyo III 1996).

Many African countries have used the bar hive, which is also called the Kenyan hive, used in particular in Botswana, Cameroon, Egypt, Ghana, Kenya, Nigeria, Tanzania, and Zambia (Betayene 2008; Leven et al. 2005). The bar hive is a trough-shaped box tongue, the two sidewalls forming approximately an angle of 115° with the top (see Fig. 13.24c). It is possible to build the hive with straight sticks carefully assembled with wire (Leven et al. 2005). It is painted or varnished in forest areas and covered by soil and a mixture of cow dung and clay in areas of high temperatures (Betayene 2008). Beehives with movable frames are the most productive, but they should be made from good-quality materials at a reasonable cost and should only be used in areas where theft is not a problem (Garnery et al. 1993). For areas where theft and honey hunting prevail, the hive could be made from cement and mud brick (Betayene 2008; Leven et al. 2005).

In Egypt, Kenya, and Tanzania, the bar hives used are not well known in the other African countries. The numbers of movable frames vary between 22 and 27 wooden bars or slats (Lonyo III 1996). The width of the bar is the only standard to be most rigorously respected, which varies between 32 and 33 mm and depends on the size of the bee to be raised (Betayene 2008). Another type of top bar beehive is called the Tanzanian top bar beehive, particularly used in Botswana and Tanzania (Leven et al. 2005). The

side walls are straight for ease of construction. This type of beehive can only be used for colonies of bees that do not attach their combs to the walls (Betayene 2008).

The East African trough hives used in Tanzania, Uganda, Zambia, and other East African countries, the production of honey takes its place next to the brood chamber and not above (Lonyo III 1996). Honey is at the back of the hive, while the brood is in the front. Therefore, the honey harvest is done from the combs located at the back of this traditional hive to avoid damaging the brood. A cylindrical hive of one meter long and 40 cm in diameter corresponds to a volume of 125l (Leven et al. 2005).

The David hive is particularly widespread in the Southern Sahel, Sudan, Senegal, and Ethiopia (Shenkute et al. 2012; Sahle et al. 2018). The hive is built from natural materials (Gratzer et al. 2021). Beekeepers use wood, banana fibers, straw, clay, and thin branches (Gratzer et al. 2021) (see Fig. 13.24d). In North Africa, particularly in Algeria and Morocco, traditional beehives are made from the ferrule trunk and cork, while in the South, beekeepers use Alfa foliage (Behidj 2012). The honey extraction in traditional beekeeping is carried out after pressing it by hand (Leven et al. 2005).

13.5.3.2 Modern Beehives (See Fig. 13.24b)

In the nineteenth century, beekeeping saw considerable progress in the beehives' improvement, of which different models were created, notably those of Langstroth, Dadant, and Layens. In modern African beekeeping, only two types of beehives are chosen by African beekeepers, namely those called Dadant and Langstroth (Berkani 2007a). The Dadant hive is used on a large scale in various African countries such as Algeria, Ethiopia, Madagascar, Morocco, Senegal, and Tunisia. The Langstroth beehive was created by the American Lorenzo Lorraine Langstroth (1810–1895), who is considered the father of American beekeeping. Currently, this type is found everywhere in Africa, particularly in the countries of the greater Maghreb.

13.5.4 The State of Beekeeping in Africa

13.5.4.1 North Africa and the Big Maghreb

North Africa is the cradle of beekeeping (Berkani 2007a). Currently, in the Maghreb, beekeeping is identical to that of Mediterranean countries (Berkani 2007a). The best producers of honey in North Africa are Egypt and Morocco (Berkani 2007a). Although Algeria experienced a significant increase in honey production, the state was forced to fill the honey deficit for the needs of the population through imports. In Algeria, in the nineteenth century, during the French invasion, indigenous populations practiced beekeeping using traditional hives, but at the same time, there were modern hives operated only by European farmers. From the 1970s, in Algeria, three models of beehives were used, namely Langstroth, Dadant, and the traditional hive (Berkani 1985). In traditional Algerian beekeeping, the foliage of Alfa, the trunk of the ferrule, and the bark of cork oak are used by beekeepers for the construction of beehives (Behidj 2012). In Algeria, orientation of beekeepers and guides in beekeeping is provided by the technical institute of breeding (formerly called the institute of small animals) (Berkani 2007a). Beekeeping is practiced across the country (Chahbar et al. 2016). The tellian *Apis mellifera intermissa* and the Saharan *Apis mellifera sahariensis* are commonly used (Hepburn and Radloff 1998). The tellienne is answered throughout the territory with the exception of a few regions in the Southwest where the Saharan *Apis mellifera sahariensis* is used (Haccour 1960; Chahbar 2013). For Libya, beekeeping was practiced only traditionally, and the use of modern hives was maintained from the 1950s (Brittan 1956). In Morocco, researchers report the existence of three races of bees: *Apis mellifera intermissa, Apis mellifera major,* and *Apis mellifera sahariensis*. The most common race in the Gharb region is *Apis mellifera intermissa*. This Moroccan region is considered the best in terms of honey production. In Egypt, honey production is important for two seasons: the first is that of

clover in June, and the second is that of cotton in August (Moustafa 2001). Mainly, three types of honey are produced in Egypt: that of citrus in the spring, that of clover in the summer, and cotton in the fall (Moustafa 2001). Thus, the Egyptian flora is very rich in the number of species for the production of honey and pollen (Abou-Shaara 2014). The breed of bee exploited is *Apis mellifera lamarckii,* which has benefited from several breeding programs to increase domestic production. *Apis mellifera lamarckii* is a breed that is resistant to varroasis as well as to other parasitic mites (Moustafa 2001). Bees have also been introduced along other evolutionary routes in North African countries such as Morocco (Franck et al. 2001), Sudan (El-Niweiri and Moritz 2008), and Libya (Shaibi et al. 2009). In Sudan, analysis of mitochondrial DNA shows that Sudanese honeybee populations are members of several subspecies belonging to the three evolutionary branches, in this case A, O, and C (El-Niweiri et al. 2008). The biogeographic distribution of the races of *Apis mellifera* extant in Sudan varies depending on the ecosystem. For the humid savannah and forest ecosystems, the lineage A (*Apis mellifera adansonii* and *Apis mellifera Scutellata*) has been recorded. Desert, semidesert, and dry savannah honeybees are members of three subspecies, namely *Apis mellifera lamarckii, Apis mellifera syriaca*, belonging to the O lineage, and *A. m. carnica,* which belongs to lineage C. The race *Apis mellifera carnica* is an imported breed (El-Niweiri and Moritz 2008). The most common subspecies in Sudan is *Apis mellifera jemenitica* (Garnery et al. 1995). Sudanese beekeeping is practiced in the presence of two farming methods, modern and traditional (El-Niweiri et al. 2008). Beekeepers seek to improve their beekeeping herds by importing other breeds from other African countries, notably Egypt (El-Niweiri and Moritz 2008). Algeria has not escaped the phenomenon of genetic pollution caused by the uncontrolled and unofficial importation of foreign races. Indeed, for several years, Algerian beekeepers unofficially introduced foreign breeds (*Apis mellifera ligustica* and *buckfast*) to improve honey production.

13.5.4.2 Central Africa

Beekeepers in Central Africa have attempted several times, but without success, to introduce milder European bees. Colonies, after replacing their queens, begin to grow, but then they become weak and die (Paterson 2006). This may be due to several factors, including disease and the phenomenon of adaptation. Historically, the *Varroa destructor* mite is the natural parasite of the Asian bee *Apis cerana* (Anderson and Trueman 2000), but with the importation of queens of *Apis cerana* by European beekeepers, the European bee *Apis mellifera* was parasitized by this plague (Anderson and Trueman 2000; Beetsma et al. 1999), which caused enormous damage to the bees (Bailey 1991). According to another hypothesis, the workers of the introduced European bee continue to work throughout the day, even when the temperature is too high, and end up exhausting themselves, unlike the workers of the local bee, who only come out when it is less hot (Paterson 2006). Eucalyptus honey is known in most of the Central African countries, notably in Cameroon, Guinea, and Mozambique (D'Albore and Piatti 2004). In Cameroon, the breeds exploited are *Apis mellifera adansonii, Apis mellifera jemenitica,* and *Apis mellifera monticola* (Hepburn and Radloff 1998). Nevertheless, *Apis mellifera adansonii* is the most common in Cameroon (Fotso et al. 2021), and traditional beekeeping is the most practiced (Mayazine 2019). The expansion of apiaries is carried out by two methods: those of trapping and recovering the swarms (Betayene 2008). In Cameroon, the forests cover more than 46% of the national territory, which corresponds to about 23 million hectares being characterized by a very rich biodiversity (Mayazine 2019). In this country, beekeeping is mostly done by peasants, and it is mainly carried out by retirees and elderly people (Betayene 2008). The beekeeping sector in most of the Central African countries remains underexploited and marginalized (Betayene 2008). Village beekeeping is based on honey hunting (Mayazine 2019), whereby colonies are destroyed during fire harvesting. Therefore, the harvested honey is dirty, very low in quantity, and of poor quality (Betayene 2008). In central African

countries, two breeding methods are followed, namely honey hunting and the Kenyan beehives. For the production of honey, in some regions, three types of honey are produced, namely white honey comes from the Oku within the Northwest region, brown honey from forest areas, and black honey from Sahelian areas (Mayazine 2019). White honey is the most abundant, white in color, which is due to the plant species *Schefflera abyssinica, Nuxia congesta,* and *Prunus africana* (Mayazine 2019), but the national production of honey has remained very low, with poor quality.

13.5.4.3 East Africa

In East Africa, the best honey-producing countries are Ethiopia, Madagascar, and Tanzania (Mamo 2016; Berkani 2007b), where breeding and production of wax are practiced. In terms of honey production in the East African countries, not only the honey that has been the subject of this breeding, but also the production of wax is important (FAOSTAT 2020). East African countries export important quantities of beeswax (Moustafa 2001; FAOSTAT 2020). In Ethiopia, people have practiced beekeeping for about 5,000 years (Gezahegne 2001). To date, beekeeping in this country is based mainly on traditional techniques (Gratzer et al. 2021; Yirga and Teferi 2010). For the construction of beehives, beekeepers use natural materials (Akinwande and Badejo 2009). Usually, beehives are constructed from wood, straw, and clay (Aygun et al. 2012). Traditional beekeeping is considered among the oldest agricultural activities in Ethiopia and is part of the country's current agricultural economy (Fikru 2015). Despite the traditional breeding techniques used, Ethiopia has become an important beekeeping country (Gratzer et al. 2021), and beekeeping has great potential to contribute to the development of the country's economy (Bareke et al. 2018; Fikadu 2019). Currently, this country is considered among the best producers of honey and wax in Africa (FAOSTAT 2020).

However, this activity is practiced only by men, as it is considered a tillage forestry activity, and the harvest of bee products is done at night (Shenkute et al. 2012). The task of Ethiopian women in beekeeping remains limited to marketing (Kebede et al. 2018). Honey obtained from traditional beehives is called raw honey, and it is a mixture of honey, wax, bee parts, and pollen (Shenkute et al. 2012). The average honey production per hive has been estimated at 5–8 kg and 15–20 kg for traditional and modern hives, respectively (Beyene et al. 2016; Gemechis 2016).

In order to enlarge their apiaries, beekeepers purchase colonies from local markets as well as hunt bees from naturally existing swarms or from the swarming of their colonies (Gebretinsae and Tesfay 2014; Hailu and Tadesse 2016). Unfortunately, no beekeeping improvement program has been launched in Ethiopia (Gratzer et al. 2021).

The subspecies of *Apis mellifera* being used in Ethiopia belongs to the branch Y (Franck et al. 2001; Boardman et al. 2020). Their introduction traces queens belonging to other evolutionary branches from northern Ethiopia (Hailu and Tadesse 2016). Beekeepers mainly exploit three subspecies, namely *Apis mellifera jemenitica*, *Apis mellifera scutellata*, and *Apis mellifera monticola* (Franck et al. 2001; Boardman et al. 2020). However, three other subspecies have been mentioned, namely *Apis mellifera bandasii, Apis mellifera sudanensis,* and *Apis mellifera woyi-gambell (*Radloff and Hepburn 2000*)*. However, Meixner et al. (Meixner et al. 2011) grouped all Ethiopian honeybee breeds into a single *Apis mellifera simensis*. This subspecies is endemic to the volcanic dome system of Ethiopia (Meixner et al. 2011).

In Tanzania, several breeds of bees exist: *Apis mellifera scutellata, Apis mellifera monticola,* and *Apis mellifera littorea (*Hepburn and Radloff 1998*)*. It has been reported that the mountain systems in Tanzania are dominated by *Apis mellifera monticola* with black pigmentation (Hepburn and Radloff 1998). However, the breed most used by Tanzanian beekeepers is *A. m. scutellata* (Gupta et al. 2014). Given the zootechnical performance of *Apis mellifera monticola*, its softness, productivity, and adaptive capacity to low temperatures, beekeepers belonging to the low-altitude sectors have introduced this native race to the mountain above 2500 m altitude (Paterson 2006).

13.5.4.4 West Africa

Beekeeping in West African countries is done by two farming methods, the traditional and the modern. In Nigeria, it is based mainly on the traditional method (Akinwande and Badejo 2009). Beekeepers use natural materials, including tree trunks and wood, for the construction of beehives (Malaka and Fasasi 2002). Generally, two methods are followed in breeding: the top bar method, whose hive is rectangular and horizontal, with a length that is more than twice that of the Langstroth hive, and has removable frames in numbers that exceed 20 executives. For the second method, beekeepers use Langstroth hives. There are no professional beekeepers, and the average number of hives per beekeeper varies between 20 and 27. More than 51 melliferous species belonging to more than 32 botanical families are exploited to produce honey. The tiger lotus honey, *Nymphaea lotus,* is the most abundant. The subspecies present in Nigeria is *Apis mellifera adansonii* (Amakpe 2010). This breed is known for its honey productivity and pollination activity (Ikediobi et al. 1995), but also for its aggressiveness (Fletcher 1978). In Benin, the subspecies exploited by beekeepers is *Apis mellifera adansonii (*Amakpe 2010*)*. This subspecies occurs in two forms. The first has a relatively small size, is yellow in color, with the forest as its natural habitat (Paraïso et al. 2011). However, the second bee is black, large, and habituated to the savanna (Paraïso et al. 2011). The forest type is more productive than the Savannah type. The subspecies *Apis mellifera adansonii* is characterized by high diversity (Amakpe 2010). About 60% of honey production is obtained by the honey hunting technique (Paraïso et al. 2011). This technique has caused bee populations to decline because the bee products are harvested after the bee colonies are destroyed by fire (Yeates 1978).

13.5.4.5 Southern Africa

Beekeeping in Southern Africa is traditional, based on the use of beehives made from barks and logs. It is part of the local economy of the Savannah in South-Central Africa (Fischer 2013). However, the so-called traditional farming method does not allow frequent visits to the colonies. Beekeeping in Southern Africa is carried out by men, but in several regions, women are engaged in the processing and sale of bee products (Fischer 2013; Clauss 1991), except in a few areas of Zambia, where women participate in the search for honey (Clauss 1991).

13.5.4.6 South Africa

Two breeds of honeybees are exploited in South Africa, namely *Apis mellifera capensis* (Cape honeybee) and *Apis mellifera scutellata* (African honeybee/savannah) (Hepburn and Radloff 1998). The two subspecies differ in their geographic distribution and several other morphological and behavioral traits (Johannsmeier 2001). However, in 1990, transhumance of the Cape bee *Apis mellifera capensis* was carried out by South African beekeepers in the Limpopo province in South Africa, which is the natural biotope of the African Savannah bee *Apis mellifera scutellata* (Allsopp 1993). These beekeeping practices, transhumance, have led to a decline in populations of the Savannah bee. This depopulation is known as the "capensis problem" (Allsopp 1993). The capensis problem is caused by the ability of *Apis mellifera capensis* workers to produce females by the phenomenon of thelytokous parthenogenesis (Onions 1912; Anderson 1963). In the other subspecies of *Apis mellifera*, in the absence of the queen, the workers produce males by the phenomenon of arrhenotokous parthenogenesis. As a result, the workers of *Apis mellifera capensis* parasitize the colonies of *Apis mellifera scutellata* by producing pseudo-queens that end in a reproductive dominance of *A. m. capensis* and a decline in *Apis mellifera scutellata* (Pirk et al. 2014). The dominant honeybee breed in South Africa is *Apis mellifera capensis;* however, the number of colonies of *Apis mellifera scutellata* has declined (Dietemann et al. 2009). South African beekeeping is very advanced, with bees kept in modern Langstroth-type hives (Johannsmeier 2001). The majority of beekeepers practice transhumance to seek resources in honey plants, and the most abundant type of honey is Eucalyptus (Johannsmeier 2001; Hutton-Squire 2014). More than 58 plant species

have been the subject of honey production in this country (Masehela 2017). Professional beekeepers own up to 7000 hives per beekeeper, one commercial beekeeper manages around 1,000 hives, and a developing beekeeper has a maximum of 500 hives (NAMC Report 2008). Despite the advanced technologies in breeding and the production of good-quality honey, the local market is under threat from cheap imports of poor-quality honey (NAMC Report 2008).

13.5.5 Main Risk Factors Threatening the Honeybee

In Africa, the honeybee *Apis mellifera* is threatened by several diseases: viruses (Loucif-Ayad et al. 2015), parasites (Chahbar et al. 2016), fungal diseases (Chahbar 2017), and bacteria, including the American foulbrood *Paenibacillus larvae* (Haddad et al. 2015). In addition, it is also threatened by a neurological disease, which is in fact due to the consumption of neonicotinoids. Neonicotinoid insecticides include imidacloprid, thiacloprid, dinotefuran, thiamethoxam, nitenpyram, clothianidin, and acetamiprid. Thiamethoxams are pesticides used for coating seeds.

13.5.5.1 Nosemosis

Nosema apis and *Nosema ceranae*, downgraded from protozoa and classified as fungi (Adl et al. 2005), are parasites of the European bee *Apis mellifera* and the Asian bee *Apis ceranae,* respectively. Nosemosis, caused by these parasites, is widespread throughout the world; it is the major factor in economic losses in beekeeping. Recently, in 2017, a new species of *Nosema* was detected in Uganda, namely, *Nosema neumanni*. Nosemosis is a cosmopolitan disease, which has been detected in almost all African countries. In Algeria, *Nosema* spores are detected in both races, the tellienne *Apis mellifera intermissa* and the Saharan *Apis mellifera sahariensis*. However, when an experimental infection was performed, the Tell bee exhibited greater resistance than the Saharan bee (Chahbar 2017). In Kenya, nosemosis was only recently detected (Muli et al. 2014), but a few years after its introduction, different levels of infection were noted in different agro-ecological zones. This plague has also been detected in South Africa and Zimbabwe. *Nosema ceranae* was reported in only two African countries, in Benin and Algeria, in *Apis mellifera adansonii* and *Apis mellifera intermissa*, respectively (Paraïso et al. 2011); however, in some African countries, in Ghana and Sudan, nosemosis was not detected (Abdal Aziz and El-Niweiri 2013).

13.5.5.2 American Foulbrood

Among the factors threatening the survival of honeybees, American foulbrood, *Paenibacillus larvae,* is a devastating disease of colonies at a fairly high rate, preventing the development of beekeeping (Haddad et al. 2015). This disease is caused by a bacterium, *Paenibacillus larvae,* which occurs as a Gram-positive rod. This plague has been declared by the International Office of Epizootics (OIE) as a notifiable contagious disease. It is a cosmopolitan disease (Haddad et al. 2015) but found mainly in temperate countries and/or subtropical environments (Gregorc and Poklukar 2003). However, in most African countries, this disease is found with low levels of infection (Paraïso et al. 2011). After 2006, American foulbrood was detected in several African countries, namely Kenya, Senegal, South Africa, Tanzania, and Uganda, but not before (Allsopp 1993). In South Africa, the first appearance of this disease was presumed between 2006 and 2008 (Veldtman and Allsopp 2011). Algeria, which has the highest beekeeping production, has also recorded a high frequency of transhumance and high levels of infection (Chahbar 2017). However, some colonies infected with this disease did not develop clinical signs, namely the shooting mass in the hexagonal capped cells, which can be observed in the field by the match test (Fig. 13.25a), and the appearance of a mosaic brood and collapsed gills (Fig. 13.25b).

13.5.5.3 Varroasis

Varroasis, induced by the agent *Varroa destructor,* is a disease listed by the OIE (WOAH 2023). Discovered at the beginning of the twentieth

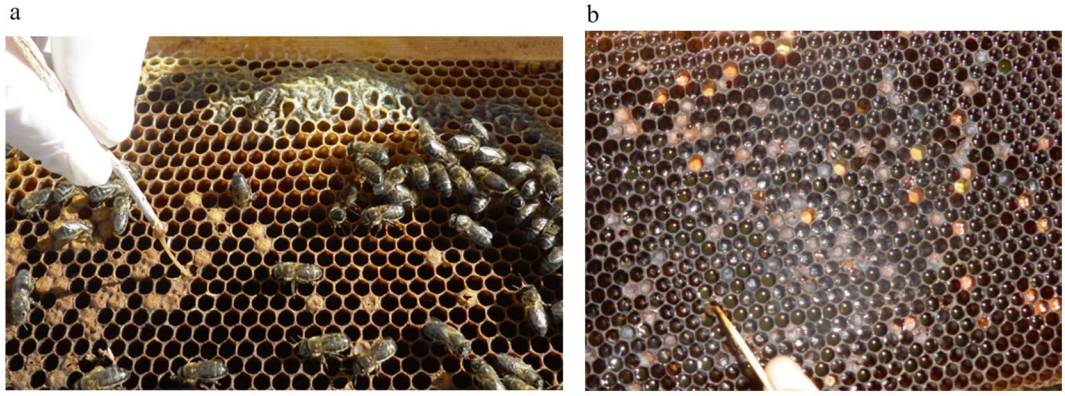

Fig. 13.25 The clinical signs of American foulbrood *P. larvae* observed in the field. (Onions 1912)

century in Indonesia, on the bee *Apis cerana,* the *Varroa jacobsoni* Oudemans mite develops rapidly on its new host, *Apis mellifera*. It was later renamed *Varroa destructor* (Anderson and Trueman 2000). The development cycle of this ectoparasite takes place mainly in the brood and lasts about eight days. Adult females invade brood cells a few hours before operculation (Beetsma et al. 1999). About 60 h after the operculation, the female mite lays her first egg, which will give birth to a male, and the subsequent eggs will give birth to females. Thus, the capping time of the worker brood of *Apis mellifera* generally allows for the production of three mature females of the parasite, and that of the male brood, the production of five mature females. The parasite feeds on the hemolymph of nymphs and adults. Infestation by *Varroa destructor* is extremely damaging to honeybee colonies. The main deleterious effects are caused by breeding females, which, by feeding on the hemolymph of larvae, nymphs, and workers, weaken them, and this affects the entire colony. This mite is also a vector of other pathogens, in particular viral agents.

In Africa, the *Varroa destructor* has been identified in Algeria, Egypt, Morocco, and Tunisia (Haddad et al. 2015). By comparing the genome of *Apis mellifera intermissa* with those of other subspecies, it appears that the latter has significant adaptation potential and has evolved for resistance to high temperatures and against infestations of the *Varroa destructor* parasite (Haddad et al. 2015). In Libya, the arrival of this formidable enemy of the bee was not until 1976 (Crane 1979). In Kenya, *V. destructor* was probably introduced between the years 1998 and 2009, and then from the year 2014, it spread to all regions of the country except a few regions in the North (Muli et al. 2014). In Nigeria, the detection of varroasis in bee colonies was not until 2012 (Akinwade et al. 2012). However, reports from Kenya and Nigeria showed that the presence of varroasis did not have a negative impact on bee health (Muli et al. 2014; Akinwade et al. 2012). *V. destructor* has been found in Benin, Ethiopia, Senegal, Niger and Zimbabwe (Paraïso et al. 2011; Scholmke and Schmolke 2003). In South Africa, *V. destructor* was first detected in 1997 and has caused significant bee colony mortalities (Pirk et al. 2014).

13.5.5.4 Viruses

There are more than 25 viruses affecting honey bees in Africa (Loucif-Ayad et al. 2015), most of which are RNA viruses. The most common viruses are deformed wing virus (DWV), black queen cell virus (BQCV), chronic bee paralysis virus (CBPV), Kashmir bee virus (KBV), sacbrood virus (SBV), Varroa destructor virus (VdV1), acute bee paralysis virus (ABPV), and Israeli acute paralysis virus (IAPV). Some could be present in colonies without causing visible signs. Thus, many colonies continue to appear healthy, even when several viruses are simultaneously present. However, in some cases, these viruses weaken the colonies. These viruses are

mainly transmitted by the mite *V. destructor*. In Ethiopia, 25 viruses have been detected. In Algeria, six viruses were detected with different prevalence. CBPV was the most prevalent virus, followed by BQCV, DWV, IAPV, ABPV, and SBV (Loucif-Ayad et al. 2015). The two viruses, BQCV and DWV, are the most common in Uganda. In Kenya, the presence of viruses such as BQCV, DWV, and ABPV is associated with that of Varroa (Muli et al. 2014). In Kenya, viruses were not detected in northern areas where *V. destructor* was absent (Muli et al. 2014). In addition, the DWV virus was systematically present on the *Varroa* mites taken from each apiary. It is recognized that the spread of *V. destructor* has resulted, among other things, in altering the prevalence of bee viruses and their impact on colony health. Of all the bee viruses, only two can cause fatalities and characteristic clinical signs. These two viruses are sacciform brood virus (SBV) and chronic bee paralysis virus (CBPV), which are also known as black disease. Sacciform brood virus (SBV) kills larvae, described as sac-forming, due to the accumulation of fluid between the seed coat and the body. Chronic paralysis virus (CBPV) is the only viral disease of adult bees causing visible symptoms in flight steps and in front of hives. This disease can lead to abnormal wing and body tremors of infected bees, inability to fly, and death within days of the onset of symptoms.

13.5.6 The Fight Against Bee Diseases Using Natural Products

African researchers and beekeepers have tried to replace chemicals used to fight honeybee diseases with other natural products. For example, to control *Varroa* mite, oxalic acid and formic acid are used successfully. In addition to acids, plant extracts have been used, including neem oil (Qayyoum et al. 2013) and thymol powder. Other natural products that have been successfully used include steaming rice vinegar, which inhibits fungal spore germination. In contrast, treatments for ascospherosis are not recommended with antibiotics (Chahbar 2017). These treatments have negative side effects on brood, adult bees, and honey. Another method in the confirmation phase is the use of plant resins by bees, in the form of propolis (Wilson et al. 2015). Transhumance in regions characterized by abundant coniferous plants has very high effects against bee diseases, such as American foulbrood and ascospherosis (Chahbar 2017). It, therefore, becomes very important to test the activity of propolis against multiple pathogens by considering the functional role of propolis in bee health (Wilson et al. 2015). However, the main mechanism of resistance to ascospherosis is the hygienic behavior of adult bees.

13.5.7 Characterization of Honeybees

13.5.7.1 Morphometric Approach

A typological characterization of the local bee conducted by Khedim et al. (Khedim et al. 2021) was carried out by means of a questionnaire in Algeria. These researchers also carried out a classical morphological characterization at the level of several localities in the Algerian Northwest. For this purpose, 15 worker bee specimens were sampled at the level of 30 hives per beekeeping farm (15 morphometric parameters were analyzed). At the same time, they carried out a geomorphometric characterization using the geometry of the wings, which highlights the geotechnical potential for the production of bee populations. The analyses revealed a biogeographic variation within the honeybee colonies in Algeria. These results, thus, made it possible to discriminate among local populations. Assielou et al. (2016) used morphometry to identify the possible breeds and ecotypes of honeybees in central Côte d'Ivoire. Samples of 30 workers per hive were collected in 2–3 hives in beekeeping apiaries located in N'Guessankro, Soungassou, Kouassikouassikro, Lengbe-kouassikro de Yobouekro, and the "Institut National Polytechnique" Félix Houphouet-Boigny in Yamoussoukro. A total of 18 morphometric parameters were measured using a binocular magnifying glass and a

microscope. Analyses revealed biogeographic variation within honeybee colonies in Côte d'Ivoire, allowing them to be subdivided into local populations.

A study conducted by Bamidele et al. (2021) evaluated the body allometry of honeybees, *Apis mellifera adansonii Latreille* (Hymenoptera, Apidae), from the rainforest, the Guinean Savannah, and the derived Savannah in Nigeria. Honeybee samples were dissected, and morphological parameters were measured using the PhotoScan method. They showed significantly higher mean body weight, total body length, and mouth width ($P < 0.05$) in honeybees from the rainforest zone. The thorax and abdomen lengths of honeybees from the tropical rainforest and Guinean savanna areas showed a significant linear relationship with the total body length of honeybees. In addition, the lengths of the abdomen, thorax, head, antenna, proboscis, pollen basket, jawbones, hind limbs, and fore and hind wings of honeybees in the three ecological zones exhibited a negative allometric growth pattern with total body length. The length–weight relationship, however, revealed a positive allometric growth pattern in honeybees from the tropical forest zone and negative allometry in those from the Guinean Savannah and derived savanna zones. Thus, these researchers deduced that the length–weight relationship could be a more sensitive tool for evaluating the allometric model of honeybees from different environments.

Fotso et al. (Fotso et al. 2021) conducted a study in the Western Highlands of Cameroon to better understand the biodiversity of honeybees for their preservation and genetic improvement. Samples of 420 worker bees belonging to *Apis mellifera* subspecies were obtained from 14 localities in the study zone. Body measurements in mm were: length (10.98 ± 0.06), abdomen length (6.71 ± 0.03), width of the yellow band on the second (2nd) abdominal tergite (1.48 ± 0.01), width of fourth (4th) abdominal tergite (1.32 ± 0.01), length of cover hair on the fifth (5th) abdominal tergite (0.29 ± 0.00), antenna length (4.27 ± 0.02), proboscis length (4.39 ± 0.11), length of nervure A (0.60 ± 0.00), length of nervure B (0.25 ± 0.00), discoidal shift (−0.13 ± 0.01), anterior right wing length (9.31 ± 0.03), anterior right wing width (3.14 ± 0.01), posterior right wing length (6.38 ± 0.03), and posterior right wing width (1.69 ± 0.01). A correlation coefficient ($r = 0.72$; $p < 0.01$) was obtained between the length of the posterior right wing and the length of the anterior right wing. The cubital index is 2.36 ± 0.04. Populations of honeybees studied consist of three genetic types/ecotypes; the cubital types 2 and 3 were not different. The observed biodiversity suggests that honeybees constitute a natural resource with genetic variability needed for preservation and genetic improvement in Cameroon.

Radloff and Hepburn (2000) studied morphometric characters and sting pheromones of worker honeybees, *Apis mellifera Linnaeus*, to delineate the honeybee populations of the Horn of Africa. Four discrete and statistically homogeneous populations were identified: *Apis jemenitica* Ruttner, *Apis mellifera bandasii* Mogga, *Apis mellifera sudanensis* Rashad in Ethiopia, and an unclassified group in southwestern Somalia. There are two endemic subspecies of Western honeybees (*Apis mellifera* L.) in the Republic of South Africa (RSA), *A. m. capensis* and *A. m. scutellata*. They have traditionally been identified using morphometric characteristics, but the geometric morphometric data of honeybee wings is easier to collect, making them perhaps a useful alternative for identifying these subspecies. Bustamante et al. (2020) compared the precision of morphometric and geometric morphometric methods using linear discriminant and classification and regression tree analyses. The authors found that using the geometric shape data of the fore and hind wings resulted in lower classification accuracy (73.7%) than using models derived from the full set of standard morphometric data (precision at 97%) in the cross-validation. The color of the tergite and the average number of ovarioles were the most important characteristics to distinguish the two subspecies. Finally, these researchers used Kreiger's interpolation to construct maps illustrating the probable distributions of *Apis mellifera capensis* and *Apis mellifera scutellata* in the Republic of South Africa.

13.5.7.2 Biochemical Approach

Proteins and isozymes were used to assess the biochemical characterization of three subspecies of worker bees, *Apis mellifera* L. (Egyptian, Italian, and Carniolan subspecies). Low percentages of polymorphism were recorded in different protein profiles, ranging from 18% to 42%. The isoenzyme systems also recorded low percentages of polymorphism, with the exception of peroxidase (67%). The dendrogram separated the Egyptian subspecies from the other two subspecies with a significant distance of 0.25. The Italian and Carniolan subspecies were grouped into a single group with a genetic distance of 0.01 between them (El-Bermawy et al. 2012).

13.5.7.3 Molecular Approach

The study of Loucif-Ayad et al. (2015) evaluated the genetic diversity of honeybees (*Apis mellifera*) in Algeria (North Africa), using the mtDNA COI-COII molecular marker (Cytochrome Oxidase I and II). In total, 582 beekeeping workers were sampled in 22 regions of the country. Polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP) analysis of mtDNA samples distinguished evolutionary bee lineages and mtDNA haplotypes from each region. These data revealed the presence of three different bee lineages among the populations studied, including the African (A), North Mediterranean (C), and West Mediterranean (M) lineages. Eight different mtDNA haplotypes were recorded at different frequencies (A1, A2, A8, A9, A10, A13, C7, and M4). For the first time, these results identified a weak genetic introgression (3.1%) of non-local mtDNA haplotypes (C7 and M4) among Algerian local bees, most likely due to the importation of foreign bees.

Awodiran et al. (2021) studied the genetic diversity of four populations of honeybees, *Apis mellifera,* from two vegetation zones in Southwestern tropical forest and the North-central derived savanna of Nigeria using 15 morphometric characters and 5 microsatellite loci. Discriminant function analysis of morphometric data revealed considerable variation in morphological characters between sampled localities, while principal component analysis and canonical variable analysis produced clusters overlapping populations sampled, indicating a lack of separation between different populations. Genetic diversity (F_{ST}) revealed poor differentiation between the populations, suggesting that geographic distance was not a barrier to gene flow between populations. All four populations had a heterozygous deficiency, suggesting the presence of inbreeding within the populations. Analysis of molecular variance showed that 91% of the total molecular variance existed within populations while 9% existed between populations. These researchers suggested that there is an apparent loss of genetic diversity in populations of *Apis mellifera* studied in the two vegetation zones of Nigeria.

Fuller et al. (2015) used a new suite of integrated web-based programs to examine population dynamics and selection signatures across the genome using several well-established assays, including FST, pN/pS, and McDonald-Kreitman. These researchers applied these techniques to study populations of honeybees (*Apis mellifera*) in East Africa. In Kenya, there are several descriptions of the subspecies of *Apis mellifera*, which these researchers believe are located in distinct ecological regions. Whole genome sequencing of 11 worker bees from apiaries throughout Kenya was performed using 3.6 million SNPs. The dense coverage allowed several computational procedures to be applied to study population structure and evolutionary relationships between them and to detect signs of adaptive evolution across the genome. Although there is considerable gene flow among the sampled populations, there were clear distinctions between populations in the Northern desert region and those in the temperate savanna region. The study identified several genes showing genetic population models compatible with positive selection within African bee populations and between these populations and the populations of European *Apis mellifera* or Asian *Apis florea*.

Honeybees, *Apis mellifera* subspecies, of the East African populations were also assessed by Kibogo (2017) for phylogenetic relationships using mitochondrial markers. *Apis mellifera cutellata, Apis mellifera litorea,* and *Apis*

mellifera monticola were shown to have a close genetic relationship and are largely indistinguishable. However, based on altitude, three groups were documented: lowland, medium altitude, and mountain bees. Populations of *Apis mellifera* from Kenya, Uganda, Tanzania, and Madagascar were also genotyped with eight microsatellite loci. The mean number of alleles and the mean observed heterozygosity were high at 8.201 ± 2.5035 and 0.781 ± 0.00346, respectively, for all populations. The average genetic diversity per locus and per population was high at 0.783 for all populations. A low overall mean population differentiation value of 0.056 ± 0.04 signified moderate levels of genetic structuring and differentiation between populations. The probability values for the genetic assignment of individuals to populations were less than 0.5, indicating that the populations are not isolated and that there was substantial hybridization. The results of clustering, mixing, genetic diversity attributed to variance, and phylogenetics showed that the dynamics of the honeybee subspecies in East Africa are associated with a relatively stable population demographic structure, especially in unfragmented habitats, natural forests, and mountainous regions. In these regions, the results suggest a living demographic historical pattern of their existence characterized by recent evolutionary expansions and no bottlenecks. Association studies have shown that, on average, colonies store more nectar (69%) than pollen (31%). There is a positive correlation between sting and pln (0.184458), suggesting that defensive colonies feed more on nectar than less defensive colonies. The search for candidate genes identified three genes, each associated with foraging (GB46589, GB44258, GB44259) and tingling behavior (GB48999, GB49000, GB55730).

Eimanifar et al. (2020) recently performed whole mitogenome sequencing using SNPs to study the genetic diversity of *Apis mellifera capensis* and *Apis mellifera cutellata* with data from the Republic of South Africa (N = 813 bees from 75 apiaries) using 19 DNA microsatellite loci. The populations averaged between 9.2 and 11.3 alleles per locus, with unbiased heterozygosity values ranging from 0.81 to 0.86 per population. Bayesian clustering analyses revealed two distinct evolutionary units, although the results did not match those of previous morphometric and molecular analyses. This suggests that the microsatellites these researchers tested were not sufficient for identifying subspecies, especially for Cape bees and hybrid bees. Nevertheless, the microsatellite data show considerable genetic diversity within the two populations and a larger than expected hybridization zone between the natural distributions of *Apis mellifera capensis* and Apis *mellifera cutellata*.

13.6 Conclusion and Future Perspectives

The colossal amphibian, Goliath Frog (*Conraua goliath*), occupies a unique place in the animal kingdom due to its enormous size. This is not only important ecologically, but also culturally in certain African regions. Preserving its habitat and genetic diversity is crucial. Various species of snails, such as the giant African snail (Achatina species), have economic value for their meat and shells. Sustainable management of snail populations is essential to avoid overexploitation. Although not unique to Africa, rabbits provide valuable genetic diversity for food production. Local breeds must be preserved and managed for their potential contribution to nutrition and livelihoods. African bee subspecies are essential pollinators for agriculture. Protecting the genetic diversity of these bees is essential for food security and ecosystem health.

The main challenges of nonconventional animal genetic resources include: (1) habitat loss/destruction due to urbanization, agriculture and deforestation, which threatens the survival of these species; (2) overexploitation, which impacts their population growth; (3) climate change, which disrupts habitats, potentially pushing these species into new areas or reduction of available habitats; and (4) invasive or non-native species, which can outcompete native species, thereby affecting genetic diversity.

Opportunities for the preservation of nonconventional animal genetic resources include

tailored breeding strategies to increase productivity as well as generate other products that can be used by humans, such as shell and slime from snails and the wax from bees. African countries can collaborate on conservation efforts, creating protected areas and implementing sustainable harvesting practices. Further research into the genetics and biology of these species can guide conservation strategies. Economic diversification through exploiting these unique species for ecotourism or sustainable agriculture can provide economic incentives for conservation. Education of farmers through raising awareness among local communities of the value of these species can encourage their conservation. Establishing gene banks for these species can ensure that their genetic diversity is preserved for future use.

In conclusion, unconventional animal genetic resources in Africa, including the Goliath frog, snails, rabbits, and bees, represent both ecological and economic assets. Protecting their diversity and unique features requires concerted conservation efforts, sustainable practices, and increased awareness of their importance among local communities and policymakers. These resources have the potential to contribute to food security, livelihoods, and biodiversity conservation in Africa and beyond.

14 Contributions of African Livestock Production Systems to Greenhouse Gas Emissions and Global Warming in the Face of Climate Change

Mizeck G. G. Chagunda, Kingsley A. Etchu, Kwamboka Tirimba, and Okeyo Mwai

Abstract

Greenhouse gases (GHG) have the ability to trap radiant energy from the sun in the atmosphere. The accumulation of GHGs in the atmosphere significantly contributes to climate change. Methane is 21 times more potent than CO_2 as a greenhouse gas (GHG), however, this is one area where there is a lack of robust data to reflect the amount of GHG different breeds of cattle in Africa produce per day. With an increasing global population placing pressure on land resources, coupled with environmental degradation of existing agricultural land, climate change mitigation and adaptation becomes even a more urgent issue to deal with. Livestock contributes to approximately 15% of global methane (CH_4) emissions and 65% of global nitrous oxide (N_2O) emissions, contributing to an estimated 8–11% of global anthropogenic GHG emissions. The production of GHG from ruminants and their impact on climate change are a major concern worldwide. Although the amounts of GHG from African livestock systems may not be as huge as from other production systems in the world, the inefficiencies in African livestock production systems are a call for concern and deserve quantification. Increasing the efficiency of ruminant production is not only vital in reducing the GHG intensity, but also important for food production to meet increasing demands. Strategies to reduce GHG emissions should include the effects of different feeding systems, the level of intensification and genetics/breeding for reduced GHG emissions. Increasing productivity per animal, that is, efficiency, will reduce GHG emissions per kg of livestock product that is needed to improve livestock production without compromising the environment.

14.1 Introduction

Greenhouse gases have the ability to trap radiant energy from the sun in the atmosphere. This alters the Earth's average near-surface air temperature. As observed by the Intergovernmental Panel on Climate Change (IPCC), warming of the climate system is unequivocal (Intergovernmental Panel on Climate Change (IPCC) 2007). Climate change is widely recognised as a serious potential threat to the world's environment. However, the greenhouse effect of the Earth's atmosphere is a natural phenomenon, without which the Earth's temperature would be much lower, whereby atmospheric concentrations of water vapour and carbon dioxide (CO_2) trap infrared radiation. The IPCC observes that most of the increase in global average temperatures since the mid-twentieth century is due to an increase in anthropogenic greenhouse gas (GHG) concentrations in the atmosphere (Intergovernmental Panel on Climate Change (IPCC) 2007). The main GHGs emitted globally are carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O). Greenhouse gas emissions have been escalating since the Industrial Revolution (Intergovernmental Panel on Climate Change (IPCC) 2007). The atmospheric concentration of CO_2 has risen to its highest level in at least 800,000 years (Lüthi et al. 2008). If unchecked, future climate implications of this rise could include further increases in mean annual temperature and a reduction in mean precipitation (Lahn 2021). At the present rate, the IPCC projects a global mean temperature rise of 0.2 °C for each of the next two decades. In the longer term, projections range between a 2 and 4 °C rise by 2100 compared to the end of the twentieth century, depending on global GHG emissions scenarios (Intergovernmental Panel on Climate Change (IPCC) 2021).

The recent Living Planet Report stated that if GHG emissions continue at or above current rates, the natural resilience and natural adaptability of many ecosystems are likely to be exceeded (Lupinacci and Happel-Parkins 2016), with far-reaching consequences and an uncertain future for global biodiversity, agriculture, and livestock production. With an increasing global population placing pressure on land resources, coupled with environmental degradation of existing agricultural land, the number of people per hectare of arable land has been steadily increasing. The United Nations Environment Programme predicts that 25% of the world's food production may become lost due to environmental breakdown by 2050, largely as a result of climate change and agricultural practices, including overgrazing. Collectively, these issues point to an increasing demand on current grazing land and forage production areas, particularly where crop production for direct human consumption is viable, emphasising the need for improved efficiency and adaptation of livestock systems in future climates (Eckard et al. 2018). The Intergovernmental Panel on Climate Change (IPCC) reports that livestock contributes approximately 15% of global CH_4 emissions and 65% of global N_2O emissions, contributing an estimated 8–11% of global anthropogenic GHG emissions. The energy and nitrogen losses associated with these GHG also represent two of the most significant inefficiencies in livestock production systems. Losses of nitrogen and energy are greater in ruminant production systems (e.g. cattle, sheep, goats) than in livestock with a simple single-chambered stomach (e.g. pigs and poultry), with greater gains in breeding for improved feed and energy conversion efficiency having been made in the latter (Eckard et al. 2018).

14.2 Climate Change and Food Security

Climate change is among the biggest threats to food security and thus to human existence. The adverse effects of increased frequency of sporadic rainfall, severe floods and droughts seriously undermine the achievement of food security and sustainable livelihoods of communities in middle-income and low-income countries, where agriculture is the backbone of the economy. Agricultural systems are more vulnerable to climate change as they are dependent on nature. The

impacts of climate change on food systems are more prevalent in the global south, where most agricultural activities are carried out by smallholder farmers. Consequently, their nutritional security is limited as they rely heavily on their own production to meet their food security and economic needs. The agricultural sector is currently faced with the challenge of feeding a growing population predicted to peak at 9.2 billion people by 2050 (Alexandratos et al. 2006), whilst meeting social and environmental obligations to reduce greenhouse gas (GHG) emissions. Whilst having an overview of the global climate change issues, this chapter focuses on the contributions of African livestock production systems to greenhouse gas emissions and hence global warming.

14.3 The Greenhouse Gases

Since the beginning of industrialisation around 1750, the atmospheric concentration of CO_2 has increased from around 280 parts-per-million (ppm) to around 379 ppm, with over half of that increase arising since 1970 (Parry 2007). Atmospheric CH_4 has increased from 715 to 1774 parts-per-billion (ppb) and N_2O from 270 to 319 ppb over the same period. These different GHGs vary in their capacity to reflect or trap energy in the atmosphere, referred to as their global warming potential (GWP). Traditionally, this has been a comparison of each GHG with a standardised 100-year period and expressed in units of kilogrammes of CO_2 equivalent (kg CO_2e). In this method, the GWP of CH_4 and N_2O are estimated to be 25 and 298 times greater, respectively, than that of CO_2 (Eggleston et al. 2006). However, this approach has been modified to account for two things. First, methane degrades in about ten years from the time when it is emitted into the atmosphere. Second, enteric CH_4 essentially is methane that is produced from carbohydrates from feed whose carbon got into the feed through the process called photosynthesis from the atmosphere when the plant was growing. This then indicates that the carbon in enteric CH_4 is recycled carbon in CH_4 continuing it's life as it gets involved in the biogenic cycle (Chen et al. 2019). Traditionally, biogenic methanogenesis is the formation of methane under strictly anoxic conditions by microbes from the domain Archaea (Chen et al. 2019). In the past decade, there has been growing evidence that CH_4 associated with animal agriculture is not new carbon in the atmosphere (Liu et al. 2021). Further, Liu et al (2021) argue that in the natural biogenic carbon cycle, plants assimilate CO_2 from the atmosphere during photosynthesis and store it as carbohydrates (e.g. cellulose or starch). Ruminant animals consume the plants and convert some of the carbon contained in plant carbohydrates into CH_4, which is then exhaled or belched out into the atmosphere. Therefore, biogenic carbon is "recycled carbon" and not new and additional to our atmosphere, though the warming effects during its atmospheric presence should still be recognised (Liu et al. 2021).

Apart from livestock, GHGs have other sources. For example, multiple processes emit CO_2: carbon dioxide enters the atmosphere through burning fossil fuels (coal, natural gas, and oil), solid waste, trees and other biological materials, and also as a result of certain chemical reactions (e.g. manufacture of cement). Methane is emitted during the production and transport of coal, natural gas, and oil. Methane emissions also result from livestock and other agricultural practices, land use and the decay of organic waste in municipal solid waste landfills. Nitrous oxide is emitted during agricultural land use, industrial activities, combustion of fossil fuels and solid waste, as well as during the treatment of wastewater. Nitrous oxide emissions account for about 10% of global GHG emissions, with about 90% derived from agricultural practices (Henry and Eckard 2009). Other powerful GHGs such as hydrofluorocarbons, perfluorocarbons, sulphur hexafluoride and nitrogen trifluoride are emitted from a variety of industrial processes. Fluorinated gases are sometimes used as substitutes for stratospheric ozone-depleting substances such as chlorofluorocarbons, hydrochlorofluorocarbons, and halons. These gases are typically emitted in smaller quantities but are said to be potent GHGs. They are sometimes referred to as high global warming potential (GWP) gases (Lee 2007).

Agricultural activities contribute substantially to anthropogenic GHG emissions (Weiske et al. 2006). About 49% of CH_4 and 63% of N_2O emissions can be attributed to agricultural production (Weiske et al. 2006). The nutrition of animals has environmental consequences. Nutrition has important effects on the environment as a consequence of the processes of digestion (CH_4 and phosphorus) or a combination of digestion and metabolism N. Methane is produced by fermentation in the gut and the degradation of manure. Ruminants contribute substantially to emissions of GHG. Large emissions occur from enteric fermentation in ruminants and also from anaerobic storage of manure (Hensen et al. 2006). Nitrous oxide arises from the degradation of animal wastes and from all parts of the agricultural nitrogen cycle, and hence, there may be diverse sources of N_2O emissions from livestock farms (Hensen et al. 2006). Methane and nitrates are important GHGs from livestock production. Quantification of GHGs in livestock production is a subject of great interest. Together, enteric fermentation and manure represent some 80% of agricultural CH_4 emissions and about 30–40% of the total anthropogenic methane emissions (FAO 2006). The following are the major GHGs from livestock.

14.3.1 Carbon Dioxide

The major source of CO_2 is animal respiration, followed by less significant emissions from manure storage and the barn floor. Carbon dioxide is sequestered when it is absorbed by plants as part of the biological carbon cycle and emits CO_2 through plant and soil respiration. It should be noted that the plants capture more CO_2 through photosynthesis than is emitted through respiration. Furthermore, the simple sugars produced in the first stage of carbohydrate digestion in the rumen are rarely detectable in the rumen liquor because they are immediately taken up and metabolised intracellularly by the microorganisms. Consequently, carbohydrate is converted to pyruvate that is linked with the major end products of rumen carbohydrate digestion, which are acetic, propionic and butyric acids, CO_2 and CH_4 (Henry and Eckard 2009; McDonald et al. 2011).

14.3.2 Methane

Methane is a by-product of the anaerobic digestive process (enteric fermentation). In the first stage of digestion, the forage is acted on by the varied population of microorganisms, including bacteria, fungi, and protozoa, in the fore stomach. This process releases hydrogen while producing volatile fatty acids and microbial cells containing energy and essential proteins to be made available for the growth of the animal. In ruminants, the hydrogen is removed through the action of a group of microbes called methanogenic archaea (methanogens) that gain their energy through combining CO_2 with H_2 to form CH_4. Hence, CH_4 emissions provide a mechanism for preventing hydrogen from building up in the rumen with resultant adverse effects on animal productivity, and therefore strategies to reduce CH_4 emissions must also provide for an alternative pathway to remove hydrogen (Henry and Eckard 2009; McDonald et al. 2011; Rotz et al. 2016).

So far, it has been estimated that 70% of the CH_4 in the Earth's atmosphere is a result of human activity, and agriculture accounts for 60% of this. Enteric fermentation makes up around 80% of the agricultural production of CH_4, and around 20% arises from animal wastes. Rumen and hindgut fermentation are similar processes. During rumen fermentation of organic matter, hydrogen is produced, and methanogenic bacteria use this with CO_2 to produce CH_4 and water. The CH_4 leaves the rumen by eructation, and this represents a loss of 6–10% of the gross energy of fermented foods. However, the methanogenic bacteria use hydrogen as an energy source for growth and thereby make a small contribution to the microbial matter to be digested in the small intestine. The removal of hydrogen has a benefi-

cial effect on the fermentation of plant cell wall carbohydrates. Hydrogen is also used by other bacteria to synthesise propionic and butyric acids, and the pathway of use depends on the diet and the pH of the rumen contents (McDonald et al. 2011). Within the agriculture sector, the production of CH_4 is the primary concern. Methane emissions account for 40–45% of GHG emissions from ruminant livestock, with over 90% of these emissions arising from enteric fermentation. Consequently, enteric CH_4 emissions are by far the single most important emission source that can be targeted for mitigation within the ruminant production cycle (Meale et al. 2012a).

14.3.3 Nitrous Oxide

Nitrous oxide is produced from nitrogen fertilisers, urine deposited by livestock on soils and from manure and effluent during storage and treatment. Of the dietary nitrogen consumed by ruminants, less than 30% is utilised for production, with more than 60% being lost from the grazing system (Henry and Eckard 2009; McDonald et al. 2011). Nitrates coming from livestock represent the feed nitrogen component that is not utilised by livestock and has the polluting potential of underground water systems (Jonker et al. 2002). It is important, therefore, to account for the effects of genotype and feed (production system) when one considers the polluting effect of livestock (Ross et al. 2014).

The global challenge associated with lowering GHG emissions from livestock production is that most of the livestock are in developing countries (72% of all cattle and 67% of all sheep and goats) and remote rangeland systems of the world, where mitigation practices are unlikely to be a high priority or where regular intervention is not practical (Eckard et al. 2018). Although livestock production has a significant role to play in global GHG emissions, numerous technical options have been identified to mitigate these emissions (Gerber et al. 2013).

14.4 The Contribution of African Livestock Production Systems to GHG Emissions

In Africa, livestock are kept for multiple purposes such as milk, meat, hides, horns, fertiliser and income generation, and hence are important both socially and economically in households. Although in Africa total emissions from livestock are still lower than in the member states of the Organisation for Economic Cooperation and Development (OECD), the emissions intensities per unit of animal product produced are very high, which is a cause for concern given the rapid growth projected for the sector (Herrero et al. 2013). Inefficient production systems lead to high GHG emissions intensity, measured as the amount of GHG per unit of product (meat, milk, calories, protein). For example, the intensity of CH_4 emissions (g/kg milk) is much larger in Africa compared to the rest of the world (Beauchemin et al. 2009). The mean milk production in Africa ranged from 108 to 3368 kg/cow per year (FAOSTAT 2018), with about half of the countries producing below 500 kg of milk/cow per year (FAOSTAT 2018). Consequently, African countries contribute to about 10% of enteric CH_4 emissions from dairy cattle worldwide despite producing only 3.9% of the world's milk (FAOSTAT 2018).

Husbandry and management practices play a big role in African livestock GHG emissions. Recent reports from the North West Region of Cameroon stipulated a 98% CH_4 contribution to total GHG emissions from cows kept in groups overnight (Ngwabie et al. 2019). Mali witnessed a doubling (increased by 102%) of GHG emissions from the agricultural sector (58%) and manure left on pasture (38%) from 1990 to 2014 (Galford et al. 2020). In the Northwest region of Cameroon, cattle herding poses several challenges and has marked effects on the biodiversity of the Savannah system. For instance, overgrazing is progressively accounting for the replacement of pasture by weeds to the detriment of feed for cattle, and the amount of GHG emitted by

cattle wastes keeps growing with a corresponding increase in cattle population (Gideon et al. 2017). Assessing GHG emissions from outdoor cattle sleeping areas in Cameroon indicated that mitigation strategies should be geared more towards CH_4 in the sleeping areas during the wet season (Ngwabie et al. 2019). The GHG emission factors estimated in this study were the first of their kind in Cameroon and can be used as a basis for planning management practices that mitigate emissions.

Apart from cattle, one of the contributing sectors to African livestock GHG emissions is the small ruminant sector. For example, small ruminants are a major source of CH_4 emissions in the South African agricultural sector. The sheep industry contributed an estimated 167 Gg of CH_4 in 2010, and the goat industry 40.7 Gg, with a combined 15.6% of South Africa's total livestock CH_4 emissions in 2010. The commercial sheep industry contributed an estimated 91% of sheep emissions, whereas 56% of goat CH_4 emissions originated from the emerging/communal sector (Du Toit et al. 2013).

14.5 Current Situation in GHG Emission Work in Africa

The GHG of focus in African livestock production systems has been CH_4. While there has been research progress on enteric CH_4 emissions from SSA in recent years, there are still relatively few studies and several major data gaps for important categories (Graham et al. 2022). A further gap in GHG work is the generally insufficient finance for climate-related goals, lack of research capacity and poor research infrastructure (López-Ballesteros et al. 2018). In order to fill in this gap, the International Livestock Research Institute (ILRI) at its Nairobi campus are undertaking various studies to quantify CH_4 from different livestock production systems. This work is being undertaken at the Mazingira centre using metabolic chambers, SF6 technique and other gas analysis techniques Fig. 14.1).

14.6 Why Should Lack of Quantification of GHG Emissions Be a Cause for Concern in African Livestock Production Systems?

The production of GHG from ruminants and their impact on climate change are a major concern worldwide. Although the amounts of GHG from African livestock systems may not be as huge as from other production systems in the world, the inefficiencies in African livestock production systems are a cause for concern and deserve quantification. Quantification is a good starting point for GHG mitigation. Methane is one of the three main GHGs, together with CO_2 and N_2O. The contribution of these three gases to the different activities involved in livestock farming has been estimated using the life cycle assessment method. It has been reported that enteric CH_4 is the most important GHG emitted (50–60%), at the farm scale, in ruminant production systems. Decreasing enteric CH_4 emissions from ruminants without altering animal production is desirable both as a strategy to reduce global GHG emissions and as a means of improving feed conversion efficiency. However, before determining any mitigation strategies, it is important to quantify the GHG of concern. Different methods are used to measure and estimate GHGs from livestock. Examples of such methods are respiration calorimetry chambers, isotopic techniques, tracer techniques (sulphur hexafluoride (SF_6)) and mass balance/micrometeorological techniques (Russell et al. 2007). In the respirometer/calorimeter method, air is typically passed through a chamber containing one or more animals. The volume of gas passed through and the inlet and outlet concentrations of oxygen, carbon dioxide and methane are usually measured (Murray et al. 1999; Kelly et al. 1994). The tracer technique involves placing a source of SF6 in the rumen with a known release rate and measuring the amount of release of SF6 released from the source over a period. The concentration of methane is calculated from the

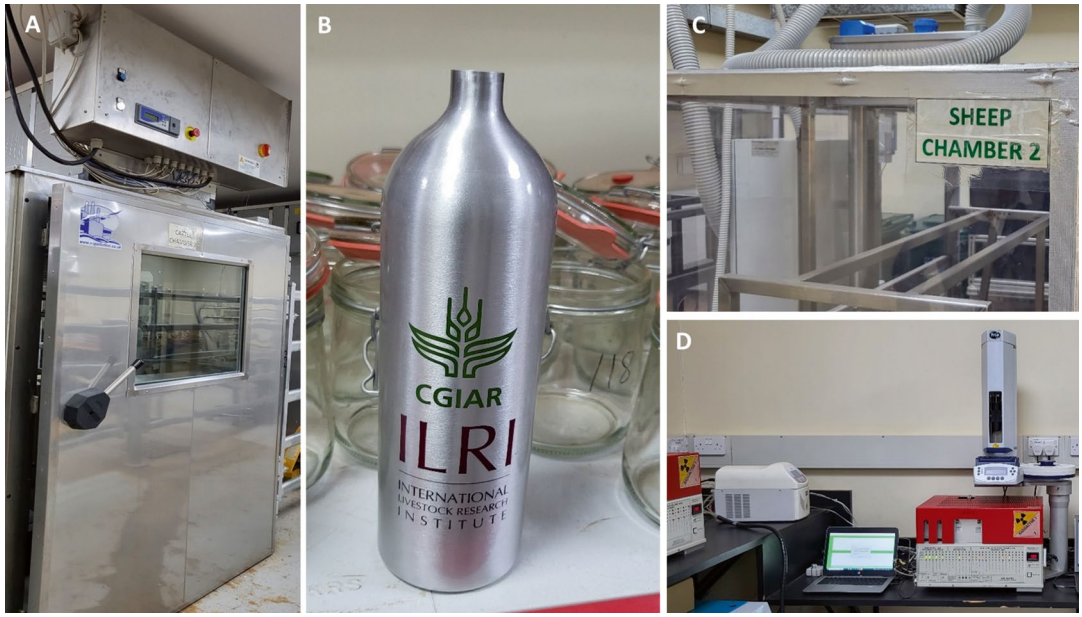

Fig. 14.1 Various methane emission measuring techniques at Mazingira centres of the International Livestock Research Institute (ILRI). Cattle metabolic chamber (**a**), SF6 gas cylinder (**b**), sheep metabolic chamber (**c**) and gas analysis kit (**d**). (Photos by Mizeck Chagunda)

ratio of CH_4 to SF6 in the expired breath of the test animals, factored by the relative molecular weights of SF6 and CH_4, and the known SF6 release rate (Johnson et al. 1994; McGinn et al. 2006). Mass balance and micro-meteorological techniques range from the use of aircraft to sample CH_4 concentrations at different levels in the atmosphere to paddock scale applications (Lassey et al. 2000; Chagunda et al. 2009). Other methods that do not just concentrate on CH_4 are methods such as the use of Flux towers. Flux towers measure GHG emissions (CH_4 and CO_2 fluxes) over landscapes. As such, this method may be appropriate for grazing animals and rangeland management. With a rapid increase in livestock numbers across some landscapes resulting in an increase in GHG emissions, changes in micro-climate, and carbon sink, such methods would help in mapping hot-spots over landscapes. These methods also use the simulation of production and utilisation of rangeland modelling to pinpoint and quantify GHG gas emissions, nutrients, and carbon fluxes under varying rangeland management scenarios involving different numbers of livestock. Other methods include spot measurements such as the use of the proprietary, laser methane detector (LMD), which measures the CH_4 concentration from the expired breath without any disturbance to the normal activity of the animals (McGinn et al. 2006; Crowcon Detection Instruments 2006). The LMD is a hand-held gas detector for remote measurements of column density for methane-containing gases is manufactured by Tokyo Gas Engineering (Fig. 14.2). The LMD has been widely used in detection applications such as gas transmission networks, landfill sites and other areas where methane leakage or build-up is a risk (Yates et al. 2000). Since the first publication on the feasibility of the use of the LMD in livestock (Chagunda, et al. 2009), different research groups and livestock practitioners have adopted the use of the LMD. In the African context, this presents a practical, easy-to-use, and yet cost-effective proxy for methane quantification in both extensive grazing systems and remotely located and yet intensive smallholder farms.

Fig. 14.2 Laser methane detector. On the left, a scientist taking methane measurements and on the right, two different models of the laser methane detector. (Photo by A. Ross)

Enteric methane production per cow per day can also be predicted using equations that use total dry matter (DM) intake, DM intake from concentrate component of the feed (CDMI), and the neutral detergent fibre (NDF) in the feed (Martin et al. 2010), that is, CH_4 (MJ/day) = 1.3 6 + 1.21 × DMI − 0.825 × CDMI + 12.8 × ND F. Other methods include assessing the rumen microbiome diversity to predict the GHG emission of the host animal. Rumen microbe diversity can be modelled utilising information from the host genotype, microbial flora, forage, and the environment to predict GHG emissions. The GHG estimating equations can also be used in a larger system of equations, such as the IPCC methodologies that apply life cycle analysis (LCA). This scientific method has been used in previous empirical studies to calculate the carbon footprints of products and processes. The transferability of the LCA across various industries and regions, as well as its flexible methodological structure, makes this method particularly suited to the many variables and complexities such as mixed farming systems, various land and herd sizes and different feeding systems.

14.7 Mitigation Strategies for GHG in the African Context

Methane mitigation in ruminants is possible through various strategies. According to (Wood and Knipmeyer 1998), the feeding management approach is the most developed; other strategies (biotechnologies, additives) are promising, but the diversity and plasticity of functions of the rumen bacterial and methanogenic communities may be a limiting factor for their successful application (Wood and Knipmeyer 1998). One most promising and cost-effective way to reduce GHG emissions from livestock is to improve the efficiency of the production system (Manson and Leaver 1989). In dairy cattle, for example, an efficient cow will have lower GHG emissions relative to the amount of milk and meat it produces. Although highly productive livestock usually emit more GHG per head in absolute terms than less productive ones, they also produce more products (Manson and Leaver 1989). As a result, the ratio of GHG emissions per product produced is lower than in less productive livestock. Management efficiencies such as reducing the

number of unproductive animals and increasing reproductive efficiency to enable fewer breeders to provide the same number of offspring per year will reduce methane emissions as well as increase profitability.

Increasing the efficiency of ruminant production is not only vital in reducing the GHG intensity, but also important for food production to meet increasing demands. Despite the social and economic importance of ruminant products, their contribution to GHG emissions is often criticised. Intensification of production systems may not necessarily lead to increased efficiencies. It is important to identify the changes and the trajectory of change in the production systems that lead to increased efficiency. Sustainable intensification aims to achieve this by identifying specific problems and challenges that come with intensification. In this process, it is important to have a detailed characterisation of the production systems and the biophysical conditions in which the animals are raised. In this characterisation, direct cattle-based measurements to assess animal health and welfare parameters are used. This is important because there is a link between health and welfare, productivity and GHG emissions. Examples of such measurements are: scoring systems developed to assess lameness (Cook 2007), claw length and cleanliness (Wildman et al. 1982), body condition (Rutherford et al. 2008), hock and knee lesions (Gibbons et al. 2009), behaviour (Gibbons et al. 2010), as well as other direct health and welfare changes (Sørensen et al. 2001) in dairy cattle. In addition, animal-based systems of classification have the advantages of describing relevant and significant aspects of what matters from the point of view of the animal, express change over time, are capable of being influenced by decisions taken by the individual farmer and can be measured in a relatively cheap and easy manner (Chagunda et al. 2010). An effective disease-management plan will improve productivity of the herd and result in a reduction in CH_4 emissions per unit of product (Henry and Eckard 2009).

Good feed quality and maintaining animal health will improve the fertility of the herd and increase the weaning rate, with flow-on effects to lower total CH_4 emissions from the herd (Henry and Eckard 2009). Feed is a key limiting factor and often the most expensive input in livestock production. However, poorly utilised feed is also a source of pollution, including GHGs. Generally, in dairy cattle as an example, high forage systems have higher CH_4 production per kg of milk than low forage systems. However, low forage systems have higher N loss than high forage systems. The N loss is mainly a reflection of unutilised protein that is lost through urine and faeces (Smith et al. 2013). Hence, animals with increased productivity in terms of milk yield and body energy reserves are associated with a decrease in CH_4 emissions per kg of milk but an increase in N loss. This highlights the important dynamics of emission burden and pollution potential of different livestock feeding systems. Obviously, feeding should not be considered in isolation. Integrating feed and forage, and pest management with improved cattle health and genetics can lead to significant enhancements in cattle production, up to 240% (Herrero et al. 2013). In mixed crop–cattle systems, which often have the potential to intensify, the most important contributors to feed resources are forages, crop residues and rangelands (Herrero et al. 2013), while in pastoral and agro-pastoral systems, grazing of rangelands is the principal, often the only, source of feed. Feed shortages, in terms of both quantity and nutritional quality, either seasonally or, in the case of dryland pastoral systems, inter-annually, are widespread, slowing the sector's growth and periodically causing severe losses. Improved feed and forage management practices, such as better management of rangeland, increased cut-and-carry of pasture resources, improved feed utilisation of crop residues and other agricultural by-products, have considerable underexploited potential to improve cattle productivity, while also contributing to the resilience of agro-ecosystems and environmental sustainability (Rao et al. 2015; McAllister and Newbold 2008). The digestibility and quality of feed are major determinants of energy available for animal growth and, therefore, of the performance of ruminants and of CH_4 production. The efficiency of nutrient utilisation by microbial organisms in

the rumen controls the fermentation process, which in turn affects the activity of methanogens relative to other microbial species (Henry and Eckard 2009). Improvements in livestock feeding could be achieved by the following:

- Feeding forages with lower fibre and higher soluble carbohydrates, changing from C4 tropical grasses to mostly temperate C3 species, or grazing less mature pastures (Beauchemin et al. 2009).
- Addition of grain to a forage diet increases starch and reduces fibre intake, reduces rumen pH and promotes the production of propionate in the rumen (Wattiaux 2023). Propionate production tends to reduce methanogenesis in the rumen. Methane emissions are also commonly lower with higher proportions of forage legumes in the diet, partly due to lower fibre content, faster rate of passage and, in some cases, the presence of condensed tannins (Beauchemin et al. 2009). Plant breeding, therefore, offers some potential to improve the efficiency of digestion while reducing CH_4 production.
- Aguirre-Villegas and Larson (2017) showed that the adoption of best nutritional, cropping, and manure management practices may substantially reduce on-farm GHG emissions in all dairy systems. Modelling and assessment methods must be improved to better account for interactions among system components and co-products of milk production.

Apart from the feed management strategy, there are other strategies, such as waste management strategies. An example is highlighted by (Galford et al. 2020), who demonstrated that a GHG ($CH_4 + N_2O$) emission rate of 241 mg CO_2e m^{-2} min^{-1} indicates that CH_4 contributes 83% of the total, even though it is stored in a pile. Stringent waste management strategies, such as anaerobic digestion for biogas production or the use of covers over waste heaps, are needed in abattoirs to mitigate GHG emissions. In addition, long-term measurements are needed to cover seasonal variations in outdoor waste storage in different abattoirs.

Mitigation strategies such as genetic selection, use of chemicals and vaccines, and the capture of CH_4 have been proposed, yet dietary manipulation is considered the most promising strategy for the abatement of CH_4 from ruminant production systems (Meale et al. 2012b). According to Meale et al. (2012b), there have been several reviews published on different CH_4 abatement strategies for ruminant livestock (Boadi et al. 2004; Balehegn et al. 2021; Wood and Knipmeyer 1998). Selection for genetic lines of sheep and cattle that have lower CH_4 emissions (both in absolute terms and as a function of productivity) has the potential to be an effective long-term and economically sound approach to reducing CH_4 emissions from livestock. Genetic approaches are suited to extensive grazing systems, where management and husbandry interventions will continue to be impractical, at least in the near future (Fig. 14.3). In more intensive livestock systems, genetic improvements can be combined with management approaches. One of the innovations being implemented includes climate-smart farming practices (CSFPs). A study in Malawi show that the practices, when adopted by farmers, reduced the adverse impacts of climate change (drought and flooding) experienced by farming communities (Jones et al. 2014).

It should be noted that the mitigation strategies provide opportunities to reduce GHG emissions from ruminants, while maintaining (and potentially increasing) productivity. The degree of abatement achievable is mostly not large hence not suitable to deliver the level of reduction desirable to mitigate the threat of dangerous climate change. Significant levels of abatement will require additional innovation from intensive research and development over some years, and this will be achieved only with dedicated resources. The challenge would be demanding for extensive production systems, where few options currently exist for practical intervention considering African livestock production systems. In all this, however, there has to be emphasis on the importance and need to link national and regional policies to global strategies to reduce emissions of greenhouse gases and enhance carbon sequestration potential (Mgalula et al. 2021).

14.8 Conclusion

Climate change is among the biggest threats to food security and thus to human existence. The adverse effects of increased frequency of sporadic rainfall, severe floods and droughts seriously undermine the achievement of food security and sustainable livelihoods of communities in middle-income and low-income countries, where agriculture is the backbone of the economy. Agricultural systems are very vulnerable to climate change as they are dependent on nature. The impacts of climate change on food systems are more prevalent in the global south, where most agricultural activities are carried out by smallholder farmers. Consequently, their nutritional security is limited as they rely heavily on their own production to meet their food security and economic needs. While African livestock are responsible for the livelihoods of millions of farmers across the continent, they are also responsible for contributing to GHG emissions, which cause climate change. The majority of the GHG is CH_4. Due to a lack of data, the estimates of GHGs in SSA are associated with a huge level of uncertainty. This provides a huge opportunity to act.

14.9 Future Perspectives

Filling data gaps on GHG emissions will require additional studies using both direct and indirect methods. For CH_4 emissions, respiration chambers are considered the "gold standard" for direct measurements. These, however, are expensive to run and need highly trained technicians. The use of proxies that can be used in the animals' natural environment can assist in not only collecting the much-needed data but also account for animal x environmental interactions. This provides a huge opportunity to act.

Opportunities for Improved Utilization of African Livestock Genetic Resources

15 Defining Breeding Goals and Breeding Strategies for Improving Livestock Under Various Production Systems in Africa: Concept and Brief Overview

Raphael Mrode, David A. Mbah, and Julie M. K. Ojango

Abstract

This chapter presents an overview of the concept and functions of breeding goals in livestock improvement programs. The first section (Sect. 15.1 Breeding Goals in Livestock Improvement Programs) provides an overview of the definition and functions of breeding goals, critical elements required for their development, and variations in their adoption across different species. The section also outlines global and continental frameworks and intervention initiatives aimed to facilitate the wide adoption of breeding goals for the diverse species and breeds found in Africa. The second section (Sect. 15.2 Breeding Strategies and Livestock Improvement) presents the concept and options related to breeding strategies to realize the defined breeding goals. The section highlights essential elements for successful breeding strategies to increase productivity and incomes including livestock performance data, farmer participation, appropriate dissemination of outcomes, and continuous evaluation. Examples of breeding strategies for cattle and small ruminants are presented to highlight the integration of some of the essential elements of breeding strategies in the African context. The last section of this chapter (Sect. 15.3 Future Perspective) stresses the futuristic importance of breeding goals and strategies for livestock production in line with changing environments and global demands for products.

15.1 Breeding Goals in Livestock Improvement Programs

15.1.1 Fundamental Role of Breeding Goals

A breeding goal consists of the traits to be improved and the relative emphasis to be placed on each trait (Box 15.1). Hazel (Hazel 1943) defined a breeding goal as a linear combination of traits in which the coefficient for each trait represents its effect on profit when all other traits are held constant. Breeding goals are futuristic in the sense that they define what we want the population to be in the future and therefore occupy a central role in any breed improvement program. The definition of breeding objectives is the first step (see Fig. 15.1) in the design of any breeding program (Goddard 1998) and it can result in large inefficiency if inappropriate objectives are defined resulting in the application of too much selection pressure on the wrong traits.

The major aim of defining breeding goals is to ensure the profitability of farmers in the production system. Therefore, breeding goals must be relevant to the farming system targeted with the aim of delivering economic and social benefits. It may be added that this should be achieved without causing detrimental effects to the animal's health and welfare or the environment. Usually, profitability to the farmers depends on more than one trait, hence, in most cases breeding goals consist of more than one trait.

Breeding goals are fundamental in terms of determining the direction and rate of genetic change (Box 15.1); the traits to be collected, the genetic evaluation system, and appropriate dissemination for selected animals. In short, in any breeding program, breeding goals enable us to decide on the choice of individual animals as parents, the choice of breeds or crosses, and the evaluation of investment in breeding programs in terms of the economic value of the predicted genetic change (Goddard 1998; Hutu et al. 2020).

Box 15.1 Some Useful Terms in Defining Breeding Goals and Breeding Strategies

1. *A breeding goal is the specification of the traits to be improved including the emphasis given to each trait.*
2. *A breeding goal gives the direction in which we want to improve the population. A notion of what* constitutes the

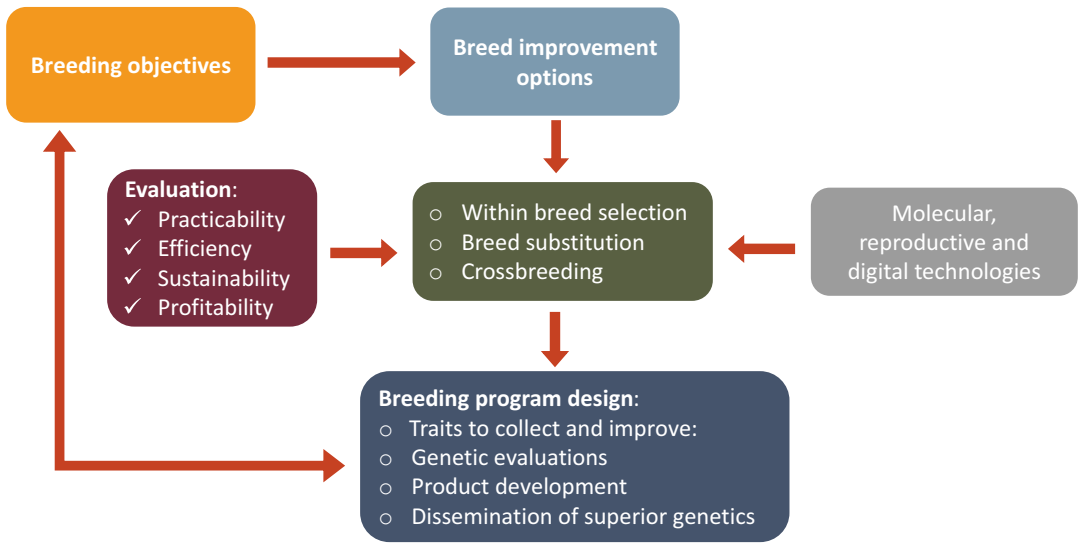

Fig. 15.1 A schematic illustration of the main components of a breeding strategy

best or desired animal phenotype for the population (equivalent to the "vision" of the breeding strategy)
3. The combination of traits in a breeding goal each with their relative weight or emphasis is referred to as a selection index.
4. Breeding strategies: Refer to different ways of using parental generation(s) to generate animals of *desired types. Examples include. Within-breed selection, line breeding, crossbreeding, line crossing, etc*
5. A breeding program is a setup designed to generate the next and subsequent generations of animals that (ultimately) deliver the defined breeding objectives.
6. Genetic evaluation system refers to the procedures and models used in the estimation of the breeding values of animals in a population
7. Rate of genetic change is the rate of change in the estimated breeding value of a population per unit of time such as year or generation

15.1.2 Factors that Underpin the Definition of Breeding Goals in Practice and Challenges of the African Production System

(i) The needs (economic, social, and cultural) of farmers and the production system: In many farming systems in Africa, livestock deliver more than direct economic benefits to families as they contribute to other important societal and cultural values including the provision of traction, provide a means of asset building, provide insurance (ability to sell animals to raise cash to pay medical and educational expenses), and convert crop residue to manure used either as biofuel or as fertilizer. These factors should be considered in defining a breeding goal, since productivity may not necessarily be the key trait but a wide range of other traits related to adaptation, disease resistance, and survival could be very important. Some of these traits could be more difficult to measure or put values on, therefore farmers' involvement is required to appropriately include these traits in the breeding goal.

In many societies in Africa, gender dynamics are strong determinants of livestock ownership patterns, management practices, trait preferences, and breed adoption (Njuki and Sanginga 2013). The need to integrate gender differences in livestock improvement programs has been advocated for sheep and goat production under pastoral systems (Kariuki et al. 2021) as it is evident that gender dynamics can influence breeding outcomes.

In a recent study involving the analysis of 68 research works (Chawala et al. 2020) involving smallholder and medium to large dairy farms, the top four main groups of trait preferences identified were (a) productivity in terms of milk yield per lactation, fat and protein percentages, and lactation length; (b) disease resistance and reproduction, age at first service and calving, days open, number of services per conception, calving interval, and survival; (c) body conformation and temperament and (d) growth rate of animals. However, from the cluster analysis, they reported that trait preferences differed between production systems. While production traits have a similar emphasis on both smallholder and large-scale dairy systems, smallholder dairy farmers put an equal emphasis on reproduction and disease resistance, and then on growth and body conformation. However, large-scale farmers gave equal emphasis to reproduction and growth and then to body conformation and temperament.

(ii) The traits considered important for profitability and of value to the farmer (Philipsson et al. 2011) should easily be measured in a large proportion of the population to be improved either directly or through other proxy-related traits. Another requirement for traits in the breeding goal is that these should be collected with very good precision, at a low cost, and be heritable. In most African settings, this posed a real challenge

prior to the advent and transformational use of information and communications technologies (ICT) from the year 2010. Production systems in Africa lack routine methods and systems for collecting performance data. Since 2010 however, innovative approaches for data collection involving the use of digital tools such as mobile applications with data flowing to a database have started to emerge in Africa (Oyieng et al. 2020) and these are discussed in detail in Chap. 16. However, capturing precise information on traits with societal and cultural values which are rather subjective, and the value associated with them poses a challenge. Some studies have employed discrete choice experiment methodology or focus group discussion to gauge the value of traits preferred by farmers (Wurzinger et al. 2008; Leroy et al. 2017; Onzima et al. 2018; Chawala et al. 2019).

(iii) Determining the appropriate emphasis or weight to be given to each trait in the breeding goal. When the traits in a breeding goal are each assigned a weight, it is usually referred to as a selection index (Box 15.1). For example, if the intention is to set a breeding goal to improve growth rate and final weight in goats for example, then a selection index (I) to achieve this goal could be:

$I = wt_1(\text{growth rate}) + wt_2\ (\text{final weight})$; where wt_i are the weights or relative emphasis on each trait

The relative emphasis or weights can be derived solely on the basis of economic returns to the farmer. Such an index is termed an economic index. In simple terms, the economic weight of a trait in the index could be defined as the effect of a marginal (one unit, for instance, one genetic standard deviation) change in the genetic level of the trait on the breeding objective, keeping all other traits in the index constant. Economic weights can be derived using several methods including:

(a) *Simple accounting* method, where the economic index (A) is the difference between the extra return (g) and the cost (c) from a one-unit increase in the mean of trait: A = (g—c). Note that g and c are evaluated as marginal increases of the trait value above its current value and attempts must be made to avoid double counting of information when dealing with several correlated traits in the index. For example, if computing an economic value for milk yield, the mean of correlated traits such as fat or protein yield must be kept constant.

(b) *Profit functions* have been used extensively and involve the use of an equation to compute the difference between income and expenses of a given system using all herd sources of income and expenses derived from several biological and economic parameters (Ponzoni and Newman 1989; Goddard 1998). With this approach, the economic value of a trait is derived as the first partial derivative of the profit function evaluated at the current population mean for all traits.

(c) *Bioeconomic model* which involves the use of several equations to model inputs or cost and outputs (revenue) for the full-cycle production system utilizing relevant biological and economic parameters. Some examples: bioeconomic models for Brazilian Aberdeen Angus (Campos et al. 2014), sheep (Bohan et al. 2019), dairy cattle (Mbah and Hargove 1982; Schmidtmann 2021), and goats (Bett et al. 2007; Gizaw et al. 2018). The application of the bioeconomic models usually involves several steps: (1) Initially running the model using the means of all traits for the current population, including the trait of interest. The average profit per animal is computed under this scenario (scenario I) (2). Running the model with the mean of the trait of interest increased by a defined amount while the means for all other traits were kept constant. The average profit per animal is then computed under this scenario (scenario II) (3). The economic weight for the trait of interest can be computed as the difference in the average profit of the animal in scenario II and scenario I, divided by the amount of change in scenario II.

However, for societal or cultural traits, the emphasis to be placed on such traits could be determined through focus group meetings or choice experiments as mentioned earlier. Weights for these traits are an outcome of farmers' preferences and predetermined changes with no economic consideration. Such breeding goals are usually termed desired gain indexes.

15.1.3 Types of Breeding Goals (General Objectives) and Issues Relevant to Different Livestock Species

While livestock breeding goals (general objectives) may differ from species-to-species relative to country/region, they share the same concepts discussed in Sects. 15.1.1 and 15.1.2. Generally, the main principle guiding the definition of breeding goals for different species relates to the primary products that define profitability, social, and cultural values in those species.

Thus, as outlined below for different species and summarized in Table 15.1, the breeding goals vary depending on the products derived from them, with the main emphasis on increasing their productivity for food and income.

Beef Cattle The main breeding goal is increased production of beef for food and income.

The associated strategies to meet the specific objective within the goal are different and include the following:

(a) Increased meat production (increased body weight) and meat quality through selection within specialized breeds.
(b) Increased meat production (increase in body weight) through planned crossbreeding of specialized local breeds with specialized exotic breeds.

Dairy Cattle The main breeding goal is increased production of milk for food and income.

Different strategies to meet the specific objectives within the goal include the following:

(a) Increased milk yield and components such as fat and protein yield milk through selection in open/close nucleus of specialized local breeds.
(b) Increased milk yield and components such as fat and protein yield milk through crossbreeding of specialized local breeds with prioritized exotic breeds.

Further reading: Tebong (1985), Tawah et al. (1993, 1994, 1999), Ebangi et al. (1999), Djoko et al. (2003), Ema et al. (2018), Pingpoh et al. (2019), Ouedrago et al. (2020).

Sheep The main breeding goals include increased production of mutton/lamb, milk, and revenue.

The strategies involved include the following:

(a) Increased meat production (growth-related traits) or milk production or more lambs (litter size) through selection (open/close nucleus) of local breed(s) for increased mutton/lamb production.
(b) Increased meat production (growth-related traits) or milk production or more lambs (litter size) through crossbreeding of prioritized local breed(s) with prioritized exotic breed(s) for increased production of mutton/lamb.

Goat The main breeding goals include increased meat and milk production and meeting sociocultural needs.

The strategies involved include the following:

(a) Increased meat production (growth-related traits) or milk production through selection (open/close nucleus) of local prioritized breed(s) for increased goat meat.
(b) Increased meat production (growth-related traits) through crossbreeding of prioritized local breed(s) with prioritized exotic breed(s) for increased goat meat.

Further reading (sheep and goats): Kosgey (2004), Yapi-Gnaore et al. (1997), Bosso et al. (2007), Ojango et al. (2021), Djoko (2019).

Table 15.1 Summary of main breeding goals by species

Specie	Main breeding goals	Sources
Cattle Beef Dairy	Improved growth rate for meat Increased milk production and improved fertility	Tebong (1985), Tawah et al. (1993, 1994), Ebangi et al. (1999), Djoko et al. (2003), Ema et al. (2018), Pingpoh et al. (2019)
Sheep Goats	Improved growth rate for mutton, increased milk, resistance to parasites Improved growth rate for meat, increased milk production	Kosgey (2004), Yapi-Gnaore et al. (1997), Bosso et al. (2007), Ojango et al. (2021), Djoko (2019)
Camels	Improved rate of growth for meat and increased milk production	Morton (1984)
Pigs	Improved growth rate for pork	Dotche et al. (2020), Verhulst (1993)
Poultry	Improved growth rate, increased eggs production	IRZ (1986), Hans (2012)
Rabbits	Improved growth for meat	Nwakalor and Ngo Ndjon (2000), Ngo Ndjon and Nwakalor (1999)
Horses	Race performance, trotting, pacing	IRZ (1986), Amasou and van Vleck (2000), Pretorius (2003), Tennah et al. (2014)
Donkeys	Traction/work, transport	Blench (2000). Ebangi and Vall (1998)

Camels The main breeding goals include increased meat production and milk yield for food and revenue.

Strategies involved include the following:

(a) Selection of local breeds for increased camel meat production (growth-related traits) and milk yield.

Further reading: Morton (1984).

Pig The main breeding goals include increased production of pork for food and revenue.

Strategies involved include the following:

(a) Increased pork production through the selection of prioritized local breeds for growth-related traits.
(b) Increased pork production through crossbreeding of local breeds with exotic breeds for improvement in growth-related traits.

Further reading: Dotche et al. (2020), Verhulst (1993).

Poultry The main breeding goals include increased production of table birds for meat and egg production.

Strategies involved include the following:

(a) Improvement in body weight or increased egg production through selection in specialized local breeds.
(b) Improvement in body weight or increased egg production through crossbreeding of specialized local and exotic breeds.

Further reading: IRZ (1986), Hans (2012).

Rabbits The main breeding goals include increased production of rabbit meat for food and revenue.

Strategies involved include the following:

(a) Improvement in growth-related traits through selection of local breeds.
(b) Improvement in growth-related traits through crossbreeding of specialized local and exotic breeds.

Further reading: Nwakalor and Ngo Ndjon (2000), Ngo Ndjon and Nwakalor (1999).

Horse The main breeding goal is improvement in race performance, trotting, and pacing.

Strategies involved include the following:

(a) Selection of local breeds for increased racing ability or trotting /pacing ability.
(b) Crossbreeding of specialized local and exotic breeds for racing ability or trotting /pacing ability.

Further reading: IRZ (1986), Amason and van Vleck (2000)., Pretorius (2003), Tennah et al. (2014).

Donkeys The main breeding goals include increased traction(work) ability and transportation ability.

Strategies involved include the following:
(a) Improvement in traction ability or transportation ability through selection in local breeds.

Further reading: Blench (2000), Ebangi and Vall (1998).

Two breeding strategies that are common to all the species listed above include the following:
(a) Evaluation of adaptation of selected genotypes to biotic and abiotic stresses
(b) Socioeconomic evaluation of selected genotypes

15.1.4 Adopting Breeding Goals in Livestock Improvement at the Continental Level

To initiate change, breed improvement programs in the continent of Africa have been driven by governments and bilateral organizations seeking to change the productivity within the existing systems. Through these programs, some basic structures were put in place at the individual country level. Glaring gaps in information on practices and breeding strategies for indigenous genetic resources across the continent however made it difficult for many African countries to provide information on their livestock populations for the "State of the World Animal Genetic Resources" report prepared by the FAO (2007). The publication of the FAO report in 2007 led to the international community developing the Global Plan of Action (GPA) for Animal Genetic Resources (AnGR) *and the* Interlaken Declaration on AnGR. The Global Plan of Action (Box 15.2) emphasized the need for improved productivity and long-term breeding strategies if the use of indigenous livestock breeds is going to be sustainable. Details on the GPA are outlined in Sect. 30.2.4 (Chap. 30). Countries in Africa followed up with a concerted effort to characterize animal genetic resources in the continent and the practices adopted in their management.

Box 15.2 The Global Plan of Action (GPA, 2007)

Strategic areas

Characterization, Inventory and Monitoring.
Sustainable Use and Development.
Conservation.
Policies, Institutions and Capacity-building.

Aims

Support and increase the overall effectiveness of national, regional and global efforts for the sustainable use, development and conservation of animal genetic resources,
Contribute to the development of a comprehensive framework for the management of agricultural biodiversity.
Facilitate international cooperation and the mobilization of resources.

A second report on the "State of the World Animal Genetic Resources" was published in 2015 (FAO 2015). To broaden the scope and adoption of breed improvement, the African-Union Inter-African Bureau for Animal Resources (AU-IBAR) developed an overarching policy framework, and published information on farm animal genetic resources in Africa (AU-IBAR 2019), (See Box 15.3).

Box 15.3 AU-IBAR Animal Genetics Project

To fill the gap in information on the existing animal genetic resources on the African Continent that was required as a basic building block for developing sustainable breeding programs, in 2013 AU-IBAR led a continental effort to characterize and develop an inventory of Animal Genetic Resources (AnGR) in Africa, outlined in detail at Sect. 30.3.1 (Chap. 30). In addition to instituting more targeted breeding management interventions, the project aimed to build capacity for effective formulation and implementation of policies and strategies for the management of AnGR.

Through the project, reports submitted to the FAO by 44 African states on genetic resources and breeding programs in place in 2015 were reviewed and summarized in "The State of Farm Animal Genetic Resources in Africa (AU-IBAR 2019).

Additionally, a series of policy briefs on breeding program options for the continent were published and availed. The brief on Crossbreeding in Africa (AU-IBAR 2020) revealed that among 42 of the African Union countries in 2015, crossbreeding for improvement of animals was instituted in:

30.2% of all breeding improvement programs for cattle.
10.6% of all breeding improvement programs for sheep.
32.6% of all breeding improvement programs for goats.

Results from the study indicated that the main reasons for crossbreeding among local and exotic breeds were for general improvement in meat and milk production. Often the local breeds were deemed to have poor meat production, and/or milk production.

Most of the systems utilizing crossbreeding among sheep and goats sought to produce dual-purpose animals.

15.1.5 Summary of Essential Elements of an Appropriate Breeding Goal for Low Input Systems

A critical element for the successful implementation of appropriate breeding goals in low input systems is that they must have a farmer focus. Goals must ensure profitability for farmers in the production system, delivering economic, cultural, and social benefits to the farmers. In addition, the participation of farmers in identifying the appropriate traits in the goal is essential for adoption and effectiveness. Farmer involvement has been attributed as one of the major factors for the success of the community breeding programs for small ruminants implemented in Ethiopia (Haile et al. 2019). It must be added that breeding goals should have no detrimental effects on animals' health and welfare or the environment. These goals should result in outputs for which there is regional and national demand; in other words, there should be market opportunities. Therefore, a good understanding of the future consumers' demands or good foresight of both farmer and consumer needs and future market trends is fundamental. Finally, such goals should be linked with or rooted in government policies (e.g., national livestock development policy) to promote government buy-in and widespread adoption.

15.2 Breeding Strategies and Livestock Improvement

Breeding strategies involve the design and evaluation of different breeding improvement options including the integration of new technologies, for the purpose of maximizing particular breeding objectives or performance of existing livestock. At the national level, the livestock policy of some countries may include animal breeding strategy components that govern the development and genetic improvement of their animal genetic resources. In general, the overall purpose of breeding strategies is to produce future generations of animals that will produce more efficiently under future production systems.

Therefore, the fundamental components of a breeding strategy involve a clearly defined breeding objective, and evaluation of different breed improvement options to address this objective in terms of practicability, efficiency, sustainability, and profitability to the farmer (Fig. 15.1). For example, let us assume that we wish to improve milk yield in smallholder systems in Southern Kenya. To realize this goal, we can consider several strategies: (1) *within breed selection* of the dairy cattle in Southern Kenya, (2) *importation* of some other dairy breed from another African country or a developed country in another continent, or (3) undertake *crossbreeding* between the existing indigenous breed and an imported breed. We can evaluate these various options in terms of cost (efficiency), practical issues, sustainability (cost and impact on the local breeds, environmental impact), and farmers' profitability. After this evaluation stage, the next steps will involve the detailed design of an actual breed improvement program in terms of defining an appropriate selection index for the breeding objective, the capture of relevant phenotypes, genetic evaluation systems, and selection of the superior genetics based on the breeding objectives as parents of the next generation.

In large farms, the superior stock selected could be used within farms and the implementation of the improvement program will consider issues such as mating ratios and controlling of inbreeding. In some large beef systems, the use of reproductive technologies such as artificial insemination (AI), multiple ovulation and embryo transfer (MOET) are employed. However, in Africa, where smallholder farmers play an important role in the livestock sector, accounting for about 80% of the productivity (Ojango et al. 2018), the delivery of superior genetics to the farmers becomes more complicated and may involve working with national artificial inseminations centers (NAIC) and enrolling superior bulls for AI. This may be coupled with other reproductive technologies such as synchronization to enhance the success of AI.

Reviewing the major components of breeding strategies in Fig. 15.1, some of the bottlenecks for the successful conceptualization and implementation of breeding strategies in developing countries include (i) the definition of breeding objectives that do not account for the farmer's perspective in addition to the production system. Dekkers and Gibson (Dekkers and Gibson 1998) rightly indicated that breeding objectives and selection criteria may never be used in practice if those definitions do not take into account the perceptions and wishes of the breeders for whom they are designed; (ii) narrow breeding options often focused on breed replacement and/or indiscriminate crossbreeding of native with exotic breeds with no plan on how to maintain suitable exotic blood levels and no selection in the local breed (Wurzinger et al. 2014), and (iii) the lack of systematic systems for performance data capture for improved farm management and implementation of genetic improvement programs. However, advances in modern digital, genetic, and reproductivity technologies are providing opportunities to overcome some of these bottlenecks, and in subsequent chapters (18 and 19), these are outlined in more detail in different livestock species.

15.2.1 Example Breeding Strategies Adopted for Targeted Outcomes

It has become more evident that the sustainability of breeding programs in different communities in Africa is highly influenced by socioeconomic factors that affect access to livestock resources, and the use of the resultant products by different gender groups. This also affects the adoption of interventions in the form of breeding management practices. In Kenya's mixed crop-livestock production systems, the introduction of improved livestock breeds with markets for dairy products leads to an increased demand for women's labor resulting from zero-grazing strategies, and men's appropriation of milk incomes—traditionally under women's control (Wangui 2008). Civil unrest and global events such as the Covid-19 pandemic from 2020–2021 also affect breeding practices and choice of breeds in different regions of the continent. For example, the national unrest

in Rwanda in 1994 which resulted in loss of livelihoods also resulted in huge losses in existing livestock breeds. To restore and resettle the population and improve livelihoods and household nutrition, the "Girinka" program was initiated through which one dairy cow was provided per family to improve milk production (Ezeanya and Kennedy 2017).

15.2.1.1 Example Strategy Adopted for Dairy Production in Africa

Crossbreeding of indigenous tropical livestock breeds with exotic more temperate breeds is the most widely adopted strategy across the African continent for dairy production. It is however notable that despite using the practice for more than 100 years to improve milk production in cattle, a stabilized crossbred with a known proportion of *Bos taurus* and *Bos indicus* genes has not yet been developed for the low input farming systems of Africa. In a review of the achievements, challenges, and opportunities of using crossbreeding to increase milk production in cattle (Galukande et al. 2013), it was noted that milk production by local animals was more than doubled when they had 50% Bos *taurus* blood. The greatest challenges reported in adopting crossbreeding include uncoordinated crossing among animals, limited understanding of how to use crossbreeding to achieve the long-term breeding goal by the farming communities, lack of national breeding policies, and a lack of consistent records on the performance of crossbred animals to guide selection decisions (Djoko et al. 2003; Roschinsky et al. 2015). At the end of intervention efforts to introduce new breeds into populations, the livestock keepers are unable to follow through on the breeding for a stabilized breed combination in line with their goal to increase milk production.

15.2.1.2 Examples from Sheep and Goat Production in Different Systems

Sheep and goat breeding programs in Africa present a unique diversity in approaches, from breeding programs designed to supply animals for smallholder farming systems in which few animals are reared on small land holdings under controlled management to produce milk to meet household requirements (e.g., FARM Africa Goat program, Heifer project international) to interventions involving the use of improved breeding males of exotic genotypes to enhance growth rates under larger scale operations (Chap. 17). The most common type of breeding programs implemented for sheep and goats in developing countries since the year 2000 are Community-Based Breeding Programs (CBBP) (Mueller et al. 2015; Weldemariam and Mezgebe 2021) that take into consideration and build on indigenous knowledge of communities on breeding practices, resulting in greater appreciation and use of indigenous breeds.

15.2.1.3 Breeding Strategies for Pastoral Production Systems

One way of demonstrating that a breeding program will result in change is to adopt impact pathway models. The impact pathway presented in Fig. 15.2 was adopted to introduce the most optimal breeding practices for sheep and goat production under pastoral systems in Kenya (Ojango et al. 2018). Through the progressive community interactions outlined in which critical socioeconomic aspects related to gendered ownership and use of livestock were taken into consideration (Kariuki et al. 2021), pastoral communities in the arid lands of Kenya have embraced improved breeding management strategies for their small ruminants (Ojango et al. 2021).

15.2.2 Summary of Essential Elements for a Successful Breeding Strategy

A successful breeding strategy(specific objective) would be characterized by the following essential elements: (a) two-way triangular free flow of information among four key partners (research (ministry/institute), development (livestock ministry) and producers (livestock farmers, and consumers); (b) dissemination of results gen-

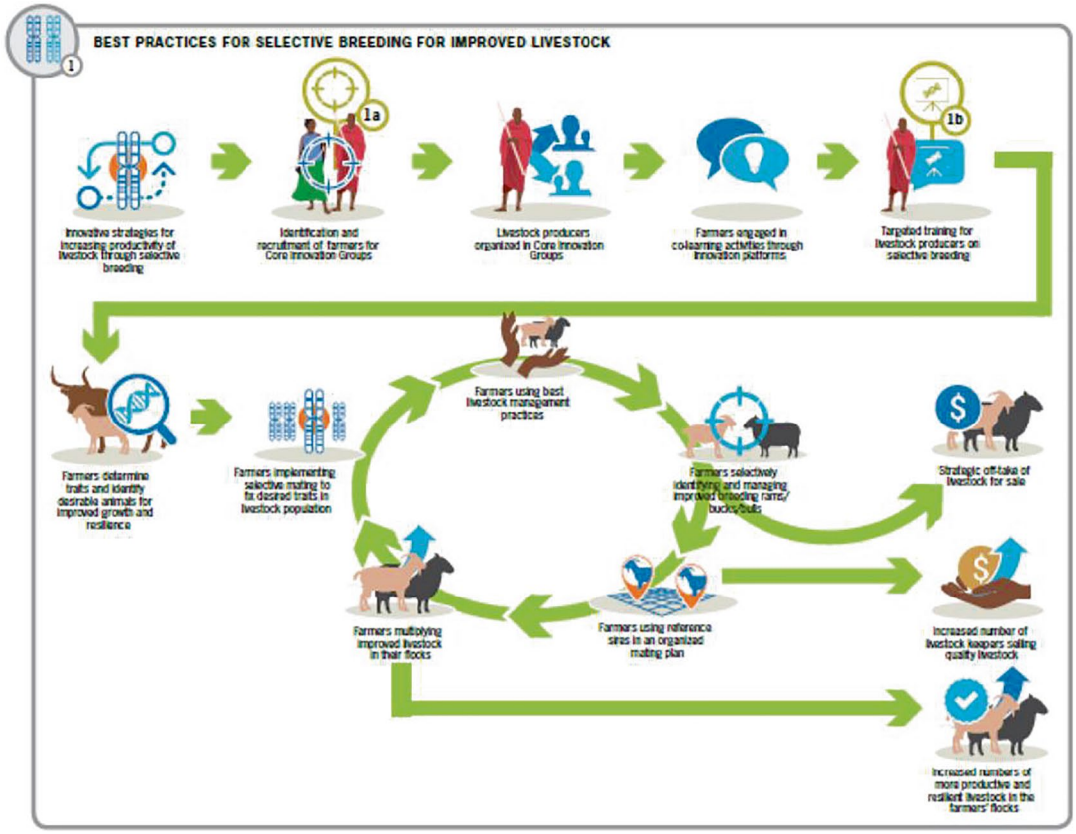

Fig. 15.2 Impact pathway for best practices for selective breeding for improved livestock (Ojango et al. 2018)

erated by the strategy; (c) farmers' participation at all stages of the strategy including design and implementation; (d) continuous evaluation and feedback to farmers researchers and development partners, and (e) increased productivity leading to improved revenue for farmers and fulfillment of several sociocultural roles.

Further reading: IRZ (1986), Tebong (1985).

15.3 Future Perspectives

Emerging markets, changes in consumer attitude, and advances in technology are critical in the design of breeding goals and strategies so that future trends can be accommodated. Notable changes in climate that have a huge impact on livestock productivity and consumers' desire for more healthy diets and preferences for livestock raised in management systems with more welfare considerations are now apparent. These factors will have to be considered in the definition of future breeding goals. Breeding strategies for the mitigation of climate change and the adaptation of livestock systems to accommodate climate change will play central roles in the design of future breeding goals in addition to the incorporation of emerging reproduction, molecular, and digital technologies. Changes in the design of breeding strategies to accommodate some of these new trends are discussed in subsequent chapters on breeding goals for different livestock species.

Acknowledgments The authors acknowledge the contributions of Prof. Ed Rege to the brief definitions in Box 15.1 in this chapter.

16 Defining Breeding Goals and Breeding Strategies for Improving the Productivity of Cattle Breeds and Buffaloes in African Production Systems

Raphael Mrode, David A. Mbah, Chi L. Tawah, Julie M. K. Ojango, Sunday O. Peters, Eveline M. Ibeagha-Awemu, Oluyinka Opoola, Isidore Houaga, Richard Osei-Amponsah, Moses Okpeku, and John E. O. Rege

Abstract

The previous chapter discussed the fundamental concepts and principles that underpin the definition of breeding goals and strategies. In this chapter, some of the peculiar aspects of breeding goals and strategies for the improvement of cattle and buffaloes in Africa, in addition to lessons drawn from past cattle improvement projects, are examined. The chapter is broadly presented in

four sections. Section 16.1 deals with the concept of breeding goals in the context of the most dominant production system in Africa and examines evolving trends in breeding goals that incorporate health and welfare considerations. This is followed by Sect. 16.2 which presents the fundamental role of market situations in the design of breeding goals and the influence of some regional institutions and policies on breeding programmes. Breeding goals for beef and dairy cattle production and some lessons from the design of breeding goals from previous breeding programmes were then outlined. Section 16.3 considers breeding strategies aimed at promoting sustainable animal production systems in African diverse environments. It then delves into the different breeding strategies including breed substitution and cross-breeding, selection approaches for cattle improvement, nucleus or group breeding schemes, community-based livestock breeding schemes and unplanned selection programmes. Section 16.3.2 is focused on emerging molecular and reproductive technologies in breeding strategies relevant to genetic improvement in various cattle and buffalo production systems in Africa. It deep dived into the different technologies as follows: molecular and genomic technologies for breeding strategies, reproductive technologies for African cattle and buffalo breeding strategies, nucleus breeding schemes for assisted reproduction in cattle and buffaloes, in vitro fertilization, somatic cell nuclear transfer and multiple ovulation and embryo transfer. The chapter concludes with some final remarks and future perspectives.

16.1 Overview of Breeding Goals in the Context of Current Production System in Africa

In Chap. 15, the fundamental concepts and principles that underpin the definition of breeding goals and strategies were defined and discussed. In this chapter, some of the peculiar aspects of breeding goals and strategies for the improvement of cattle and buffaloes in Africa are examined in addition to lessons drawn from past cattle improvement projects.

Production traits such as milk, fat and protein yields, and most other traits in the breeding goal for dairy cattle and buffaloes are only measurable in the cows and are, thus, termed as sex-limited traits. However, most of the genetic improvement in the dairy system comes from the selection of bulls. In general, genetic improvement in the dairy systems is through the four pathways: bulls to breed bulls (bb), bulls to breed cows (bc), cows to breed bulls (cb) and cows to breed cows (cc), with the proportion of genetic gains from the four pathways being 39%, 27%, 32% and 2%, respectively (Schmidt and Van Vleck 1974). Thus 66% (bb + bc) of the genetic improvement comes from the selection of bulls.

In developing countries of Africa, farms are predominately managed by smallholders, with 80% of land holdings being smaller than ten hectares (Lowder et al. 2021). Thus, smallholder dairy farming has a huge potential to substantially contribute to sustainable household livelihoods through economic well-being, household food security and nutritional stability. To achieve these potentials, it is important that appropriate breeding strategies are implemented in line with the production systems (Chagunda et al. 2016). A detailed description of the various production systems is presented in Sect. 2.3 of Chap. 2. Therefore, traits in the breeding goals for these systems must be relevant, taking into account the environment and the level of management. Such traits must be easy to measure either directly or through other proxy-related traits in large number of daughters and also early in life to achieve efficient rate of genetic improvement. The top four main groups of trait preferences identified for dairy cattle from a summary of 68 published research work (Chawala et al. 2020) for small and medium large farms in Africa are (a) productivity in terms of milk yield per lactation, fat and protein percentages and lactation length; (b) disease resistance and reproduction, age at first service and calving, days open, number of services per conception, calving interval and survival; (c) body conformation and temperament and (d) growth rate of animals. Usually, traits in the breeding goals should be measurable with very good precision, at low cost and are heritable.

From the list of goal traits identified by Chawala et al (2020), milk yield, age at first caving and lactation length meet these various criteria to a high degree, but other traits such as fat and protein yields, disease traits such as mastitis or its indirect predictor such as somatic cell count are more challenging in an African context as they are not regularly measured.

In general, most African countries lack routine systems for individual animal identification and data collection even for easy-to-measure traits such as milk yield. The advent of information and communications technology (ICT) has resulted in the piloting of innovative approaches for data collection involving the use of digital tools such as mobile apps with data flowing to centralized databases in some African countries (Gebreyohanes et al. 2021). In addition, through data platforms like the Africa Dairy Genetic Gains (ADGG), the recording of fat and protein percent, and somatic cell counts in milk have been initiated in Kenya, Tanzania and Ethiopia in smallholder dairy systems. The ADGG project highlights the important role of digital tools in capturing performance traits in the production systems in Africa and hence efficient design of breeding goals.

Current African indigenous cattle populations have mainly dual-purpose functions, producing both milk and beef or beef production and draught purpose. The low productivity of the indigenous animals, especially for milk and related traits, has created the perception that faster genetic progress in dairy productivity can be achieved by importing exotic breeds. This has resulted in most national governments not developing any comprehensive policy on genetic improvement for dairy cattle. The characteristics of the resultant breeding schemes are that these are usually unplanned or not designed with any focus, and are therefore unsustainable. The imported animals are usually not adapted to the production systems and environmental stressors in Africa, leading to a high rate of mortality due to diseases, lack of adequate feed resources and inadequate management of these animals. In a majority of the cases, the imported dairy bulls are used haphazardly in cross-breeding. The major limitations of such cross-breeding schemes are that they are reliant on the continual importation of foreign genetics which represents a huge drain of financial resources and therefore are not sustainable in the long term; they lack any definite and well-designed breeding objectives underpinning the importation and genetic diversity is lost through the erosion of existing indigenous dairy breeds.

The question that arises is whether breeding programmes can be designed to utilize the cross-bred animals that have resulted from the haphazard cross-breeding over the years and thus lay a foundation of a sustainable breeding programme that evaluates and disseminates superior and adapted cross-bred sires for use in Africa? The ADGG programme was designed to begin to address this challenge in East Africa by employing the rapidly expanding ICT infrastructure and developments in genomics. Usually, in the smallholder farming systems, parentage and breed composition are unknown due to a lack of adequate pedigree recording. Accurate estimation of the breed composition is important in determining the animals with the appropriate breed composition most suitable for the different agro-ecological zones. Using developments in genomic technologies, ADGG developed an assay of 200–400 SNPs for breed composition determination and parentage verification (Strucken et al. 2017). In addition, the lack of pedigree recording schemes in smallholder dairy systems constitutes a major bottleneck to genetic evaluation and the implementation of breeding programmes in developing countries (Kosgey and Okeyo 2007). The availability of genotypic information implies that the genomic relationship matrix can be computed thereby enabling the prediction of the genetic merit of animals, indicating less reliance on pedigree information. A simulation study by Kariuki et al. (2014) showed that genomic selection schemes for smallholder dairy production systems could yield higher responses to selection compared to strategies that used only pedigree data. Mrode et al. (2021), reported genomic prediction for daily milk yield and body weight for cross-bred cattle in Tanzania using genomic relationships constructed from genotypes. While the primary breeding goal in

these cross-bred populations under ADGG is milk yield and body weight, attempts are being made to include fertility traits, milk fat, and protein percentages and somatic cell counts in the goals.

In contrast to dairy cattle, beef cattle have performance traits measurable in both sexes and growth rate, the major trait of interest is easy to capture. However, similar to dairy cattle, the establishment of systems to record performance routinely is also lacking. In addition, in many communities of Africa, several traits in beef cattle have societal and cultural values which are rather subjective. A classic example is the nature of horns in Ankole cattle found across several East African countries (Ndumu et al. 2008). Capturing these traits precisely and the value associated with them is a challenge. Some studies have employed discrete choice experiment methodology (Ndumu et al. 2008; Kugonza et al. 2012; Chawala et al. 2019) or focus group discussion to gauge the value of traits preferred by farmers.

16.1.1 Trends in Breeding Goals for Evolving Production Systems and Health and Welfare Considerations

Given strong trends in climate change and a society that is more aware of animal health and welfare issues, it is inevitable that the production systems in Africa will have to evolve to accommodate these changes. The contribution of African livestock production systems to GHG emissions and mitigation strategies are fully discussed in Sects. 14.5 and 14.8 of Chap. 14. Global surface temperatures are reported to be 1.09 °C higher between 2001 and 2020 compared with the period 1850–1900 (IPCC 2021). This has a huge potential impact on livestock in terms of feed resources, the emergence of new diseases and reduced productivity. Globally, methane gas (CH_4), generated through enteric fermentation in ruminants is reported to represent 17% of greenhouse gas (GHG) emissions (Knapp et al. 2014). The impact that the smallholder farming production systems for cattle have on climate is not clearly understood as data quantifying GHG emissions in these systems are limited. About 5% higher CH_4 emission per unit product has been attributed to smallholder systems compared to dairy and beef systems in Europe and North America (Gerber et al. 2013), mainly due to the low productive efficiency of the smallholder systems. Therefore, giving higher weights to traits associated with superior productivity and resilience in the breeding goal under conditions of climate change, such as heat and drought tolerance and resistance to certain diseases, will be important. In addition, the definition of breeding goals should directly include traits to mitigate GHG emissions. In developed countries, direct selection for CH_4 emission and the efficiency of feed intake have been used as approaches to mitigate CH_4 emission (Manzanilla-Pech et al. 2021). de Haas et al. (2021) reported that selection for feed efficiency was a good proxy for mitigating CH_4 emission resulting in about 26% reduction in methane over a 10-year period. Consequently, several countries have developed indices to improve feed efficiency (usually termed Feed saved or Feed advantage) in their dairy breeding programmes (Lidauer et al. 2019). There is currently no corresponding breeding goal being implemented in Africa; however, the ADGG programme has included body weight in a selection index for dairy cattle for Tanzania as an indirect approach to improve feed utilization (Mrode et al. 2021 https://cgspace.cgiar.org/handle/10568/113071).

There is ongoing research to improve the adaptive ability of beef and dairy cattle, mostly aimed at identifying the genomic regions that confer adaptiveness in indigenous breeds and for later incorporation of these regions in breeding programmes. Kim et al. (2017) reported selection signatures and genes or pathways controlling anaemia and feeding behaviour in the trypanotolerant N'Dama, coat colour and horn development in Ankole, and heat tolerance and tick resistance across African zebu cattle breeds such as Boran, Kenana and Ogaden. In a further analysis of 16 indigenous African cattle breeds, Kim et al. (2020) identified genomic regions composed of

16 loci associated with immune, heat-tolerance, trypanotolerance and reproduction-related adaptive characteristics of African cattle. This research is still at an early stage in terms of identifying with adequate precision the genomic regions which confer adaptiveness to the indigenous cattle breeds to enable their incorporation in any breeding programme. However, possible ways to incorporate such regions in future breeding programmes include gene editing to create surrogate sires or the inclusion of Bayesian or weighted GBLUP in the prediction of genomic breeding values (Cheruiyot et al. 2022).

16.2 Defining Breeding Goals for Cattle and Buffaloes in Various African Production Systems

This session examines the fundamental role of production systems and market situations in the design of breeding goals and the influence of some of the regional institutions and policies on breeding programmes in Africa. A detailed description of various production systems in Africa and the challenges and interventions for livestock development are presented in Sects. 2.3 and 2.4 of Chap. 2. It then outlines the breeding goals for beef and dairy cattle production and some lessons from the design of breeding goals from previous breeding programmes.

16.2.1 Outline of Market and Aesthetic Products from Dairy Cattle Systems

Prevailing and emerging market situations are fundamental to the design of efficient breeding goals for any livestock species. The drivers for growth in dairy production and markets include optimization of milk production systems, improved animal health and welfare, improved efficiencies in feeding and improved genetics. FAOSTAT (2021) reported that although dairy production improved in most continents globally, Africa's dairy output (excluding camel's milk) has adversely been affected by prevalent market conditions, stemming from economic meltdowns, arable land shortage, conflicts and displacements, and climate issues such as drought and floods in some regions (GDP F 2018).

Dairy and dairy products contribute 27% to global agricultural gross domestic product (AgGDP) and 5% to AgGDP in Africa. Dairy systems form part of the demand for dairy and dairy aesthetic products. The markets for dairy products in Africa can be organized into two main types; informal and formal markets. Alonso et al. (2018) defined the formal dairy sector as a dairy value chain that commercializes industrially processed and packed dairy products by legally registered value chain actors, while the informal dairy sector is described as value chains commercializing dairy products that are not industrially processed by either the legally licensed or unlicensed enterprises. Informally marketed products include raw, traditionally pasteurized milk, boiled milk and other traditionally derived milk products. The informal sector is mainly operationalized by small-scale dairy farmers, milk transport traders, milk bar operators and mobile milk traders with limited infrastructure such as electricity, water, sanitation, refrigeration and other infrastructure and amenities. The informal sector receives little or no support from the government and other development partners (Grace 2015; McDermott et al. 2010). The informal markets have diverse prices and are unstructured while for the formal market, prices for livestock products are streamlined and defined in a structured manner. Studies by Otieno and Owuor (2019) have demonstrated the relevance of policies in informal markets for the dairy sector so that monopolistic tendencies are restricted, thereby creating a level playing field for all milk traders in the industry.

However, despite changing market dynamics and dairy prices in Africa, there is there is still huge potential to develop systems to support the demand and supply of dairy and dairy products such as meat, milk, leather and other related-derived products as well as manure (bio-gas), draught power, art, musical and historic artefact products. The demand for livestock and livestock

products in the future could be heavily moderated by socio-economic factors such as human health concerns, changing socio-cultural values (Steinfeld et al. 2006) and increased purchasing power (OECD, F 2016; OECD/FAO 2020). In addition, there is a growing emphasis on the sustainability of dairy and dairy products as customers are now well informed about dairy and dairy products available to them. People are concerned about the environment, animal welfare and the quality of their food in a bid to enhance climate-friendly environment for the dairy systems in Africa. However, all the aforementioned issues could be mitigated in Africa if there are adequate and functional systems for improvement in genetics, animal welfare, a streamlined market for dairy productions, and collaborations among stakeholders involved in dairy production system and national governments. Also, accelerating the adoption of existing best practices and technologies is essential to further improve production efficiency and overall dairy productivity in Africa.

16.2.2 Essential Elements of a Sustainable Breeding Goal: Lessons from Past and Ongoing Breeding Programmes

Breeding Programmes at Continental and Regional Levels

Breeding programmes in the continent of Africa have mainly been driven by governments and bilateral organizations seeking to change the productivity within the existing farming systems. Through these programmes the basic structures that have been put in place include; (i) policies to guide the adoption and use of different breeds in the target environments (AU-IBAR); (ii) the establishment of departments in key ministries to support the implementation of breeding activities and (iii) simulation studies and pilot projects to test select breeding goals in more controlled environments. Additionally, within the different regions of the continent, supported through the regional centres for agricultural research including; Centre for Coordination of Agricultural Research and Development for Southern Africa (CCARDESA), Association for Strengthening Agricultural Research in Eastern and Central Africa (ASARECA) and West and Central African Council for Agricultural Research and Development (CORAF), structures, policies and capacities have been developed to support the establishment of centres of excellence for livestock production (AUIBAR 2019). Details on these different organizations are outlined in Sects. 30.3 and 30.4 of Chap. 30.

The dearth of the documentation of indigenous breeding practices across the continent resulted in a concerted effort to characterize existing indigenous animal genetic resources, initially driven by the inability of many countries to provide information on their livestock populations for the 'State of the World Animal Genetic Resources' report prepared by the FAO in 2007. Changing agro-economic landscapes, climatic conditions and population pressures are however resulting in the transformation of cattle production in Africa with a greater need to adapt technologies and practices to derive increased products from existing animals. The increased demand for quality animal products against a low level of supply in the different markets requires critical evaluation of bottlenecks in adopting targeted breeding goals in cattle populations.

Most of the livestock in Africa are reared in rural communities and provide social, cultural and economic benefits for households. Any practical implementation of breed improvement towards a targeted breeding goal would require documented records on the animal performance. Efforts at large-scale recording and monitoring of performance and productivity in most African Countries are limited. By 2015, some countries in Southern Africa (Botswana, Lesotho, Namibia, South Africa, Zimbabwe), East Africa (Kenya) and West Africa (Cameroon) had operational national livestock recording systems in place (AUIBAR 2019). The proportion of the livestock populations documented through the systems is however very low (<1%) in most of the countries except South Africa.

Table 16.1 Example of breeding goals and breeds developed for meat production using indigenous breeds[a] in different regions of Africa

Breeding goals	Breeds developed	Regions	References
Adaptability to tropical conditions and meat quality	Africaner Renitelo Wakwa	Southern Africa Western Africa	Raeliarijaona (2017), Casey (2021), and Nsangou et al. (2021)
Adaptability to tropical conditions, growth rate and meat quality	Bonsmara, DrakensbergerBoran	Southern Africa Eastern Africa	Casey (2021) and Rewe (2009)
Disease tolerance and meat quality	Tswana	Southern Africa	Saki (2020)
Fertility, adaptability and growth rate	Nguni	Southern Africa	Saki (2020)

[a]Characteristics of different breeds and their development in the continent are presented in Chaps. 3 and 4, and also available through DAGRIS (http://dagris.ilri.cgiar.org/) and the Animal Genetics Training Resource (http://agtr.ilri.org/)

Across Africa, breeding goals for specific products from cattle (Table 16.1) have been adopted at different rates. The high focus on economic returns from animals while overlooking socio-cultural significance of the animal species in the diverse communities across the continent has resulted in the slow adoption of the concept of using breeding goals to drive cattle production in Africa.

Breeding Goals for Beef Production

The challenging climates with vector-transmitted diseases that tend to be better tolerated by existing indigenous breed types enabled interest in the indigenous breeds in different regions for beef production, rather than the use of purebred introduced temperate breeds as was the practice in the dairy sector. The development and use of breeding goals in the beef sector are most evident in the Southern Africa region where the establishment of breed societies was extensively used to enhance the image and use of different breeds using performance data (Casey 2021). In South Africa, state-initiated performance recording schemes were launched to improve production efficiency using targeted breeding goals.

In Eastern Africa, the improved Boran cattle have been selected for beef (Rewe 2009). Strategies adopted to develop the different breeds are outlined in Sect. 16.4 of this chapter.

Breeding Goals for Dairy Production

The lack of clear breeding objectives, recording of animal performance and large-scale uncontrolled cross-breeding of temperate *Bos taurus* breeds with local *Bos indicus* breeds has made it difficult to identify better-performing genotypes in the different farming systems of sub-Saharan Africa. Key issues noted to impact dairy production in 15 sub-Saharan African countries include (i) poor productivity of imported exotic breeds and their crosses in Africa (62.3%), (ii) fluctuations in milk prices in both formal and informal markets (50.9%), (iii) inadequate genetic evaluations of individual animals and sires (39.6%), (iv) poor management systems in terms of herd health, feeding and housing (32.1%) and (v) poor infrastructural facilities (30.3%) (Opoola et al. 2019).

The need to adopt alternative strategies to transform dairy production in the continent was magnified in the second report on the State of the World Animal Genetic Resources (FAO 2015). In 2013, the Centre for Development Innovation in Wageningen, The Netherlands, was tasked by the Inter-Agency Donor Group on pro-poor livestock research and development to study and document the state of dairy development in different countries of East Africa (Makoni et al. 2014) in order to identify opportunities to improve coordination in dairy development among development agencies and create synergies across the countries. Lack of data, information services, infrastructure and institutional capacity-building programmes

for the dairy industry were identified as some of the critical challenges to be addressed. In the same year, different pilot projects were designed to test options for adapting genomic technologies to catalyse change among the large number smallholder dairy producers on the continent. The International Livestock Research Institute (ILRI) in partnership with different national partners implemented pilot projects in Eastern Africa (Box 16.1) and West Africa (Box 16.2).

Box 16.1: Genomics to Identify Appropriate Cross-Bred Dairy Cattle for Smallholder Farming Systems in East Africa—The Dairy Genetics East Africa Project

Challenge: Smallholder farmers mostly keep crosses between indigenous cattle and exotic dairy breeds such as Holstein, Friesian, Ayrshire and Jersey. There is however no systematic breeding of the cross-bred cattle, and farmers rarely keep pedigree or performance records. Most mating events involve local cross-bred or indigenous bulls, where the cross-bred bulls are of unknown breed composition.

Goal: To determine the most appropriate genotypes for the range of dairy production systems and levels of production operated by small-holder farmers in East Africa, and how the genotypes could be delivered to smallholders.

Methodology: Apply high-density single nucleotide polymorphism (SNP) technology to determine breed composition of cows owned by smallholders in combination with traditional and participatory appraisal of animal and farm performance to determine which genotypes are most profitable at different levels of production.

Working with smallholder farmers in targeted areas, performance data were collated on milk yield, reproduction events and disease incidences over 2 years. The recorded animals were genotyped using the Illumina bovine high-density SNP (HD, 780 k) assay with the HD SNP data used to perform admixture analyses, using the ADMIXTURE software (Alexander et al. 2009), to generate an estimate of the ancestral breed composition of each animal. This was the first accurate information on breed composition to be combined with in situ performance data from smallholder farming environments of East Africa.

Key results

A comparison of the farmer and extension agent assessment of breed composition based on phenotypic appearance and farmer recollection on cow origin, with the admixture determinations of actual breed composition revealed that phenotype-based assessments were poor predictors of actual breed composition ($R^2 = 0.16$).

Intermediate to low grade (<50% exotic breed ancestry) cows performed better in the majority of the smallholder farms where inputs were low, while animals with higher grades (>50%) performed better in the best environments where farmers invested in providing inputs for dairy production (Ojango et al. 2014).

The use of genomic testing demonstrated the value and feasibility of establishing long-term genetic improvement programmes, which led to the establishment of the Africa Dairy Genetic Gains (ADGG) programme in 2016.

Box 16.2: West Africa

A study similar to the DGEA (Box 16.1) was implemented for cattle reared in smallholder farming systems in Senegal (Marshall et al. 2019). The breeds evaluated were cross-breeds between indigenous Zebu and Guzerat, and indigenous Zebu and *Bos taurus* breeds (Montbéliard and

Jersey), pure indigenous Zebu breeds and pure *Bos taurus* breeds (Tebug et al. 2018). Genotyping in this case was performed using the Bovine 50 K SNP assay and admixture analysis was performed using the Bayesian Analysis of Population Structure software (Corrander et al. 2008) .

In this study, cross-bred indigenous zebu by *Bos taurus* dairy cattle kept under better management produced up to 7.5 times higher milk yields, eightfold higher household profit, and threefold lower greenhouse gas emission intensity, per cow per annum, in comparison to indigenous Zebu kept under poorer management, for a typical herd size of eight animals (Marshall et al. 2016; Salmon et al. 2018).

Following successful pilot programmes on data capture, monitoring and feedback to inform and develop breeding programmes for dairy production in smallholder systems of Africa, from 2016 The African Dairy Genetic Gains (ADGG) programme was designed under the leadership of ILRI and different partners, supported by the Bill and Melinda Gates Foundation, to address limitations in data from smallholder dairy systems and to identify and promote the use of more productive dairy genetics suited to the local production environments (Box 16.3).

Box 16.3: The ADGG Programme (https://portal.adgg.ilri.org/)

The African Dairy Genetic Gains (ADGG) project was developed and from 2016 to identify and promote the use of more productive dairy genetics suited for local production conditions/systems through collaboration with local and international genetics and artificial insemination companies. The programme is developing and testing a multi-country genetic gains platform that uses on-farm performance information and basic genomic data to identify and provide superior cross-bred bulls for artificial insemination (AI) delivery and planned natural mating to smallholder farmers in Africa.

Western Africa

In Burkina Faso, the 'Vache du Faso' project funded by CEVA-SANTE ANIMALE was implemented between 2016 and 2019. The aim of the project was to improve the milk production capacity of indigenous zebu cattle breeds of Burkina Faso through cross-breeding with exotic French cattle breeds (Tarentaise and Montbeliarde). During the 3-year period of the project, the local project team conducted 6 separate reproduction (heat synchronization and reproduction) campaigns targeting 5 541 cows and 1500 F1 cross-bred calves were born between 2017 and 2019. However, there was no plan for performance recording and genetic evaluation of the F1 cross-breds.

Lessons in Developing Breeding Goals for Production Systems in Africa

1. Breeding goals should cater to both economic and socio-economic aspects related to the target products as the social role of cattle in different communities greatly influences the choice of breeds and the structure of the herd.
2. The emphasis on breeding goal traits should incorporate gendered preferences as the successful management of select animals is determined by the labour requirements from different gender groups. For instance, in smallholder zero grazing systems of Eastern Africa, the adoption of high-yielding dairy animals requires greater labour inputs to meet the animal's requirements for feed, water and milking. The stall-fed animals are often left in the care of women in households who have diverse demands on their time. This often results in periods when animals have no feed or water, leading to fluctuations in productivity. Lactation curves of animals within small-

holder farming systems reflect low levels of production following an initial high yield in the first few weeks following calving (Ojango et al. 2017; Migose et al. 2020).
3. Adoption of technologies to boost productivity must be preceded by capacity building within community groups for correct adoption.
4. Special interest groups are important for safeguarding and marketing cattle breeds. Without an interest group, selecting and enhancing breeding goal traits will not be implemented resulting in haphazard cross-breeding of animals in populations.
5. Supportive infrastructure and markets for products need to be in place to help drive the adoption of breeding goals.
6. A consistent level of public investment is required to enable the recording and monitoring of animal performance to support regular monitoring and evaluation of breeding goals. Support should include policies to govern custody and use of information collated, standards for data capture and availability of services to enhance productivity in targeted livestock enterprises.

16.3 Breeding Strategies for Cattle Improvement in Various Production Systems

In Chap. 15 and Sect. 15.2, the basic principles of defining breeding strategies were examined. In this section, we look at some peculiar features of such designs for cattle and buffaloes. As indicated in Sect. 16.1, most of the genetic improvement in dairy cattle and buffaloes (about 66%) comes from the selection of bulls and this has a huge influence in designing a breeding strategy for the dairy system. Strategies that will permit the estimation of the genetic merit of bulls and their selection for use early in life will reduce generation interval, for example, genomic selection and hence a higher rate of genetic progress. Similarly, strategies that will permit obtaining phenotypes on daughters of bulls early in life such as indirect prediction of fertility or will permit rapid multiplication of animals of superior genetic merit such as MOET are very important in improving the rate of genetic improvement in the dairy cattle or buffaloes. Initially, we examine past breeding strategies, lessons learnt and present some future perspectives.

16.3.1 Different Types of Breeding Strategies; Historical Lessons in Various Input Cattle Systems and Future Perspectives

This section considers breeding strategies aimed at promoting sustainable animal production systems in Africa. The African environment is quite diverse and characterized by nutritional diversity, geographical diversity, diversity of animal and human resources, severe poverty and hunger and a high level of indebtedness among others. Therefore, any breed improvements should be related to the environments where performance and production are expected to occur.

16.3.1.1 Breed Substitution and Cross-Breeding

Breed substitution has been defined as the import of males and females of a breed to replace local breed(s) in the pursuit of a production goal (Vaccaro and Steane 1990). At this level of breed substitution are the cases of South Africa in the 1800s where European settlers introduced dairy cattle (Holstein, Jersey, Guernsey, Ayrshire, Milking Shorthorn) (Gertenbach 2021). Today, these breeds are the only ones recognized as dairy cattle in South Africa. In Kenya, Holstein, Jersey, Guernsey and Ayreshire dairy cattle were also introduced from Europe in the nineteenth century (Initiative 2020). Today, they are the only recognized dairy cattle breeds in Kenya. A similar strategy has been followed by Morocco where massive imports of dairy cattle (350,000 since the 1970s) have been made in pursuit of a national dairy production goal (Taher 2011). Forty per cent (40%) of these imports died within 3 years of importation. This indicates that this level of

breed substitution may be the least satisfactory. Otherwise, careful evaluation of environmental factors (biotic and abiotic) and necessary modifications need to be made before the introduction of exotic breeds.

Adaptive Breed Substitution

Adaptive breed substitution is the case of breed substitution where ethnically owned local cattle are substituted by another local breed when pastoralists, for one reason or another, move into a new environment with their cattle. This is the case of the Fulani of West Africa in Burkina Faso who moved with their cattle to an ecological zone infested by the tsetse fly, a vector of trypanosomiasis-causing parasite (Boutrais 2007). The cattle native to the new environment are trypanotolerant. The immigrant pastoralist cross-bred their Zebu (Bos indicus) cattle with the local trypanotolerant *Bos taurus* cattle. The crosses are relatively more tolerant to trypanosomiasis than the exotic local Zebu cattle. This is done purely by pastoralists without input from public research and policy sectors.

In another breed substitution strategy, the Fulanis of the Cameroon grasslands replaced their Red Mbororo Zebu breed with another Zebu breed (preferred), the Gudali of Adamawa. The decision was based mainly on the physical features of the Gudali (size, hump, coat colour, size and form of horns). This is implemented by importing the Gudali into their region or by cross-breeding (Gudali bulls with Red Mbororo females), a move encouraged by the colonial policy (Boutrais 2007). The Fulanis are generally regarded as people known for their ability to adapt breeds, refashion and construct them. Another example is the 'Bakalandji' cattle in the Adamawa region of Cameroon which have resulted from cross-breeding Gudali with the Red Mbororo cattle in order to adopt the breed qualities of the former without necessarily replacing the Red Fulani type.

Substitution by Upgrading or Cross-Breeding

Substitution by upgrading (cross-breeding) local breed(s) with the exotic breed(s) to combine or benefit from the productivity advantage(s) of two or more breeds involved. Usually, the levels of breed/genotype mix most suited to the desired goal are accepted after genetic, environmental and economic analyses have been made. These may be considered as synthetics/composites in which local breeds are only partially genetically substituted, or upgrades in which the local breeds are substantially genetically modified to look and perform like the exotic breed(s).

Briefly defined, cross-breeding is the mating of two or more breeds to exploit the merit(s) of each breed in the resulting product (composite). Attention is given to the choice of dam and sire breeds in an attempt to maximize the productive and reproductive efficiency of the cross-bred. The gain could be higher productivity of the cross-bred due to quantitative genetic inheritance and hybrid vigour/heterosis; therefore, cross-breeding combines the genetic advantages of both breeds and heterosis. Maximum heterosis is generated in the first filial generation (F1); hence, different systems of cross-breeding are usually practiced in an attempt to maximize the heterosis in other cross-breds. Cross-breeding cattle for improved beef and dairy production has been practiced in Africa with diverse results and outcomes.

Two to four case studies from each of the five sub-regions of Africa are handled below with two of the cases summarized in Boxes 16.4 and 16.5. Each case is considered from the point of view of goal(s), specific objectives, design, funding, implementation, outcomes, status and the way forward.

Cross-Breeding for Beef Production: South Africa Case Studies

A very good example of this include the Bonsmara, a synthetic breed in South Africa (AGTR: agtr.ilri-cgiar.org/bonsmara). At the policy level, the development of the breed was initiated at the Mara Research Station in Transvaal in 1936 by Bonsma. The goal was to improve beef production. The strategy was to cross-breed local Africander cows with European Shorthorn and Hereford bulls in a three-breed mating design. The details of this breed in terms of characteris-

tics and production statistics are described in Sect. 4.4 of Chap. 4.

Another example is the Renitelo, a Synthetic Beef Breed in Madagascar (Gilibert 1974; Raeliarijaona 2017): The aim was to develop a cattle breed with improved beef production and it started at the Centre de Recherches zootechniques de Kianjasoa, Madagascar, in 1930. The strategy was a 3-breed 3-step mating plan involving the Madagascar Zebu, Limousin from France and Africander from South Africa. The purpose was to create a breed that would satisfy both the meat and draft power needs of the people of Madagascar. It was recognized as Renitelo breed in 1962. More information on this breed has been presented in Chap. 4 (Sect. 4.4).

Cross-Breeding for Beef Production: West and Central Africa Case Studies

Box 16.4: Wakwa, a Synthetic Beef Breed in Cameroon

According to Nsangou et al. (2021) at the policy level, the project started in 1952 as a successor to the Montbeliard project of the 1930s that failed to consider the local production system and the inputs of the farmers into the policy formulation process. The goal was to improve the local Zebu (Gudali) for beef production. The strategy/specific objective was to cross-breed the exotic Zebu (Brahman) with local Gudali to achieve a synthetic or composite of 50% Brahman and 50% Gudali.

The design involved three steps: (1) production of F1; (2) inter se mating of F1 individuals to produce F2 and (3) selection and inter se mating of F2 to produce F3. These F3 were considered stabilized and were designated as the Wakwa breed (Fig. 16.1)

The Wakwa cattle were disseminated among farmers who had a training period at the Fory Station of Livestock Production managed by the Ministry of Livestock, Fisheries and Animal Industries. Funding was by the colonial administration until the 1970s when independent Cameroon created the Institute of Animal Research (IRZ) and assumed financial responsibility in partnership with multiple partners (France, Germany, United Kingdom and the United States). The research was greatly reinforced, and economics and farmer inputs became a component of its activities.

Analyses have shown that the Wakwa is more productive than the local Gudali despite greater susceptibility to dermatophilosis. Analyses of economic traits show that they are adequately heritable and genetic trends are positive (Tawah et al. 1993, 1994; Ebangi et al. 2001, 2002). This genetic potential was transmitted to the farmers as already indicated above.

Sustainability of Wakwa: There was no plan to maintain the Wakwa blood levels in farmers's herds. Hence, it can be said that Wakwa blood in farmers' herds varied from 50% Brahman to 25% or less in subsequent generations as these animals were gradually backcrossed to the Gudali Zebu on-farm. As such, no sustainability strategy (e.g. formation of a breed association, cooperative society or common interest group) was made for the breed to survive the risk of extinction or dilution. Today, only the Tadu Dairy Cooperative Society (TDCS) produces F1 (Fig. 16.1) given the demand by farmers in the Northwest region of Cameroon.

For the way forward, given the demand by producers, the Ministry in Charge of Livestock Production should strengthen its policy and partnership between research (institute) and management (livestock ministry). It should promote the creation of breed associations as well.

Box 16.5: Genetic Improvement of Cattle in Ghana

At the policy/decision level, the first efforts at cattle breed improvement in Ghana started with imports from Europe in 1909 followed by another import in 1919. The objective was to upgrade the local *Bos taurus* to the exotic breed(s). Both efforts failed (Okantah 2009) for lack of adaptability to the local pathological environment. Three institutions are important actors in the genetic improvement of cattle in Ghana. These include the University—Faculty of Agriculture, the Animal Research Institute and the Ministry of Food and Agriculture. Each of these institutions has its own objectives.

The objectives of the Ministry of Food and Agriculture include the extension of improvement to farmers, production of breeding stock for farmers and multiplication and supply of cross-breds to farmers. To achieve these objectives, the Ministry imported exotics from Europe and Australia and N'Dama from other West African countries (Okantah 2009).

The objectives of the Animal Research Institute include the development of the local production system into a dual-purpose (meat and milk) production system, cross-breeding local breeds with exotic breeds leading to a composite genotype of 50% local and 50% exotic, and selection of the composite.

The University of Ghana's objectives included cross-breeding exotic breeds with indigenous breeds leading to a composite of four breeds: 37.5% local breed and 62.5% exotic composed of three breeds. The goal was the improvement of beef production.

The efforts of the three actors were not coordinated. However, a unified breeding policy and animal breeding plans were developed in 1995 (Okantah 2009). The objectives were as follows: (1) The selection of the West African Shorthorn for meat and (2) The development of Sanga as a dual purpose (meat and milk) by cross-breeding the local Sanga with an exotic dairy cattle breed (Friesian).

Of the two breed improvement approaches (University of Ghana and Animal Research Institute), the most extensive was that of the University of Ghana (Okantah 2009). The design of the University of Ghana project (1967–1982) was as follows: (1) cross-breeding Jersey (J) with the West African Shorthorn or Ghana Shorthorn (GSH), (2) cross-breeding Jersey with Sokoto Gudali (G), (3) backcrossing the F1s to Jersey and (4) pure breeding local breeds (Rege et al. 1994). The resulting genotypes were GSH1/2J1/2, GSH1/4J3/4, G1/2J1/2 and G1/4J3/4.

Results (Rege et al. 1994): The Gudali was better than the Ghana Shorthorn in production traits for milk. The F1s were better than the purebred locals. The G1/4J3/4 was better than the corresponding F1s. For milk yield, G1/4J3/4 had no advantage over corresponding F1s. Heterosis was important for Shorthorn crosses but not for Gudali crosses for milk production traits. Heterosis effects were positive/larger for Gudali crosses than for Shorthorn crosses.

Impact: There was no impact of the efforts of the University—Faculty of Agriculture and Animal Research Institute on the local production system since the efforts were limited to research stations only (Okantah 2009). The efforts of the Ministry of Food and Agriculture impacted the local production system (results of Zebu—taurine cross-breeding adopted by farmers) (Okantah 2009).

Sustainability/way forward: the review recommends that genetic improvement in Ghana should be based on local/indigenous breeds—West African Shorthorn and Sanga—and a clear breeding policy. Sustainability can be assured by the existence of breed associations/cooperatives. More information has also been presented on the Ghana Sanga breeds in Chap. 4, Sect. 4.2.3.

Cross-Breeding for Dairy Production

By their nature, dairy cattle require more optimum environmental and management conditions to perform. These conditions include good quality nutrition, good health delivery and tolerable ambient temperatures among others (Osei-Amponsah et al. 2019). In the subtropical environment with shade and no shade temperatures of 28.4 and 36.7, respectively, respiration (54 vs. 82) and rectal temperatures (38.9 °C vs. 39.4 °C) of dairy cattle increased. Conception rates (44.4% vs. 25.3%) and milk yield (16.6 kg/day vs. 15.0 kg/day) were reduced (Roman-Ponce et al., 1976). The impact of the environment varies with the stage of the life cycle and the level of adaptation of the given breeds/genotypes (Collier et al. 1981).

Rectal temperature is moderately heritable (0.17 ± 0.13). It is genetically positively correlated with production traits (yields of milk, fat, protein, production life, net merit). It is, however, negatively genetically correlated with somatic cell score and daughter pregnancy rate. Hence, attention must be paid to these correlations when selection is contemplated (Dikmen et al. 2012).

Heat tolerance is due to low metabolic heat production and low milk yield (Collier et al. 1981). Hence, high metabolic production and high milk yield would suggest heat intolerance. Critical temperatures for dairy cattle vary with physiological state (Collier et al. 1982). For peak lactation, these are −25 °C (lower) and 25 °C (upper) (Collier et al. 1982). Heat stress leads to a reduction in calf birth weight and lower milk yield for cows not in shade. When lactating cows are exposed to environmental temperatures outside their thermoneutrality zone, they tend to adjust by reducing their metabolic activities (Collier et al. 1981). These adjustments include reduced feed intake, faecal water elimination, high increases of water intake and urine excretion from the body surface as well as respiration (Collier et al. 1981).

In the tropical highlands of Cameroon (Adamawa plateau), distribution of cattle by breed/genotype and heat level (shade and no shade) at 22 °C and 20.5% relative humidity under grazing conditions, Holsteins tended to be

in the shade while Holstein × Gudali and Montbeliard × Gudali crosses tended to be in the sun (Mbah 1982). The Gudali crosses were significantly in the sun more than in the shade. They showed no evidence of heat stress. Under the same environmental conditions but with rain falling, all genetic groups were in the field and grazing. The rain apparently helped to reduce the effect of heat on the Holsteins.

The potential susceptibility to heat stress suggested here could be more severe in the hotter and drier environments to the north (Sudano-Sahelian region) and could last for about 7 months of the dry season. Hence, dairy cattle improvement strategy would need to pay attention to environmental modifications to handle potential heat stress, as well as nutrition and health stressors. Some case studies from some regions are treated hereafter (Boxes 16.6, 16.7, 16.8, and 16.9).

Cross-Breeding for Dairy Production: West and Central Africa Case Studies

Cross-Breeding for Dairy Production: East Africa Case Studies

Box 16.6: Genetic Improvement of Cattle for Dairy Production in Cameroon

Genetic improvement efforts in Cameroon started with imports of Brown Swiss cattle by the National Advanced School of Agriculture in Yaounde in 1986. This was followed by efforts with local breeds (While Fulani, Red Fulani and Gudali) at the Institute of Agricultural Research for Development (IRAD, https://irad.cm/) centres in Bambui on the Western Highlands (Munji 1973) (facility started in the 1940s as an Agricultural Experiment Station) and Wakwa on the Adamawa Highlands (Lhoste and Pierson 1975) (facility started in the 1930s as Cattle Production Improvement Station). These efforts were found inadequate for meeting national needs. Attention was quickly shifted to cross-breeding local breeds with exotic dairy breeds (Holstein, Jersey, Montbeliard). These involved importations of live animals and semen from the United States through Heifer Project International (a non-governmental organization, https://www.heifer.org/) and from France. The Dairy Research Program of the Institute of Animal and Veterinary Research is coordinated from Wakwa and is now within the Department of Animal and Fisheries Research of the Institute of Agricultural Research for Development. With funding from the World Bank, the country imported 165 gestating Montbeliard heifers from France in 2020 (MINEPIA 2020), https:www.prodel.cm/wp-content/uploads/2020/05/MAGAZINE-Fr-2020.pdf). It has as partners the Ministry in Charge of Livestock and Animal Industries, the ministry in charge of scientific research and funding partners.

Objectives: The objectives were the improvement of milk production by cross-breeding local Zebu cattle with exotic dairy breeds: the identification of adapted and productive genotypes and the evaluation of the economic impact of the research results.

The design was as follows:

(i) IRAD, Bambui Center: Holstein × Red Fulani, Holstein × Gudali, Jersey × White Fulani

(ii) IRAD, Wakwa Center: Holstein × Gudali, Montbeliard × Gudali

A dairy technology laboratory and a nutrition laboratory were developed at IRAD centres at Bambui and Mankon, respectively.

At both Research centres, breeding (artificial insemination at Bambui) was aimed at producing cross-breds with 50–75% exotic genes. For Montbeliard cross-breeding, some F2s were generated as well. The genotypes were evaluated on economic traits and adaptability. Farmers were trained in all aspects of dairy produc-

tion. Developed technologies were disseminated through extension bulletins and field days.

Funding: Funding from the 1970s through the mid-1980s was by many partners including the Government of Cameroon, USA (Heifer Project International, Land O'Lakes), German Technical Cooperation (GTZ), UK (DFID) and France (CIRAD-IEMVT). Each partner was focused with a particular component of the National Agricultural Research Project, which implies that there was a lack of coordination.

Results: The cross-bred animals (Figs. 16.2 and 16.3) were significantly more productive (3–4 times) than the local breeds and more adapted than the pure exotic breeds. Estimates of heterosis were strongly positive for lactation length but strongly negative for milk yield. The heterosis effect was, as expected, reduced in the F2. These results were economically good (Goldman et al. 1985; Pingpoh et al. 2019). Tawah et al. (1996) reported on the performance of the crosses produced in Wakwa centre.

Sustainability: Farmers involved in dairy production founded the Bamenda Dairy Cooperative (Peri-urban dairy, under a zero-grazing production system), Ngaoundere Projet Laitier (later SOGELAIT) as well as Common Initiative Groups (GIC), Tadu Dairy Cooperative Society (rural, semi-intensive (low input, animal recording) production system and mastery of artificial insemination for production of seed stock as well as milk transformation.

Subsequently, the Tadu Dairy Cooperative Society target was a synthetic dairy breed that is Holstein 5/8 Gudali 3/8 (i.e. 62.5% Holstein and 37.5% Gudali) (Figs. 16.4a and 16.4b (MINEPIA 2008)). At the policy level, the ministry in charge of Livestock Production and Animal Industries is extending dairy production improvement to the northern regions of the country (165 gestating Montbeliard heifers recently imported were destined to the hotter and drier Sudano-Sahelian region) (more challenging environment for dairy cattle) and hot and humid south. Research to determine suitable genotypes and the type of environmental modifications required for the zones is needed.

Box 16.7: Cross-Breeding Azawak Zebu Cattle with Local Sudanese Fulani Cattle for Dairy Production in Burkina Faso

At the policy level, 'Project to support the dissemination of Azawak Zebu cattle implemented from 2000 to 2015', within the national policy for local dairy production (Ouédraogo et al. 2020) had three objectives: to support local dairy production, to use the genetic potential of local breeds to increase consumption of animal protein and to increase farmers' income.

The strategy was cross-breeding Azawak Zebu (*Bos indicus*) (sire breed) and local Sudanese Fulani Zebu (*Bos indicus*) (dam breed). The design was a 3-phase plan centred on an open nucleus. There was (1) The selection of Azawak Zebu (AZ) and (2) cross-breeding Azawak Zebu with the local Sudanese Fulani Zebu (SF) as follows:

1. AZ × SF = F1: SF1/2AZ1/2
2. SF1/2AZ1/2 × AZ2/2 = F2: AZ3/4SF1/4
3. AZ3/4SF1/4 × AZ4/4 = AZ7/8SF1/8 (i. e. Z87.5%SF12.5%)

Hence, the local Sudanese Fulani Zebu was upgraded to Azawak Zebu.

Funding was from the Belgian Technical Cooperation and Luxembourg Development Cooperation.

The results were as follows:

- Birth weight: 18.9 plus/minus 3.4 kg and 20.5 plus/minus 3.4 kg for Sudanese Fulani Zebu and pure Azawak Zebu, respectively. It was 20.6 plus/minus 3.7 kg and 20.9 plus/minus 2.4 kg for F1 and F2, respectively.
- Milk yield (during 186 days) was 625 plus/minus 198 kg for pure Azawak Zebu and 516 plus/minus 218 kg for F1 and 560 plus/minus 220 kg for Sudanese Fulani Zebu.

Comment: The F1 is less productive than the parent that was being upgraded!

Box 16.8: Genetic Improvement of Cattle for Dairy Production in Ethiopia

At the policy level, the dairy development effort in Ethiopia started with imports of 300 Holstein and Brown Swiss cattle in 1947 and was followed later by small-scale imports by missionaries and private organizations (Staal et al. 2008). Between 1959 and 1969, measures were taken to improve dairy production around Addis Ababa. From the 1960s to 1991, political/policy regimes changed from imperial through socialist to democratic. However, the dairy development objective remained essentially unchanged.

Improvement has since included more exotic cattle and cross-breeding with varying policy and operational measures. This saw the creation of the Dairy Development Agency (DDA) (Staal et al. 2008) which founded 30 dairy farms, each with 40 members. Subsequently, cooperatives and agricultural development projects with strong dairy components were funded by International Development Agency (IDA) and the African Development Bank. By 1972, the dairy industry was well established around Addis Ababa (Staal et al. 2008).

In 1990, another policy change led to the democratic re-organization of the socialist model cooperatives. This revived the 1991–1992 collapse of the industry as farms were individually owned coupled with the private sector involvement. This arrangement was handled by the Dairy Development Board.

The design of the Ethiopian Dairy Development is based essentially within the Ethiopian Agricultural Research Institute (EARI). Based on four different environments (Holeta, Bako, Adami Tulu and Melka), it involves cross-breeding three indigenous breeds (Ethiopian Boran, Horro, Barka) and three exotic breeds (Holstein, Jersey, Simmental). Coordinated from Holeta, the strategy involves producing various levels of cross-bred composition adapted to different environments/ecologies of Ethiopia. At Holeta, for example, cross-breeding Boran with Holstein along with coordination of pure Jersey improvement and selection of pure Boran, while at Debre Zeit, it is cross-breeding Holstein with Barka and Boran. The national partners include the Federal and Regional research institutions and universities, particularly Alemaya College of Agriculture (Debre Zeit Agriculture Research Centre) (Tadesse and Dessie 2003).

The results indicate that all Holstein crosses are best in milk production traits (milk yield, lactation length, age at first calving, calving interval): crosses carrying 50% local and about 50% exotic blood are good for use under favourable environmental/ecological and management conditions; Jersey crosses, given their smaller size and heat tolerance potential are better than Holstein crosses where feeding is a challenge (EARI 2021).

Dissemination of the various technologies developed is effected through farmer training, multiplication and distribution/supply of seed stock.

Sustainability is assured by the involvement of dairy cooperatives, and the way forward includes continuous research policy support. It has been indicated that the Ethiopian Boran can be improved for milk or meat (and that it is practically a dual-purpose breed (Haile 2011)).

Box 16.9: Genetic Improvement of Cattle for Dairy Production in Kenya

Dairy development in Kenya started with the introduction of dairy cattle breeds—Holstein, Ayrshire—essentially in the 1920s by European settlers in the Highlands (Staal et al. 2008; Thorpe et al. 2000).

In the 1950s, indigenous Kenyans were allowed to carry out commercial agriculture which was still largely handled by settlers (Staal et al. 2008). A 1954 plan allowed Kenyan indigenous farmers to keep improved dairy cattle. Today, the sector is dominated by smallholders due to several complementary strategies, among which are research, breeding, artificial insemination and extension.

In 1958, a Dairy Industry Act established the Kenya Dairy Board (revised several times since then) aimed at improving the performance of the sector, and, in 1997, the Cooperative Development Act was revised to reinforce farmer control of the cooperatives. The policy environment is dynamic and improving. Today, there is a whole institute, the Dairy Research Institute (within the Kenya Agriculture and Livestock Development Board (Staal et al. 2008). Various programmes of the institute aim at improving the dairy productivity of cattle.

At Naivasha, where the Dairy Research Institute is based, genetic improvement strategies (Sect. 16.10) include the following:

The objectives of the institute include genetic improvement of productivity through cross-breeding, artificial insemination, multiple ovulation and embryo transfer (MOET) and genotype × environment interaction, among others. The Livestock Development Policy of 1980 expanded breeding and selection (progeny testing) and the use of state farms for breeding and multiplication of improved stock (Staal et al. 2008). Resources and support were inadequate in the 1980s and 1990s. Privatization of artificial insemination in 1991 led to imports of genetic material by the private sector and 1998–2000 saw a shift from artificial insemination to natural service.

The status of the dairy improvement strategy, now handled by the Dairy Research Institute, suggests that technically, research will continue. The policy environment appears active and is constantly evolving. The presence of dairy cooperatives with reinforced farmer control as well as commercialization outlets promises to enhance sustainability.

Dual Purpose

The goals for dual-purpose cattle may include meat and milk as well as meat and work/traction. In all local African cattle production systems, meat is usually the primary goal while milk is usually a secondary goal. Efforts of combining meat and milk production in a breed/genotype are available from Kenya (Box 16.10). Many *Bos taurus* (dairy)–*Bos indicus* genetic improvement (cross-breeding) efforts for increased milk yield in Africa end up really as dual-purpose (meat and milk) efforts.

The Mpwapwa cattle breed illustrates another cross-breeding initiative in Eastern Africa. It was developed at the Livestock Production Research Institute in Mpwapwa, Tanzania, in the 1920s with the indigenous Shorthorn Zebu being crossed with other African Zebus (Boran and Ankole) and the Bos taurus bulls (particularly

Box 16.10: Kenya Sahiwal Breed (Muhuyi et al. 1999)

The Sahiwal breed development started in 1939 with imports of pure Sahiwal from India. The main objective was to upgrade local indigenous Zebu cattle to the Sahiwal in marginal lands, while secondary objectives included the production of semen from selected bulls, production of breeding stock for farmers and conservation/improvement of the Sahiwal genetic resource at 13 Livestock Improvement Centres. A second set of imports included 60 bulls and 10 cows from Pakistan in 1945. A third round of imports included 15 bulls from India.

The foundation stock included 10 Sahiwal cows and selected local Zebu cows. This was used in grading up local cattle breeds to the Sahiwal and their subsequent multiplication. By 1962, there were 2,500 Sahiwals located at 13 Livestock Improvement Centres. In 1991, there were further imports (1000 doses of semen) of Sahiwal bulls for use at the National Sahiwal Stud (1963) located at the National Animal Husbandry Research Centre at Naivasha in an ecologically favourable environment. The mating plan for genetic improvement was based on the closed nucleus approach to facilitate artificial insemination and animal recording. The target traits were milk and growth. Within the nucleus, selection was based on progeny testing for bulls. Young bulls were selected for growth rate while cows were selected based on milk yield. The design included animal identification and characterization. The preservation methods included purebred herds (how much Indian-Pakistani Sahiwal and how much local Kenya Zebu in the Kenya Sahiwal) on state farms and individual ranches and the creation of Sahiwal semen bank as well as use in smallholder mixed farming systems. Importantly, the stud at the Research Centre is used by the Sahiwal Breeders' Society of Kenya. Breed registration standards require detailed pedigree and performance data.

The performance of the Kenya Sahiwal is indicated by the following average performance levels: milk yield: 1574 plus/minus 575 kg (heritability = 0.127 plus/minus 0.04); lactation length: 293 plus/minus 37.5 days; age at first calving: 40.1 plus/minus 3.5 months (heritability = 0.20 plus/minus 0.097) and gestation length: 287 plus/minus 5.1 days (heritability = 0.10 plus/minus 0.03).

Ayrshires) being introduced into the programme later (Syrstad, 1990). The objective was to develop cross-breed animals with improved meat and milk production. The details of the development of this breed have been outlined in Chap. 4, Sect. 4.4 on communal composite breeds.

16.3.1.2 Selection Approaches for Cattle Improvement

In developed economies, cattle genetic improvement programmes have considerably advanced because of the available infrastructure for planned breeding activities such as intensive performance recording, artificial insemination and embryo transfer coupled with advances in quantitative genetics, population genetics and statistics, which have made it possible to develop genetic improvement schemes applicable on a national and global scale. In contrast, such facilities are either lacking, have not been sustained or are inadequate in most parts of Africa. Moreover, the need for advanced breeding schemes has been constrained by the predominance of traditional methods of livestock husbandry practised, lack of livestock policies, lack of skilled manpower, weak/poor stakeholder institutions, inefficient extension services, poorly organized and poorly funded research institutions and projects. The dominant traditional livestock husbandry systems in Africa include pastoralism, agropastoralism, nomadism or backyard farming. Because of this backdrop, most African Governments have

instituted state-sponsored livestock farms and animal research stations to effect genetic improvements in herds of limited cattle breeds with the view to passing on the improved stock, mostly males, to interested farmers.

It is also worth noting that in Africa animals are kept for multiple purposes: food, labour (traction power), wealth/income, hides and skins/or wool, manure for use as fertilizer for land or fuel for a fire or as construction materials, savings account (sell an animal when needed) and social status (more is better). Due to a lack of government policy and support, selective breeding is usually not well organized and structured in the smallholder systems as the required infrastructure is absent. However, an increasing number of selective breeding programmes have been developed in some African countries, some of which have been quite successful. The increasing level of education in these countries is an important factor in that success. Many African Governments are also investing in livestock ministries and laying down animal policies that are helping to improve enabling environment for the growth of the sector.

Indigenous cattle breeds are adapted to their local environment and so constitute a unique reservoir of genetic resources for the continuous improvement of livestock productivity in Africa (Osei-Amponsah et al. 2019; Hanotte et al. 2000). However, most of these breeds show low productivity primarily because of a lack of exploitation of their genetic potential, inadequate nutrition, weak health services and poor management. Breeding strategies in Africa encounter such challenges as (i) definition of unrealistic breeding objectives, (ii) limited involvement of stakeholders, (iii) poor infrastructure and (iv) lack of sustainable funding (in most cases funding is external and generally for short periods of time coupled with uncertainty of continuity; thus, they are unlikely to yield tangible expected genetic improvement).

Among the different ways of increasing the numbers of genetically improved animals are (i) within indigenous breed selection for desired traits, from which pool, animals can be sourced for various upgrading, cross-breeding or breed constitution programmes and (ii) crossing local females with superior imported sires has gained momentum with the advent of artificial insemination. Attempts at importing live exotic bulls failed because of inadaptability to the environmental constraints of tropical and subtropical diseases and poor infrastructure. It is important to note that because of the multiple-purpose nature of cattle production in Africa, selection strategies designed for western cattle production systems may not directly apply to Africa, especially as most of these traits are not directly measurable. Besides, performance recording is not practiced in most traditional farms. Also, the production conditions tend to vary considerably, making it quite costly to establish breed improvement facilities within each agro-ecological zone. However, few cattle breeding programmes in sub-Saharan Africa have been successful (Rewe et al. 2009). Diop (1997) and Rewe (2009) have carried out simulations that have looked at integrating the interests of all stakeholders in the formulation of breeding objectives and their effect on selection response. Rewe (2009) showed that restricting growth for milk production would be beneficial in meeting the multipurpose objectives of farmers in Kenya. Dempfle (1993) reported that it is possible to improve milk yield in N'Dama cattle by including growth and trypanotolerance in the breeding objectives.

Selection is the identification of desirable traits in plants and animals coupled with the steps taken to enhance and perpetuate those traits in future generations. Selection of cattle populations involves choosing and mating the best to produce the best in the next generation. Choosing the best requires animal identification, pedigree information, performance recording and analysis of performance records using advanced statistical and quantitative genetics techniques. The selected animals (best animals) are mated to produce the next generation, which is evaluated to determine the selection progress. In cattle populations, the rate of genetic change (selection progress) is a function of the accuracy of selection, selection intensity, genetic variation and generation interval (Bourdon and Bourbon 2000). The rate of

genetic change can be increased by reducing the generation interval, or by increasing the selection intensity, accuracy of selection or genetic variation.

Genetic improvement of cattle populations requires identifying and selecting animals with the best breeding values to become parents for the next generation (Bichard 2002). On an individual basis, genetic improvement requires that the net benefit per animal be greater than the total cost of achieving the improvement (Garrick 2006). Therefore, the goal of the breeder is to produce future generations that are more profitable than the previous ones (Bichard 2002).

Accuracy of selection is defined as the correlation between the true breeding values and their predictions for a trait under selection (Bourdon and Bourbon 2000). Increasing accuracy can enhance the rate of genetic change by more appropriate estimates of true breeding values. Therefore, accurate estimation of genetic parameters can maximize response to selection as more is known about the animals used for breeding. Accuracy of breeding values for cattle can be improved by the use of statistical tools like Best Linear Unbiased Prediction (BLUP), and progeny testing (individuals with large numbers of progeny having more accurate records than animals where only the individuals are tested).

Selection is a function of reproduction, replacement rate and recognizing genetically superior animals early in life for breeding (Bichard 2002). The selection that drives genetic improvement is usually carried out in nucleus herds and the genetic improvement is transmitted to other herds via the multiplier herds and commercial herds. Selection is most effective and can be most intense when the traits are highly heritable (Wright 1923). Historically, selection has been more intense in males because they are able to produce more offspring during the same breeding period than females (Lush 1946). However, a negative effect of intense selection is the loss of genetic diversity (Cleveland et al. 2005).

Generation interval also affects the rate of genetic change, and it is desirable to lower the generation interval for a greater rate of genetic change. Generation interval is defined as the time required to replace one generation with the next. It is the average age of the parents at the birth of their offspring (Bourdon and Bourbon 2000). It is calculated by taking the age of each of the parents at the birth of their offspring and averaging over all the parents (Barker and Davey 1960).

Importance of Selecting for Indigenous Breeds of Cattle in Africa

As stated above, traditional systems of cattle husbandry tend to dominate the livestock industry in Africa. Therefore, the factors that advocate for the selection of indigenous cattle breeds in these conditions in Africa include the following:

(a) Adaptation to tropical/subtropical environments: Most indigenous cattle breeds have important adaptational qualities for disease and parasite resistance like trypanosomes and ticks; they can survive and reproduce in hot, humid environments and are able to exist on low-quality feed and limited water supply. Selection for increased productivity should, therefore, raise their potential for productive traits without seriously impacting their adaptational qualities.
(b) Likelihood of extinction of indigenous breeds: The heavy importation of germplasm of exotic breeds, either as live animals or frozen semen, into Africa, coupled with their systematic and random cross-breeding with indigenous stock poses a major threat to the survival of the latter. Consequently, the survival of indigenous cattle breeds can only be guaranteed by raising their genetic merit through selection (Cunningham 1979).
(c) Selection among indigenous cattle breeds: This should be an integral part of any cross-breeding programme.

Selection programmes in institutional herds in Africa should be simple in design and based on traits that are of economic value to farmers. Moreover, because of the harsh tropical/subtropical environments, adaptability traits should always be emphasized. Ensure that the population under selection is exposed to environmental conditions like those in which the offspring are expected to perform. For example, if the objective of selection in an experimental herd of beef

cattle is to supply genetically superior bulls to farmers who keep their animals on range without supplementary feeding, it would be inappropriate to keep the experimental animals on high levels of concentrate. Every effort should be made to minimize the effect of genotype × environment interactions. The same argument also applies to experimental herds that observe stringent parasite control measures such as frequent treatment with acaricides or anthelmintics. Such considerations should, however, not lead to the other extreme of imposing excessively harsh conditions that would mask the expression of genetic variation and penalize the animals for their normal performance.

Selection programmes in most African countries suffer from inefficiencies at the institutional farms because of their small- or medium-sized herds and the lack of continuity in the pursuit of selection objectives due to unpredictable funding sources. Their effectiveness can be augmented by integrating different public and private farms of the same cattle breed through links with the use of commonly selected bulls (or sires) under similar standards of management or environment. Establishing links with private farmers is important not only to extend the genetic improvement to their herds but also to increase the effective size of the population under selection and to ensure that testing of animals is also done under similar on-farm conditions.

Potential Selection Strategies

The two major selection procedures used in ruminant livestock are performance testing and progeny testing. While the former is used for characters of high heritability and easily measurable in both sexes like growth rate, the latter is used for characters with low heritability and may be measurable in only one sex, like milk yield in female animals or after slaughter, like carcass quality. These principles of genetic improvement form the basis of different types of selection schemes. These may operate within individual herds, among a group of cooperating farmers or nationally. Some of the important ones are described below.

Testing Stations/Experimental Farms: Animals from different herds are assembled in testing stations and measured under a uniform environment. The influence of the herd environment is, therefore, minimized and the population under comparison is vastly increased. It is particularly suitable for situations where a large number of small herds are involved, each of which does not have the capacity to carry out proper within-herd comparison. Testing stations can be used either for performance testing, for example, growth rate or for progeny testing, for example, milk yield.

Progeny Testing Schemes: The progeny test depends on its accuracy in having a large progeny group per sire. Where a number of herds are involved in testing, the maximum efficiency is achieved when each sire has an equal number of progeny in each of the herds. The scheme usually operates by having a central station from where the semen of the different sires on test is distributed to a network of AI centres that carry out the inseminations.

Reference Sire Scheme: A modification of this scheme called the reference sire scheme enables comparisons to be made also among bulls that are used only within individual herds. The reference sires, which are usually progeny-tested animals and available only by AI, are used alongside the individual herd's own bulls in all herds. The breeding values of home-bred bulls are then estimated in relation to the reference sires. Comparisons among bulls in different herds are made through the linkages established by the reference sires. Thus, sire replacements can be made from among all herds.

Index Selection: Hazel (1943) and Hazel and Lush (1942) provided the basis for index selection, which is defined as the method of artificial selection in which several useful traits are selected simultaneously. Index selection may be termed an approach that is usually implemented within the various selection strategies described above. Each trait that is going to be selected is assigned a relative weight, which reflects the importance of the trait. In a profitability system, the weight is the relative economic value of the trait as the desire of the producer is to maximize

profit (MacNeil et al. 1997). More details on economic selection indices are presented in Chap. 15. The index can also combine production and functionality traits (Missanjo et al. 2013). In Africa, where cattle breeding is based on multiple production, functionality and aesthetic traits, the use of the selection index would be ideal if there are possibilities of measuring all these traits. Rewe et al. (2006a, b, 2010) have demonstrated that index selection can be used in Africa for the selection of beef cattle in Kenya. The selection index combines both the production and functionality traits weighted with relative economic values. Diop et al. (1999) also showed through simulation studies that the selection index can be used to improve Gobra cattle in a nucleus breeding scheme in Senegal.

A few cases of selection for improved milk production in several regions of Africa are outlined below.

Selection of Gudali and Wakwa Cattle in Cameroon

Context and Breeding Objectives: The Gudali cattle are shorthorn Zebu herded primarily by Fulani herders in the Adamawa region of Cameroon. Its productivity has predominantly been low because of traditional husbandry practices. Efforts to improve its productivity started in the 1940s with the introduction of the semen of some exotic beef cattle breeds from France and inseminating selected indigenous Gudali and Bororo females at the Animal Production Station of the Ministry of Animal Production, Fisheries and Animal Industries in Wakwa, Cameroon (Mandon 1948). The resulting crosses turned out not to be adaptable to the disease situation in the Adamawa Highlands, and so cross-breeding with Gudali for beef production was temporarily shelved. This was resumed with the introduction of Montbeliard cattle in Wakwa as part of the research programme (Tawah et al. 1996).

Attempts to improve the beef performance of the Gudali continued with the importation between 1952 and 1958 of about 45 young Brahman bulls from the United States of America (Tawah 1992). These bulls were raised and crossed with selected local Gudali females (Le Mandon 1957). The resulting first filial generation (F1) was called Pre-Wakwa, which unfortunately suffered from dermatophylosis (a tropic skin disease) and tick-borne diseases and so many of them died (Lhoste and Pierson 1975; Le Mandon 1957). As a result, the Pre-Wakwa cattle were inter se mated to produce the second filial generation (F2) known as the Wakwa cattle, which tended to be more tolerant to the skin and tick-borne diseases. This composite breed, known as Wakwa, was eventually fixed at half Brahman and half Gudali through several generations of breeding and selection (Tawah and Mbah 1989).

Still, given the limited success in trying to improve the beef performance of the indigenous Gudali through cross-breeding, in 1969 the breeding strategy shifted to the selection of the Gudali and Wakwa cattle (LHoste 1977). The breeding objective was to improve the beef performance of the indigenous Gudali and the composite Wakwa cattle populations. The conditions at the Station in Wakwa have been well documented by Lhoste (1977, 1968, 1969). Overall, the management of the animals was like what prevails under semi-intensive conditions in the cattle-rearing regions of Cameroon. It is important to note that some of the selected bulls were sold to the two government ranches in the two major cattle-rearing regions of Cameroon (Adamawa and Northwest), where improved breeding and management were taking place. These ranches were designed to multiply and disseminate improved breeding materials to interested farmers at cost.

Breeding Scheme: The breeding scheme based on mass selection carried out at the Animal Production and Veterinary Station in Wakwa started in 1968. The Gudali and Wakwa breeding females were separately herded in fenced natural grazing areas at the station. The bulls were grazed away from the female herds. Breeding herds comprised gestating, non-gestating and lactating females. They were raised in assigned paddocks on natural pastures and routinely supplemented with concentrates and mineral licks, especially during the severe dry seasons in Wakwa. Calves were weaned at 8 months of age. Weaners were

separated into male and female herds and raised on natural pastures with supplementary feeding depending on the severity of the dry season. Each breeding herd with at least 30 breeding females and a bull was reconstituted every year following pre-selection based on age, mortalities, conformation and reproduction and selection based on growth, disease tolerance and fertility. At the herd level, information was traditionally collected for the purpose of evaluating young bulls with a view to selecting for sire replacements and sale of breeding stock; young heifers with a view to selecting them for herd replacements and cows to decide whether to retain or cull them. The data collected were stored in herdbooks at the Wakwa Animal and Veterinary Research Centre and included pedigree information, month and year of calving, birth weight, weaning weight, yearling weight, 18-month weight and treatment records. Young bulls of between 3 and 5 years were randomly mated annually to a herd of about 30–40 selected breeding females for progeny testing. Heifers were usually mated at 3–4 years old or 250 kg minimum body weight. Breeding cows were annually culled with their offspring for poor calf weaning weight, individual performance (age, conformation, agalactia, hardiness, disease tolerance, maternal instinct, temperament, etc.) and failure to conceive after two consecutive matings (Tawah et al. 1994).

Selection Process: Recurrent mass selection was aimed at increasing growth rate and was based on a weight ratio (index) at weaning, 12, 24 and 36 months of age. The index was determined as a ratio of an individual weight to the age-sex-breed contemporary group average weight at weaning, yearling, two-yearling and three-yearling ages (Ebangi et al. 2002). Selection intensity was affected in males and females and breeds by reproductive rate (fertility), deaths, culls, age, sales, emergency slaughters, finances, replacement needs, disease tolerance or susceptibility. Young males and females were also preselected for conformation and physical or structural soundness.

Selection Performance: Tawah et al. (1993) and Ebangi et al. (2002) used BLUP and Animal Models, respectively, to estimate genetic parameters for Gudali and Wakwa cattle from the breeding data from the Wakwa Animal Research Station. Tawah et al. (1993) reported estimates of direct heritability for weaning weight of 0.27 and 0.65 and for maternal heritability of 0.20 and 0.27 for Gudali and Wakwa, respectively. Correlations between direct and maternal effects for weaning weight were −0.68 and −0.39 for Gudali and Wakwa, respectively. Ebangi et al. (2001) reported direct and maternal heritability estimates of 0.37 and 0.05, 0.24 and 0.17, 0.27 and 0.19, 0.51 and 0.20, and 0.18 and 0.02, respectively, for birth weight, pre-weaning average daily gain (ADG), weaning weight, yearling weight and 18-month weight of Gudali. The corresponding total heritability estimates for these traits were 0.21, 0.07, 0.11, 0.22 and 0.18 for Gudali. They also reported corresponding estimates of 0.55 and 0.23, 0.26 and 0.07, 0.28 and 0.09, 0.18 and 0.00 and 0.14 and 0.06 for birth weight, ADG, weaning weight, yearling weight and 18-month weight of Wakwa. The corresponding total heritability estimates for these traits were 0.18, 0.12, 0.15, 0.17 and 0.17 for Wakwa.

Selection Responses: Tawah et al. (1994) estimated selection responses for weaning weight using regression of average sire estimated transmitting abilities (ETAs) and average dam estimated breeding values (EBVs) on year of calving. The ETAs and EBVs were calculated using BLUP procedures. Also, Ebangi et al. (2002) estimated EBVs for birth, weaning, yearling and 18-month weights and pre-weaning daily gain (growth rate) for Gudali and Wakwa cattle involved in this selection programme using animal model BLUP procedures. Direct and maternal and total genetic trends were estimated for each of the Gudali and Wakwa body weights and growth rate.

Tawah et al. (1994) obtained genetic trends of 0.67 kg and 1.69 kg per year for sire ETAs and −0.03 kg and −0.24 kg per year for dam EBVs for the weaning weight of Gudali and Wakwa, respectively. Ebangi et al. (2001) reported significantly positive annual mean direct genetic trends for average pre-weaning daily gain (ADG), birth weight, weaning weight, yearling weight and 18-month weight in both breeds. Corresponding

annual maternal genetic trends were significantly negative except for ADG in Gudali and yearling weight in Wakwa. Ebangi et al. (2001) reported total annual genetic trends for birth, weaning, yearly and 18-month weights of 0.29 kg, 2.39 kg, 3.08 kg and 3.94 kg, respectively, for Gudali. They also obtained corresponding total annual genetic trends for birth, weaning, yearling and 18-month weights of 0.20 kg, 2.90 kg, 4.03 kg and 4.88 kg for Wakwa. As for ADG, the total annual genetic gains were 0.01 kg/day and 0.01 kg/day, respectively, for Gudali and Wakwa. Despite the infrastructural, human resources and financial constraints for this breeding programme in Wakwa, the overall selection for growth yielded moderate selection responses in both Gudali and Wakwa. Phenotypic trends were positive except for the birth weight of the Wakwa. The above results show that selection for individual growth performance can produce substantial genetic gains in these indigenous cattle populations in a tropical environment.

Selection of Gobra Cattle in Senegal

Context and Breeding Objectives: The Gobra is a lyre-horned Zebu cattle raised in the north and centre regions of Senegal by Fulani herders. Genetic improvement of the local Gobra has involved upgrading with Indo-Pakistani breeds (Sahiwal and Guzerat) and within-breed selection. However, an evaluation of the upgrading programme resulted in its abandonment in favour of selection. The selection programme started in 1963 at the Dahra Centre for Animal Research in Senegal with a foundation herd established in 1952 with animals bought from local herds. The production environment was described by Sow et al. (1988) as semi-extensive. The climate is tropical and the natural pasture is the main source of feed. Because the nutritional value of the forage decreases in the dry season, supplementary feeding is provided, especially to suckling animals and weaned calves. Management of the herd was described by Sow et al. (1988) and is like the management in any semi-intensive system.

Breeding Scheme: Breeding females were randomly assigned to sires (30–40 cows per sire) for a breeding season that ran from December to March each year. Cows not pregnant 3 months after the launch of the breeding season were reassigned to a different bull. The station conditions were semi-extensive such that the improved breeding animals could be used in similar conditions on-farm. This was aimed at minimizing the effects of genotype × environment interactions at the on-farm level.

According to Denis and Thiongane (1974), the selection of the Gobra cattle at Dahra (Senegal) comprised several phases. The first phase was phenotypic selection to constitute the foundation herd. It was based uniquely on conformation and other empirical criteria like sex, coat colour, and shape and length of the horn. The second phase was mass selection based on growth rate and weight from birth to 24 months of age. The selection decision points were set at 10% for males destined for breeding on the station and for progeny testing, 20% for males for distribution to the pastoralists, 70% for males for culling and 80% for females retained for breeding purposes. The males were also evaluated based on the growth performance of their progeny (progeny testing) as the selection was for meat production. This was unlike the normal progeny testing with the objective of selecting bulls for their dairy potential based on the dairy performance of their daughters. Females were pre-selected based on body weight at 24 months and conformation; about 20% of the females were eliminated at each selection phase. After weaning of three calves, the females were selected based on the growth performance of their calves from birth to weaning, sexual maturity, age at first calving and calving interval. This was considered as a proxy measure of the maternal performance of the females.

Selection Process: Selection as described by Denis and Thiongane (1974) was basically mass selection based on growth performance. Selection for both males and females was based on weight at 6 months (weaning). Males were then reselected on their 18-month weight. Then, the best 10 males were subjected to a growth performance test before the final selection of 2–3 bulls to be used as replacement bulls. Females were selected

as replacements based on 24-month weight. About 5% and 80% of males and females, respectively, selected after weaning, were used as replacements. Culling of cows was based on poor reproductive performance such as long calving interval or failure to calve after two breeding seasons or poor growth performance of offspring (based on the weaning weight of offspring).

Selection Performance: Diop and Van Vleck (1998) used animal models to estimate genetic parameters for growth traits of the Gobra cattle at the Dahra Station in Senegal. Direct and maternal heritability estimates were 0.07 and 0.04, 0.20 and 0.21, 0.24 and 0.21, and 0.14 and 0.16, respectively, for birth, weaning (6 months), yearling and final (18 months) weights. Diop et al. (1999) reported similar heritability estimates for these traits when grandmaternal effects were included in the model. Correlations between direct and maternal genetic effects were negative for all traits and large for weaning and yearling weights with estimates of −0.61 and −0.50, respectively. Diop and Van Vleck (1998) reported significant positive linear phenotypic trends for weaning and yearling weights. They reported that linear trends for additive direct and maternal breeding values were not significant for all traits except the maternal breeding value for yearling weight. A review of the over two decades of the selection of the Gobra in Dahra showed that its impact on the local herds has been limited, especially as the small size of the breeding herd (200–300 cows) has limited the number of selected bulls to be distributed to farmers (Diop 1997). Similarly, an evaluation of about three decades of genetic improvement of cattle in Senegal has raised the need for (i) improving cattle productivity, (ii) thorough genetic evaluation of the selection programme, (iii) concentrating on selection within local breeds and (iv) a change in the current breeding plan to make it more efficient by considering the production objectives of the producers and their participation in defining the breeding objectives (Diop 1997). The open nucleus breeding system is considered an option to allow for the participation of producers. It is with this backdrop that Diop (1997) carried out a simulation of new breeding plans for the selection of Gobra cattle for meat and milk production under an open nucleus breeding system (a three-tier system). The results showed greater rates of genetic gain and less variation in selection response than the closed nucleus system. When the migration of pre-nucleus (multiplier) females to the nucleus was below 40%, the open nucleus showed greater rates of genetic gain.

16.3.1.3 Nucleus or Group Breeding Schemes

This scheme is based on the principle that in each herd there is a small number of genetically very superior animals which if brought together will form a nucleus whose average genetic merit is far greater than that in any of the contributing herds. The important element in this scheme is, therefore, for a group of farmers to agree to pool their high-performing animals. Once the nucleus herd is assembled, an efficient system of recording and selection is implemented. The best males are kept for breeding in the nucleus while other selected males are given to the base herds for breeding. By this means, improvements are quickly spread throughout the group.

The nucleus may remain open to animals from the base herds, the best females from the latter being admitted periodically and compared with those in the nucleus. Usually, only females are transferred from the base to the nucleus since sire selection will not be practicable in base herds due to low management conditions. The main advantage of the nucleus scheme is that the genetic superiority of sire replacements coming into the base herds from the nucleus is far greater than what is achievable in each of the base herds. It is particularly attractive in situations where within-herd selection programmes are ineffective due to small population sizes or inadequate technical skills.

Since the nucleus breeding scheme shifts the onus of operating the breeding programme from the farmer to the nucleus herd, it seems an attractive method for the tropics and subtropics because of the limitations discussed earlier. However, the organization of the scheme may have to be under government control because cooperative ventures

among farmers may not always be practicable. Practical breed improved constraints in West Africa have led to the evolution of the breeding systems of the N'Dama cattle in Mali and Senegal from a closed to an open nucleus breeding system. The open nucleus system allows animals to flow between the nucleus and the local populations in both directions, while the closed nucleus only allows animals to flow from the nucleus into the local populations. Although nucleus programmes can allow accurate recording of performance compared to the on-farm programmes, where such recording does not normally occur, they require adequate infrastructure and technical inputs to operate sustainably (Kosgey et al. 2006). Many of such programmes have failed because of the lack of sustainable support and active involvement of the communities (Sölkner et al. 1998, 2008; Wurzinger et al. 2011). A good example of the open nucleus breeding programme in West Africa that has succeeded is the Djallonke sheep breeding programme which had the support of the government and involved the active participation of the community (Yapi-Gnoare 2000). It is important to note that the failure of the closed nucleus programmes in Mali and Senegal was because of the high cost of maintaining and feeding animals in the breeding unit and the unwillingness of the participating farmers to bring their best animals to the breeding unit at central station (Kahi et al. 2005). A similar case occurred with the farmers involved with the Sudanese Fulani Zebu programme in Burkina Faso, who were eventually allowed to retain the bull candidates in their respective herds. A disadvantage of the nucleus programme is the fact that the improvement of local breeds in research stations (breeding units) may not be fully transferrable to farmers' herds.

As a result, many breeding programmes now tend to involve farmers and producers in defining breeding goals and selection criteria (Madalena et al. 2002). This is the community-based approach that has been recommended for traditional, low-input smallholder farming systems (Sölkner et al. 2008; Madalena et al. 2002; Haile et al. 2011, 2019; Mueller et al. 2015; Gizaw et al. 2018). This approach was adopted for the Baoule cattle and the Baoule × Zebu cross-breds in Burkina Faso. Contrary to the conventional top-down strategy, the community-based approach involves farmers in all stages of the process from design to implementation and considers the indigenous knowledge of breeding practices and multiple objectives. The programmes typically feature a single tier with no distinction between breeding and production units because the farmers involved are both breeders and producers (Gizaw et al. 2018). According to Ouedraogo et al. (2021a), the dispersed nucleus programmes may be less expensive because the animals are managed by the farmers themselves. Moreover, the practice of distributing genetic gain to village populations by interested farmers within the dispersed nucleus scheme tends to make the breeding programme more visible to the potential beneficiaries (Mueller et al. 2015).

Consequently, to improve indigenous cattle productivity in West Africa, diverse breeding strategies and policies have been introduced (Ouédraogo et al. 2021a), including centralized breeding schemes that are entirely managed by governments with minimal, if any, participation of farmers (Bosso et al. 2009a). The breeding objective was aimed at optimizing (i) meat and milk performance and (ii) trypanotolerance of the taurine cattle, and to achieve these objectives, the following breeding strategies were applied: (i) the closed nucleus scheme which proved to be limited, (ii) open nucleus scheme and (iii) community-based breeding programme (Ouédraogo et al. 2021a). A few of the Open Nucleus cattle breeding improvement programmes reported in West Africa include the breed improvement of N'Dama in Mali, Senegal and The Gambia. Some case studies in three African countries are outlined.

Open Nucleus D'Dama Breeding in The Gambia

Context and Breeding Objectives: The N'Dama cattle (longhorn taurine cattle) are widely distributed in West and Central Africa and reared in low-input systems under periodic extreme feed scarcity and the presence of trypanosomiasis and

tick-borne diseases (Dempfle and Jaitner 2000). In 1995, the International Trypanotolerance Centre (ITC) based in The Gambia initiated the N'Dama purebreeding programme aimed at disseminating the genetics of adapted N'Dama cattle across Western Africa in order to improve the welfare of livestock owners and their families through better performance and increased livestock productivity and to conserve the endemic ruminant cattle (Bosso et al. 2009a; Dempfle and Jaitner 2000; Jaitner et al. 2003a; Bosso 2006; Bosso et al. (2007); Olaniyan 2015). The breeding objectives of increasing meat and milk production without compromising its adaptation and resistance to disease were defined in a participatory manner with the farmers (Dempfle and Jaitner 2000; Jaitner et al. 2003a).

Breeding Scheme: According to Agyemang (1997), an open nucleus (ONBS) with three-tier breeding programme involving nucleus, multiplier and commercial herds with a multiple breeding objective (meat, milk and disease resistance) was initiated in The Gambia in 1994. As stated above, while selection increased meat and milk production, an effort was made to ensure that the unique characteristics of the N'Dama, which are trypanotolerance and adaptive traits, were maintained. In this breeding scheme, priorities were given to phenotypic selection, screening, breeding and genetic improvement of the N'Dama cattle. To minimize genotype × environment interactions, feeding and other management systems in the nucleus herd were like those in the multiplier and commercial herds (on-farm situations). An important benefit of this scheme was that the genetic gain of the animals in the nucleus herd is permanent and cumulative and can easily be disseminated to the other farmers' herds.

Sustainability and within-breed diversity in the nucleus were guaranteed through screening and the introduction of outstanding offspring from farmers' herds into the nucleus herd (Olaniyan 2015). To ensure a low operating cost and shortened generation interval, a simple young sire system was preferred over a progeny testing scheme in the Open nucleus (Ouédraogo et al. 2021a). Moreover, building the capacity of local staff, farmers and multipliers and selling breeding stock as a source of income also ensured the sustainability of the programme (Dempfle and Jaitner 2000).

A close working relationship between researchers in the nucleus and participants in the multiplier and commercial herds resulted in the formation of indigenous Livestock Breeders Associations in 2002 (Bosso 2006). This led to the adequate involvement of multipliers under their association known as the Gambian Indigenous Livestock Multipliers' Association in the dissemination of improved elite bulls to participating multiplier and commercial herds (Olaniyan 2015).

Unfortunately, the trend of these activities has been drastically affected by limited funding, reduced number of nucleus animals and the collapse of the multipliers' associations. Moreover, inadequate funding by ITC, coupled with insufficient human capacity and extension services in the nucleus herd, has led to the suspension of the introduction of new animals from outside herds into the nucleus. The consequence is the limitation in the number of improved elite bulls disseminated to the multiplier and commercial herds and limited farmers' involvement in the whole breeding programme (Olaniyan 2015).

Open Nucleus N'Dama Breeding in Senegal

Context and Breeding Objective: The N'Dama cattle breeding programme started in 1972 in Casamance and Kolda in the southern sub-humid areas of Senegal. Its breeding objective was to improve beef performance of the N'Dama cattle (Camara et al. 2020a). To involve farmers in the breeding programme, an open nucleus genetic improvement system was adopted in 1991 (Ouédraogo et al. 2021a). Milk performance and trypanotolerance were included as breeding objectives (Camara et al. 2020a), although the latter trait was not directly considered in the selection process. Since 2008 the programme has received funding from the African Development Bank and the Food and Agriculture Organization (FAO).

Breeding Scheme: Several breeding schemes have been implemented since 1972. The new programme started in 2008 as a three-tier open

nucleus scheme consisting of a selection unit and a reproduction unit comprising herds of farmers in a cooperative of N'Dama Cattle Breeders and a dissemination unit (village herds). The breeding unit was made of 200 females and 4 males with a change in inbreeding rate per generation of 0.039. It allowed the introduction and performance testing of 12–24-month-old bulls from village herds. All farmers could participate through their cooperatives by providing candidates for the breeding unit, managing the reproduction units and disseminating improved animals.

Selection Process: In the open nucleus, two pre-selection steps were performed before the final selection when bulls are 36 months old. Bulls between 6 and 18 months of age were eligible for pre-selection based on body weight and those weighing more than 150 kg at 18 months were pre-selected. The performance of pre-selected bulls was tested from 18 to 36 months of age based on daily gain. Selection criteria were expected to include haematocrit values as an indicator of trypanotolerance but this was never implemented, although the breeding programme claims indirect selection due to the positive correlation (0.40–0.70) between haematocrit value and growth. BLUP analysis reported a genetic gain of 0.43 kg per year for weight at 36 months, while heritability estimates for birth and 36-month weights were 0.07 and 0.12, respectively.

Open Nucleus N'Dama Breeding in Mali

Context and Breeding Objectives: Genetic improvement started in 1975 with the objective of improving and conserving trypanotolerant N'Dama cattle in their own niche. The selection was for beef performance. It was initially restricted to a government ranch but has since been replicated in other locations. The open nucleus scheme started in 2008 with funding from the AfDB and FAO (Camara et al. 2020a).

Breeding Scheme: A closed nucleus breeding scheme based on mass selection was carried out on the ranch from 1981 to 1986. Feed and budgetary limitations in the ranching system led to a shift towards participatory management involving livestock technical services and farmers. Consequently, selected animals on the ranch were transferred to village farms between 1991 and 1993 to test their adaptability in these village conditions and strengthen farmers' participation in the selection process by including their objectives and practices in the overall breeding objectives of the scheme. Dissemination was based on a contractual system in which farmers were to return the same number and sex of animals to the ranch after 10 years. A selection scheme based on an open village nucleus was eventually established, but it failed because of financial constraints. However, in 2008 through funding from the AfDB and FAO (PROGEBE), a new center based on an open nucleus selection scheme was established (Olaniyan 2015). The animals previously loaned to farmers were eventually used to reconstitute the selection unit at the 'Centre de Conservation et de multiplication du Betail Ruminant Endemique de Medina Diassa or Endemic Ruminant Livestock Reproduction Centre'.

Selection Process: Animals were selected based on coat colour and conformation. Unblemished fawn animals with massive stock conformation were preferred and animals meeting these conditions were selected based on their daily gain between 8 and 18 months and weight at 18 months exceeding 150kg. Trypanotolerance was included in the selection process and low drug absorption was screened as an auxiliary trait.

16.3.1.4 Community-Based Livestock Breeding Schemes (CBBP)

Community-Based Breeding Programmes (CBBP) are being promoted as a viable or sustainable alternative for improving livestock production under smallholder conditions and in low-input systems in the tropics. Mueller et al (2015) define CBBP as a low-input type livestock breed improvement system with farmers within delineated geographical boundaries having a common interest in working together to improve their genetic resources. The participating communities usually define their breeding objectives in a participatory process which are

then applied in a one to two-tier small-scale breeding structures. Since the genetic resources are generally local, CBBP can also contribute to in situ conservation. The aim of this breeding strategy is to initiate systematic breed improvement at the community level, which may include organized animal identification and recording of performance and pedigree data. To guarantee its sustainability, building capacities and ownership participation are integral parts of the approach. Also, enablers like breeding policies, market integration, legal and institutional frameworks and sustained funding are pre-requisites to ensure their continuity (Haile et al. 2019; Mueller et al. 2015; Wurzinger et al. 2021). Case studies from Burkina Faso are briefly presented:

Community-Based Breeding of Azawak Zebu Cattle in Burkina Faso

Context and Breeding Objectives: According to Ouedraogo et al. (2021a) genetic improvement programmes started in Burkina Faso in the 1990s with the objectives of enhancing local dairy potential of indigenous breeds, exploit the genetic potential of local breeds, increase the consumption of animal proteins by rural populations and increase farmers' disposable income. Between 2000 and 2015 with funding from the Belgian Technical Cooperation, a project to support the dissemination of Azawak Zebu was implemented to improve their local dairy production. To this end, pure Azawak Zebu bulls were introduced and continuously backcrossed with the local Sudanese Fulani Zebu females. This was a three-phase project with the final phase (2011–2015) funded by the BKF programme of the Luxembourg Development Cooperation and focused on the restoration of degraded pastures. The project covered 11 sites in the Sahel region and involved 329 farmers and about 2400 animals. Farmers at each site were organized into 11 Azawak Zebu breed associations, which together constituted the National Union of Azawak Zebu Breeders. The goals of the programme were to (i) increase the population of the Azawak Zebu, (ii) establish a participatory genetic improvement scheme, (iii) optimize animal management to increase milk and meat production and (iv) increase the skills of farmers.

Breeding Scheme: According to Kahi et al. (2005) and Mueller et al. (2015), a dispersed nucleus scheme was implemented with pure Azawak Zebu subjected to within-breed selection, while the Sudanese Fulani Zebu females were backcrossed to selected Azawak bulls.

Selection Process: Pure 9–12 months old Azawak bulls were selected for performance testing at a central station equipped for performing artificial insemination. Testicle size, chest girth, body weight and libido were recorded on each bull. The bulls were trained for sperm collection and sperm quality was evaluated. Bulls 30 months old were ranked according to a selection index based on daily gain and libido and then selected by a committee of technicians and farmers. Best bulls were selected and re-introduced into the breeding herds as sires, while non-selected and cross-bred bulls were destocked.

Community-Based Breeding of Sudanese Fulani Zebu Cattle in Burkina Faso

Context and Breeding Objectives: According to Ouedraogo et al. (2021b), the Sudanese Fulani Zebu cattle are the most important cattle breed in Burkina Faso, which are traditionally raised in the Sahel region because of adaptation to the conditions there. However, traditional husbandry practices are such that bulls are used for 7–8 years and the selection of replacement bulls is among their offspring, resulting in increased inbreeding in the population and reduced productivity. Also, cows with low milk yield are not milked and so they return to reproduction early, leading to 12–18 month calving intervals, while those that produce more milk and are milked tend to have calving intervals of 18–24 months, a reflection of lactation anestrus. Therefore, to improve productivity, a genetic improvement strategy was introduced through the development project to Support the Development of the Sudanese Fulani Zebu in the Sahel funded by BTC and implemented by Veterinarians Without Borders—Belgium in collaboration with a local Non-Government Organization known as 'Association Nodde Noto' from 2005 to 2018.

The objective of the project was to combine farmers' traditional knowledge with technical selection criteria to set up a breeding programme that will minimize inbreeding and improve the productivity of the Sudanese Fulani Zebu. So, the project set out to increase milk production per cow per lactation, fertility and the number of weaned calves per cow per year. The above selection criteria were determined in a participatory approach based on a long list of possible traits from the farmers. The project team, representatives of the Ministry of Livestock Resources and the farmers ranked the animals and kept the best ones for breeding. The preferred traits were milk production of the dam of the sire, body size, head and neck profile, large ears, long tail and good conformation for the males and milk production, docility, large pelvis, large and well-fixed udder, long and soft teats, belly size and fertility for the females.

Breeding Scheme: According to Kahi et al. (2005) and Mueller et al. (2015) this project was implemented in a dispersed nucleus breeding system, where the selection unit was made up of elite farmers selected by the project team because their herds contained top-breeding females with good maternal lines and the owners employed good husbandry practices and were willing to adopt the project strategy and abide by its rules. Farmers in the reproduction unit were selected by the farmers' associations. The project started with 28 farmers in the selection unit and 233 breeding cows and only 6 bulls that complied with the project's criteria for good breeding. Additional bulls were procured by the project for all 28 herds. However, a performance testing unit planned for rearing young bull candidates for selection was aborted as it turned out too technical and unappealing to the farmers (Ouédraogo et al. 2021b). Interestingly, farmers preferred to keep the young candidate bulls in their own herds. Eventually, the farmers were authorized to keep their young bulls and local barns were erected for periodic testing of the performance of the young candidate bulls.

Selection process: A controlled mating system was introduced in the selection unit involving top females from good maternal lines and selected bulls. Offspring performance was recorded, and young bulls were ranked into four groups based on an index that factored in growth, size and sexual activity (libido). The top bulls (group 1) were distributed to the farmers in the selection unit, group 2 bulls to farmers in the reproduction unit and group 3 bulls to farmers who were not part of the breeding programme. Group 4 bulls were fattened and sold on the market for meat. A selection committee of three farmers and four representatives from the Ministry of Livestock Resources and other professional organizations was responsible for overseeing the bull selection.

Community-Based Breeding of Baoule Cattle and Baoule × Zebu Cross-Breds in Burkina Faso

Context and Breeding Objectives: According to Ouedraogo et al. (2021), the Baoule cattle, also known as Lobi cattle, are the most important taurine breed in Burkina Faso. Like most Central and West African taurine breeds, these small trypanotolerant breeds are found in the hot humid agroclimatic areas and are under threat of extinction because of indiscriminate cross-breeding with Zebu cattle. Ouedraogo et al. (Ouédraogo et al. 2020a, b), reported that community-based breeding programmes were implemented in 2016 to improve the local Boaule and cross-bred cattle in southwestern Burkina Faso with funding from the Austrian Development Agency. Their goal was to implement sustainable breeding programmes to preserve and improve the local cattle breeds. Three breeding programmes, involving altogether 100 farmers and 200 animals, were introduced in three communities each with its own production system. There was one breeding programme for pure Baoule cattle in a sedentary system in Bouroum-Bouroum, another one for cross-breds in a sedentary system in Loropeni and a third one for cross-breds in a transhumant system in Kampti. A participatory approach was used to define the breeding objectives: farmers were surveyed about their trait preferences and how they ranked their own herd animals (Ouédraogo et al. 2020a). Body size was the most important selection criterion, implying that the

farmers were all interested in productive traits. Consequently, the objective of the programme was to improve body size by selecting for weight at a given age and daily gain (growth).

Breeding Scheme: According to Mueller et al. (2015), village breeding schemes were implemented following the community-based breeding approach, which aims to promote the strong participation of farmers at all stages from design to implementation. The village herd was taken as the selection unit and young males were selected.

Selection process: The body weight of young candidate bulls was recorded once and again 6 months later. An index was calculated that equally weighted current age corrected body weight and growth during the previous 6 months. Animals were classified into three groups based on the index: animals that were heavier and/or growing faster for their age were ranked higher. Trypanotolerance was not included in the index but faster-growing young bulls were assumed to be more trypanotolerant (Ouedraogo et al. 2020). A selection committee in each locality comprising 3 local men, 2 women and a youth (<25 years) was provided with weight and growth data for each of the three groups of bulls and asked to choose the best bull from each group and to justify their choices. By 2020, 3 rounds of selection involving 200 candidates were performed, resulting in the selection of 70 bulls that were distributed for breeding.

16.3.1.5 Unplanned Selection Programmes

In this section, a few cases of un-designed selection attempts for improved performance in cattle are presented.

Selection of Boran Cattle in Kenya

Beef cattle breeding started in the 1920s in Kenya with European ranchers crossing indigenous African cattle with European types (Homann et al. 2005). Subsequently, most of the research efforts focused on characterization and cross-breeding of indigenous African cattle (Trial and Gregory 1981). These studies showed that the contribution of exotic beef cattle and their crosses to meat production was either similar or worse than that of indigenous cattle. Consequently, attention was shifted to the selection of indigenous cattle with a particular focus on the indigenous Boran cattle. Rege (2001) has reported the pursuit of indigenous cattle improvement programmes in Kenya involving Boran and other Zebu breeds.

The Boran, which is a large East African Zebu cattle, is classified into improved and unimproved types. The unimproved Boran is common in subsistence and semi-commercial production systems in Ethiopia, Kenya and Somalia, where they are referred to as Borana, Boran or Awai, respectively. Further information on the Boran breed in terms of distribution and population statistics has been presented in Chap. 4, Sect. 4.1.1.1

The Kenyan Boran originated from the Borana, Somali and Orma Boran brought by European ranchers from central Kenya in the early twentieth century (Rege 2001). They are primarily reared by commercial beef producers in large-scale ranches in the semi-arid areas of Kenya. Their potential for beef production brought together cattle breeders in 1951 to form the Boran Cattle Breeders' Society (Rewe et al. 2007). Individual efforts of the Boran cattle farmers have contributed to the development of the improved Kenyan Boran. However, these independent efforts with respect to selection and genetic improvement have become a major challenge for the future of the Boran cattle (Rewe et al. 2009). Besides, the absence of an organized breeding programme has further compounded this problem and has resulted in the lack of quality breeding stock and the non-sustainability of the breeding programmes. This may explain why the improved Boran has an admixture of *Bos indicus* (zebu) and *Bos taurus* (taurine) types (Hanotte et al. 2003).

Since 1951, BCBS has developed guidelines for improving indigenous cattle and has worked hard to register the improved Boran as a distinct breed. They have also maintained the breeding objective of improving beef production while at the same time selecting for efficiency and adaptation to the harsh conditions in Kenya. However, years of selecting the Boran on growth have resulted in the breed becoming more susceptible

to tropical diseases compared to its unimproved type (Hanotte et al. 2003). The improved and unimproved Boran differ in performance for growth, reproduction and fitness. The improved Boran is heavier at birth than the unimproved type and so tends to have heavier sale weights. It also has shorter calving intervals and calves first at younger ages than the unimproved Boran type (Okeyo et al. 1998).

To better organize the breeding improvement of the Boran under the ranching scheme, a beef industry development programme and a National Beef Research Centre (NBRC) were established in 1968. A bull performance testing scheme was carried out at the NBRC, where three zebu breeds (Boran, Sahiwal and the East African Zebu) were evaluated. However, the lack of well-defined breeding objectives, over-dependence on donor funding, and diversified and decentralized breeding, production and marketing systems led to the stagnation of the programme (Rewe 2004). Also, in the 1970s a recording scheme was initiated, and producers were routinely sending animal performance records to the Livestock Recording Centre for genetic evaluation. However, inconsistencies and delays in releasing evaluation results coupled with a high cost of recording forced many producers to opt out of the scheme (Rewe 2009). Similarly, the beef bull performance evaluation also failed because of the lack of a long-term strategy for human resources and financing. The above failures notwithstanding, individual efforts of Boran cattle farmers under the BCBS have resulted in the selective breeding of the improved Boran. Consequently, the experiences of the Kenyan Boran cattle farmers coupled with the unique herd characteristics of the Boran cattle have attracted keen interest in the Boran cattle from South Africa and Australia, resulting in the creation of the Boran Cattle Breeders' Society of South Africa in 2003 (Rewe 2009).

Rewe (2009) carried out a simulation of alternate closed and open nucleus breeding programmes involving large-scale commercial ranchers and low-input beef producers involving the Boran cattle reared in the semi-arid regions of Kenya to evaluate the genetic and economic benefits of these programmes. The study showed that open nucleus schemes resulted in greater genetic gains than the closed nucleus system but with a lower profit. The application of a combined growth and adaptability breeding objective resulted in a gain in adaptability (trypanotolerance) but a decline in sales weight gain compared to a growth breeding objective scheme. The most profitable options for the selection schemes were the 25% nucleus size, 70% genetic contribution to commercial herds and 10% nucleus opening.

Ankole Cattle of Eastern Africa

The Ankole cattle are indigenous long-horned (Sanga) cattle in Uganda, which are reputed for their adaptability to the local environment and their cultural significance to the local keepers. There has been severe indiscriminate cross-breeding of the Ankole with the more productive exotic breeds, which has constituted a threat to its existence. Therefore, conservation of the Ankole cattle through selective breeding to improve on its production traits through a nucleus breeding programme has been set up at the Nschaara Stock Farm in the traditional Ankole keeping area in Southwestern Uganda. Uganda through its Poverty Eradication Plan has mandated the National Animal Genetic Resources Centre and Databank (NAGRC&DB), a corporate body under the Ministry of Agriculture, Animal Industry and Fisheries (MAAIF) to oversee animal breeding activities in the country. So, NAGRC&DB intends to operate several large cattle breeding stock farms with different types of breeds including the Ankole (Nakimbugwe et al. 2005). Chapter 4, Sect. 4.2 presents further information on the Ankole breed in terms of production characteristics, distribution and population statistics.

Ethiopian Boran Cattle of Eastern Africa

Chapter 4, Sect. 4.1.1.1 presents a description of the physical characteristics of the Ethiopian Boran cattle. According to Haile et al. (2011), in 1960 a herd of 351 Boran cows and 12 bulls was purchased from the community and established in the Adami Tulu ranch in Southern Ethiopia. The objective was the genetic improvement of Boran under ranch management conditions. In

1971, the breeding programme was disrupted and some of the animals were distributed to farmers and some were transferred to Abernossa ranch, which was established in 1962 with the aim of improving the Boran cattle. Both ranches, which are not far from each other, were combined in 1975 and named Adami Tulu and Abernossa Cattle Improvement and Multiplication Center. The objective of the Center was to conserve and improve the Boran cattle through selection and controlled breeding. Since its establishment, the Boran herd has remained closed and the ranch operated two breeding units—one unit for selection of pure Boran cattle and the other unit for cross-breeding improved Boran cows with exotic *Bos taurus* bulls. The Boran cows were inseminated with frozen semen from Friesian bulls.

The Boran breeding unit used the natural mating of Boran cows with superior Boran bulls on all-year breeding, which in 1983 shifted to 3-4 months (September to December) controlled breeding season until the programme was transferred to the Dida Tuyera ranch. The breeding unit operated a single sire mating scheme with herds composed of 50 cows and raised in separate paddocks. In addition, there was a herd of breeding bulls, a herd of pre-selection young bulls and a herd of pre-selection young heifers. Heifers from the pre-selection herd were used either as replacements for the breeding unit or as replacement stock to produce F1 cross-breds in the cross-breeding unit. Boran heifers were bred at 24 months of age and 250 kg body weight, while young bulls were selected at about 12 months of age for breeding based on pedigree, birth and weaning weight, breed characteristics and general body conformation.

The Dida Tuyera ranch was established in 1987 with the objective of conserving and improving the Boran cattle using selection and controlled breeding. The ranch produced and distributed to farmers pure Boran bulls and supplied replacement heifers to Abernossa ranch for cross-breeding. However, the improvement programme was disrupted in 1991 by the change in government and the looting of the animals on the ranch. The latter was re-established in 1993.

16.3.2 Emerging Molecular and Reproductive Technologies in Breeding Strategies Relevant for Genetic Improvement in Various Production Systems for Cattle and Buffaloes

Recent advancements in molecular and reproductive technologies have contributed to enhancing animal productivity and reproductive efficiency in livestock production systems in developed countries. Their implementation of breeding objectives for African livestock production systems will contribute to enhancing livestock production efficiency and in achieving faster genetic gain in breeding programmes for the various livestock input systems. Molecular technologies like genotyping, next-generation sequencing, gene editing and genetic engineering, and reproductive technologies like artificial insemination, cloning, oestrus synchronization, embryo transfer, transgenesis and in vitro fertilization have been described in more detail in Chap. 21. Biotechnological advances enable individuals to improve their genetic merit and their potential to pass on their genes to future generations while limiting the influence of environmental conditions; and are better positioned to advance African animal agriculture. Initially, we will examine the application of molecular and genomic technologies and their role in genetic improvement in various production systems for cattle and buffaloes.

16.3.2.1 Molecular and Genomic Technologies for Breeding Strategies

Advances in molecular and genomics technologies have made it feasible to identify genomic variations and elements that influence livestock traits of interest, and their implementation in breeding programmes. As a result, new options for achieving balanced breeding goals that include highly heritable (e.g. milk yield, fat yield and milk protein yield), lowly heritable (e.g. health, longevity, calving, fertility, conformation and workability traits) and emerging (e.g. fitness, ani-

mal welfare, environmental adaptability, heat tolerance and feed efficiency) traits and in improving selection responsiveness have emerged. These technologies are particularly of great importance in the improvement of breeding of traits with low heritability, traits for which phenotype measurement is difficult, expensive, and only possible late in life, or traits that are not possible on selection candidates (Dekkers 2004; Miglior et al. 2017).

Advanced technologies like next-generation sequencing and genotyping technologies support the identification of genetic markers, factors and genes that influence production, health, welfare and adaptation traits, and implementation of marker-assisted selection (MAS), genomic breeding, gene editing and transgenes in breeding objectives for improving livestock production. The development of molecular genetic techniques and gene manipulation started with first-generation sequencing technologies like the Sanger sequencing method (Sanger et al. 1977), the breakthrough technology of polymerase chain reaction (PCR) amplification (Mullis et al. 1992) and several developments in recombinant deoxyribonucleic acid (DNA) technologies. PCR gives the ability to amplify specific regions of the genome in large quantities for use in a myriad of applications, and is considered the primary technology in genome manipulation. While the Sanger sequencing technology supports the sequencing of short genomic sequences after PCR amplification at single base resolution and identification of genetic variations, other breakthrough technologies have emerged. For instance, next-generation sequencing (second and third generation) have transformed the genomic landscape and made it possible to sequence target genome regions and whole genomes at unprecedented depths. Next generation sequencing led to detection of millions of sequence variations; whole genome gene expression (transcriptomics) (identifies genes associated with specific conditions); whole epigenome sequencing (identify epigenetic alterations) and to genome editing (ability to insert, delete, replace or modify a portion of an organism's genome). These developments (summarized in Table 16.2) have supported

many advances in cattle and buffalo breeding and genetic improvement. Moreover, these developments made it possible to detect all kinds of genomic variations (e.g. single nucleotide polymorphisms (SNPs), insertions, deletions, translocation and copy number variants), epigenomic alterations (DNA methylation, histone modifications, etc.) and genes influencing livestock traits of economic importance. To identify these variations in large populations and implementation in cattle and buffalo breeding programmes, genotyping assays of different sizes have been developed. Most available genotyping assays are for DNA variations while none is currently available for epigenome alterations.

Thanks to the breakthrough technologies of molecular biology, genomics, statistical methodologies for quantitative trait loci (QTL) mapping, bioinformatics tools for analysing big sequence data, genetic factors influencing economically important features may now be found. These discoveries have the potential to greatly accelerate the speed of genetic improvement in African livestock populations by MAS of specific loci, genome-wide selection, genomic breeding, gene introgression, positional cloning and gene editing. Specific cases of the application of genetic markers and breeding technologies in African cattle and buffalo populations for implementation in selection programmes are presented in Chap. 22.

16.3.2.2 Reproductive Technologies for Breeding Strategies for African Cattle and Buffalo

Reproductive technologies are among the modern technologies that have revolutionized livestock production and in particular, dairy production starting from the early 1900s. Among the reproductive technologies, artificial insemination (AI) is best mastered and the most widely used assisted reproduction technology (ART) in developed and developing countries. Major advances and implementation of reproductive technologies in livestock breeding have been summarized in Table 16.2 and discussed in more detail in Chap. 21. The consideration of ART in breeding objectives for African livestock improvement will no doubt lead to rapid improvements in desired traits.

Artificial Insemination (AI)

Artificial insemination stands as one of the first reproductive technologies to be mastered and widely used and also the most widely adopted assisted reproduction technology in Africa. Developments in AI technology have resulted in the low cost of semen production, insemination and insemination success. For example, a single bull sire can produce between '100,000 and 150,000' doses of semen over the course of his life (Vishwanath 2003) and which can be used to inseminate thousands of cows. Therefore, AI is widely regarded as a successful, inexpensive and

accessible reproductive technology, which has been available to cattle producers for over a century. Artificial insemination facilitates genetic improvement through the introduction of high-quality genetic materials into thousands of females without the need to keep genetically superior males. The AI technique involves introducing the sperm of a superior male to the reproductive tract of many female animals without the process of natural mating. The practice of AI has extensive benefits, including reduction of disease transmission, reduced need for maintenance of breeding animals, increased accuracy of pedigree recording, decreased cost of the use of improved genetics, efficient use of high-quality bulls and decreased running cost associated with keeping fewer breeding bulls (Beilby et al. 2009; Lamb and Mercadante 2016; Moore and Hasler 2017b). The AI technology is used most efficiently in the development of desired livestock, and its use has led to improvements in semen freezing, cryopreservation, sperm sexing and the rapid dissemination of high-quality genetics. The adoption of the AI technique has enabled the breeding of 100s of cows from a single ejaculation and has allowed a single bull to father over 500,000 offspring (Norman et al. 2011). Details of steps in the application of AI are covered in greater depth in Sect. 20.4.1 of Chap. 20.

Artificial insemination is used extensively in dairy cattle breeding and has popularized the practice of using progeny tests to identify genetically superior bulls followed by extensive dissemination of those genetics through commercial dairy herds (Vishwanath 2003). In beef cattle, however, this practice is not as commonly used due to the temperament and large pastures often associated with this industry (Foote 2010). AI does prove useful in smaller beef herds kept in close confinement and offers a substantial advantage in cross-breeding programmes as an inexpensive alternative for maintaining bulls of many different breeds (Foote 2010).

Case studies: Increasing demand for milk and dairy products in sub-Saharan Africa has seen the rise in the adoption of the AI technique, although this demand is still low among small-scale farmers (Mugisha et al. 2014; Tefera 2013; Omondi et al. 2017; Mwanga et al. 2019). Several factors however limit the adoption of AI in breeding goals by small-scale African livestock producers including limited experience in dairy farming, limited ability to keep records, farm size, cost of semen and AI service, and lack of necessary institutional settings and support, among others.

Animal Cloning

Animal cloning has helped to rapidly incorporate improvements into livestock herds for more than two decades and has been an important tool for scientific research since the 1950s. Although the 1997 debut of Dolly (the cloned sheep) brought animal cloning to the public consciousness, Dolly was considered a scientific breakthrough not because she was a clone, but because the source of the genetic material used to produce Dolly was from an adult cell, not embryonic (Polejaeva and Campbell 2000). Recombinant DNA technologies in conjunction with animal cloning have provided researchers with excellent animal models for studying genetic diseases, ageing, cancer and drug discovery, and in the future, they will help in the evaluation of other forms of therapy, such as gene and cell therapy. Animal cloning also provides researchers with a tool to save endangered species. In Africa, cloning may be useful for the commercial production of cattle and buffaloes.

Generally, animal cloning is the production of a genetically identical individual, through the transfer of the nucleus of differentiated adult cells into an oocyte from which the nucleus has been removed (Paterson et al. 2003). This is known as 'nuclear transfer' and it is how Dolly the sheep was produced. Following the successful cloning of Dolly, somatic cell nuclear transfer (SCNT) has been used in conjunction with modern genetic engineering technologies to produce many genetically modified farm animals (Table 16.2). This possibility has unlocked new possibilities to study the function of genes and also the establishment of animal models for an assortment of human disease conditions, and avenues to improve livestock production, health and environmental adaptation traits (Karavolias et al. 2021b; Klinger and Schnieke 2021).

Case Studies: Africa's first successful cloned cattle was named 'Futhi' (meaning 'replicate' in Zulu language; Bartels et al. 2004) and denoted a major breakthrough in the development of animal biotechnology in Africa. DNA from the ear of a 9-year-old high milk-producing Holstein cow was introduced by nuclear transfer into the eggs from a second cow and the embryo was grown in a test tube for 8 days, and then transferred into a surrogate cow resulting in the birth of Futhi 9 months later (Vajta et al. 2004). The cloning of a Kenyan Boran bull by SCNT using primary embryonic fibroblasts (Yu et al. 2016) was Africa's second successful cloned cattle. The aim of the cloning was a proof-to-concept step towards the establishment of genetically modified Kenyan Boran with genome-modified fibroblasts for disease resistance and other traits. Embryonic fibroblasts used were from a 3-month-old male Kenyan Boran foetus and introduced by SCNT into oocytes from adult *B. indicus* cattle. Following the introduction of the cloned bull to a female Boran herd, two calves were born, both showing very low glucose (blood) levels (less than 30 mg/dl) and difficulty standing alone (Fig. 16.5). One calf died a few hours after birth due to low blood glucose while a second calf survived and remained healthy after supplemental glucose was administered (Fig. 16.5) (Yu et al. 2016). This example (successful cloning of a Kenyan Boran bull) opens up the possibilities of establishing genetically modified African livestock with desired genes or traits through genome-edited fibroblast cells followed by SCNT and cloning.

Embryo Transfer

Embryo transfer (ET) refers to the process of transferring a viable embryo from a donor female to a recipient female enabling the production of multiple offspring from one superior female donor (Mishra et al. 2017). The process involves the superovulation and insemination of donor females within the proper timeframe regarding ovulation. The induction of this superovulation in the donor female is monitored via ultrasound, to determine the number of oocytes that will be available, and through daily checking of the female's oestradiol levels as an indirect measure of the quality of available oocytes (DeCherney 1986). After insemination of the female, the embryos are flushed from the donor at 1 week of age, isolated and examined using microscopy for quantity and quality; the viable embryos are then inserted into the lining of the surrogate, or recipient, female's uterus (Mishra et al. 2017). Embryo transfer is widely used globally. In 2019, a total of 1,117,151 bovine embryos were transferred, including 3645 embryos transferred in Africa (Viana 2019). The ET technology provides many benefits, including decreasing the transfer of disease associated with natural mating, improving the reproductive success of superior females, facilitating the development of rare and economically important genetic stocks and contributing to livestock breeding research by the creation of numerous closely related and genetically similar animals (Moore and Hasler 2017b; Mishra et al. 2017). When compared to AI, ET is viewed as more genetically efficient due to the ability to introduce 100% of a new genome into a herd, compared to only 50% when using AI (Hazeleger and Kemp 2001). However, ET is not a widely adopted ART technique in Africa due to a wide range of challenges associated with the technology. For example, every single step in the process must be performed with success to yield offspring. Other challenges include the success rate, which tends to decrease as the donor females age due to a decrease in success of fertilization or increase in loss of the embryo in the oviduct, variability in response to superovulation, high cost associated with the technology, labour-intensive nature of superovulation procedures, time required between collections and technical knowhow (Ashry and Smith 2015; Hansen 2020). More details on ET are presented in Sect. 20.4.2 of Chap. 20.

16.3.2.3 Nucleus Breeding Schemes for Assisted Reproduction in Cattle and Buffalo

The practice of Nucleus Breeding Schemes (NBSs) allows the dissemination of superior genes in countries and herds that do not possess either the infrastructure or the financial means to

Fig. 16.5 A cloned Boran bull and its offspring (calves). Calf 1 died due to low blood glucose while calf 2 survived following supplemental glucose administration. (From Yu et al. (2016), licensed under CC-BY 4.0)

support other reproductive technologies such as AI and ET. The NBSs initially implemented within the structure of research and development projects include open nucleus, closed nucleus, dispersed nucleus and community-based breeding programmes (Ouédraogo et al. 2020). For dispersed NBS, genetic improvement is performed in the herds of elite farmers, from which improved breeding animals are distributed to other farms or herds (Kahi et al. 2005). For community-based NBS, the breeding animals are kept by elite farmers from which the best young animals are selected for breeding in a communal way (Mueller et al. 2015). The closed NBS is exclusively conducted at a central location or station from where improved animals are distributed to farmers. The open NBS on the other hand performs improved breeding of animals at a central location but also brings in select animals from farmers' herds (Kahi et al. 2005; Gicheha et al. 2006). In an open NBS, there are two types of herds: the nucleus herd, or the genetically superior herd, and the lower herd, also called the multiplier or commercial herd (Mishra et al. 2017). In this system, the genetics flow both ways between each herd, as superior animals from the nucleus herd are introduced into the lower herd to improve offspring, and members of the lower herd are introduced into the superior herd to reduce inbreeding. The open NBS can be carried out in a pedigreed herd at governmental or institutional farms, or through farming breed societies that form a cooperative breeding scheme (Mishra et al. 2017). When utilizing this system, a generation of offspring from the nucleus herd is raised, documented and the males of that generation are assessed based on the performance of their sibs, paternal half sibs or their own performance. The genetics of these superior males can then be disseminated through AI, natural service or ET based on the needs and capabilities of the producer (Mishra et al. 2017).

The open NBS system works very well for Africa and other developing countries lacking the infrastructure to support the extensive record-keeping required by AI and ET because record-keeping is only done in the nucleus herd (Kahi et al. 2005). Furthermore, an open system is more effective than a closed system due to the higher expected mean genetic value of nucleus replacements, and because the system encourages farmer participation, integrates farmer resources and reduces overhead costs (Bondoc and Smith 1993).

Case Studies: Dispersed NBS in Sudanese Fulani Zebu cattle in Burkina Faso—this was a

project undertaken to multiply improved breeding stock for distribution to farmers (Kahi et al. 2005; Mueller et al. 2015). The selection unit consisted of elite farmers chosen because: their herds contained top-breeding females with good maternal lines, they practiced good husbandry, and they were willing to adopt the project strategy and follow its rules. Farms were chosen for the reproductive unit by farmers' groups. In the beginning, the project had 28 farms in the selection unit, 233 breeding cows and only 6 bulls who met the project's breeding criteria. In order to serve all 28 herds, the project purchased more bulls. A performance testing unit was developed for rearing young bull candidates for selection, but farmers found it too technical and uninteresting, preferring to keep the young bull candidates in their own herds. Farmers were eventually allowed to keep their young bulls, and local barns were established to examine the performance of young candidates on a regular basis. In the selection unit, a regulated mating system was created, comprising top females from good maternal lines and selected bulls. Young bulls were divided into four groups based on an index that took into account growth, size and sexual activity. The top bulls (group 1) were distributed to breeding unit farms; group two animals were distributed to farmers for reproduction and group three animals were distributed to farmers who were not part of the breeding programme. Animals from group four were fattened and sold for meat (Ouédraogo et al. 2021b). Bull selection was overseen by a commission of three farmers and four officials from the Ministry of Livestock Resources and other professional groups. Further examples of NBSs in cattle and other ruminants in have been presented by Mueller et al. (2015) and Ouédraogo et al. (2021b), and some examples for cattle are summarized in Table 16.3.

16.3.2.4 In Vitro Fertilization

In vitro fertilization (IVF) reproductive technology is used when other technologies fail due to anatomical issues, the presence of disease or issues with semen collection. In this technique, fertilization occurs outside the body, or in vivo, under controlled conditions (Mishra et al. 2017). Due to recent advances in 'embryo production and cryopreservation of reproductive cells', IVF has been performed with success in many species including rabbits (the first successful IVF procedure in 1959), 'hamsters, mice, cats, squirrels, rats, guinea pigs, cow, monkeys, pigs and humans' (Mishra et al. 2017). IVF allows producers to select superior genetics from both parents via the selection of semen and egg, affording this technique the potential for a large measure of genetic improvement (Mishra et al. 2017). The success of IVF culture is dependent upon the medium, maturity of the embryo at the beginning of the culture protocol and the length of the culture protocol (Mishra et al. 2017). The use of IVF offsets the lack of technological capabilities in many regions, as it is possible to fertilize a mature oocyte with just one spermatozoon, so it is possible to yield multiple offspring with relatively few sperm through IVF (Garner and Seidel 2003). The details of the methodology and the various stages involved are outlined in greater depth in Sects. 20.4.2 and 20.4.3 of Chap. 20.

Case Study: Successful implementation of IVF leading to the birth of live calves was reported in 2001 by scientists in South Africa (Arlotto et al. 2001). For the IVF procedure, oocytes (36.2 oocytes/donor) were obtained from the ovaries of six slaughtered Bovelder cows. Out of the collected oocytes, IVF with frozen semen from a Bovelder bull resulted in 43 blastocysts from five of the six donors. The top 11 blastocysts were implanted in oestrous synchronized recipient cows. Seven calves were born without any calving difficulty thus establishing the feasibility of IVF in commercial beef herds in South Africa (Arlotto et al. 2001).

16.3.2.5 Somatic Cell Nuclear Transfer

Somatic nuclear cell transfer (SCNT) is an ART that offers another technique to reproduce animals in an extraordinary way. Somatic nuclear cell transfer is a procedure whereby the nucleus or DNA of a somatic cell is placed into an oocyte that has had its own nucleus removed to create an individual that is genetically identical to the donor of the somatic cell (Tian et al. 2003). The well-known example of Dolly the Sheep was the

first adult animal to be cloned using this technique, and her case used a 'differentiated adult mammary epithelial cell', which shows that this technique allows the reactivation of genes that were already inactivated on different tissues. This technology invites the potential to create clones of genetically superior animals and could be used in research to study the relationship between genotype and environment, as well as the dissemination of transgenics (Wheeler and Walters 2001). Somatic nuclear cell transfer finds application in genome editing by which genome-edited cells are turned into animals and it is also a route to reprogram somatic cells to pluripotency.

The SCNT technique may not be the most efficient on account of several factors. These include invasive micromanipulation nature of the technique; oocyte incompetence and variation in developmental efficiency; in vitro culture inconsistencies; early protocol deficiencies; high incidences of abortion and foetal mortality; the incidence of abnormal development due to incorrect reprogramming of nuclear DNA (epigenetic interference) and unusual conditions during in vitro processes (Tian et al. 2003; Gouveia et al. 2020). It is however worth noting that Africa's second successful cloned cattle, a Kenyan Boran bull, was by SCNT (Yu et al. 2016).

16.3.2.6 Multiple Ovulation and Embryo Transfer

Multiple ovulation and embryo transfer (*MOET*) is a reproductive technique that allows for the use of oocytes that would normally be wasted. This waste of oocytes can occur, especially in sheep, in the form of substantial loss of potentially valuable oocytes that normally undergo atresia (Naqvi et al. 2004). While an exciting and relatively newer reproductive technique, the procedure is laborious to implement by veterinarians and producers due to the high cost involved, inconsistent results and a general lack of knowledge of the procedure by producers (Mishra et al. 2017). Implementation of this procedure also requires proper facilities that are sanitary with good lighting, superovulation of the donor, early embryo collection and evaluation and transfer of embryos to synchronized recipients, which can induce further hurdles in the necessity of maintenance of both donor and recipient females (Betteridge 2003b). See Sect. 20.4.2 for more details.

Multiple ovulation and embryo transfer are not widely used for many reasons, one of which is the effects of inconsistent ovulatory responses to the hormonal treatment used to super-ovulate the female donors (González-Bulnes et al. 2004). This variability has both extrinsic and intrinsic factors; the extrinsic factors are the source, purity of gonadotropin and the protocol of administration, while the intrinsic factors are reproductive status, nutrition, age and breed (González-Bulnes et al. 2004).

Case Study: Multiple ovulation and embryo transfer technology were introduced in Kenya in the 1980s as a means of speeding up progress in milk production. An evaluation of the success of the MOET since its introduction indicated that super ovulations resulted in zero viable embryos to 13 transferable embryos and successful transfer rates of up to 67% (Kios et al. 2019). Problems encountered by the programme included the lack of suitable MOET protocols, poor technique implementation, lack of technical know-how, poor choice of donors/recipients and high cost associated with the technology (Kios et al. 2019).

16.3.3 Some Final Remarks and Future Perspective

An evaluation of past breeding programmes in Africa (Rewe et al. 2009; Ouédraogo et al. 2021a) has reported that many cattle genetic improvement programmes have failed for several reasons, including non-participation of producers/farmers in the setting of breeding objectives (Sölkner et al. 1998, 2008; Wurzinger et al. 2011), the central and sometimes unsustainable roles played by governments and international development agencies in setting up breeding herds (Rewe 2009; Ouédraogo et al. 2021a), and the limited role or absence of cattle breeders' societies or associations coupled with the absence of a clear demarcation between breeders and commercial producers resulting in producers playing the dual

role of breeding and trading in beef (Rewe 2004). The organization of cattle genetic improvement programmes without the involvement of the livestock keepers is an impediment to their sustainability (Sölkner et al. 1998).

The selection of animals for breeding purposes tends to reflect the preferences of the products' market or consumers (commercial or market-oriented production systems) or farmers (subsistence production systems). Rewe (2009) reported that optimization of animal breeding programmes can take care of these preferences and ensure efficiency in the use of limited resources. Olesen et al. (2000) demonstrated that genetic improvement of animal performance for economic benefits is associated with the maximization of both production and profitability while the inclusion of farmers' preferences (non-market traits) limits this objective to the concept of optimization.

Farmers' knowledge and preferences about breeding goals are essential for breeding programmes that target extensive smallholder production, where animals are husbanded for multiple purposes (Mueller et al. 2015). Therefore, unlike conventional market-oriented breeding programmes, economic considerations are not the only criterion for such systems (Goddard 1998). In traditional animal husbandry systems, it is a challenge to define realistic, feasible and measurable breeding objectives that reflect the beneficiaries' needs. The breeding objectives for the above selection programmes have been meat and milk production as well as disease tolerance like trypanotolerance.

Unlike the programme involving the N'Dama cattle in Mali and Senegal where the objective of improving beef performance was decided without involving farmers, the objectives of breed improvement for the Sudanese Fulani Zebu, Baoule and Crossbreds in Burkina Faso and the N'Dama cattle in The Gambia were set after taking into consideration trait preferences of farmers in a participatory process at the start of the breeding programmes (Jaitner et al. 2003a; Ouedraogo et al. 2020). Wurzinger et al. (2021) identified limited funding and weak institutionalization as the major constraints for community-based livestock breeding programmes.

The Senegal programme eventually included milk production as a breeding objective based on farmers' interest (Camara et al. 2020a), although the goal was unrealistic as the breed's milk performance was low. Besides the productive traits, disease resistance was factored into the breeding programmes involving N'Dama, Baoule and Crossbreds in Burkina Faso. Note that disease resistance was measured in different ways across the different selection programmes. In the case of Mali and Senegal, the emphasis was on coat colour which may be attractive to tsetse flies and so influence trypanotolerance, while that of Burkina Faso considered the positive correlation between growth and disease resistance, and in The Gambia young bull candidates were reared in tsetse-infested areas. Also note that among the numerous trait preferences of farmers, it is advisable to focus on a few that represent breeding goals and are heritable and easy to measure. It is important to note that the Government of Senegal in March 2016 decided to relaunch the selection programme for both the Gobra (Dahra station in the north) and N'Dama (Kolda station in the south) cattle for the purpose of producing improved breeding stock for the cattle farmers.

The above re-emphasize the essential elements of a successful breeding strategy of farmers' participation at all stages, the free flow of information among four key partners (research (ministry/institute), development (livestock ministry) and producers (livestock farmers, and consumers, continuous evaluation and feedback to farmers researchers and development partners and increased productivity leading to improved revenue for farmers and fulfilment of several socio-cultural roles.

The breeding programmes reviewed above indicate that major emphasis has been placed on improving productive traits that drive profitability. However, changes in consumers' attitude, emerging markets, climate change and advances in technology will play a key role in breeding strategies in the future; similar to the trend in developed countries. Such breeding strategies,

however, must also ensure food security and poverty alleviation in the smallholder systems, which are still dominant in the African production systems. Consumers' desire for more healthy diets and preferences for livestock raised in management systems with more welfare considerations are now apparent. Changes in the climate which could have huge impact on livestock productivity can no longer be ignored. Therefore, breeding strategies for the mitigation of climate change and the adaptation of livestock systems to accommodate climate change will play central roles in future breeding programmes. In addition, the incorporation of emerging reproductive, molecular and digital technologies must be essential elements in the design of future breeding goals and strategies in Africa to achieve efficiency in data capture, genomic predictions and rapid dissemination of superior genetics.

17 Breeding Goals and Strategies for Improving Small Ruminant Productivity in African Input Systems

Julie M. K. Ojango, Richard Osei-Amponsah, Isidore Houaga, Timothy Gondwe, Moses Okpeku, and Donald R. Kugonza

Abstract

Africa's sheep and goat genetic resources are well adapted to their production environments, are important components of the food basket, a source of employment and wealth and fulfil socio-cultural and religious roles. This chapter provides information on the key components of sheep and goat breeding programmes, including various technologies adapted in breeding programmes in Africa. Section 17.1 presents a general overview of sheep and goat production in Africa to contextualize the importance of sheep and goat breeding programmes for the continent. This is followed by an outline of the key components required to define breeding goals for sheep and goats with examples of parameters developed and breeding practices adopted in different sheep and goat populations in Africa in Sect. 17.2. Breed-specific examples of successful breeding programmes and the lessons learned in relation to genotype–environment interaction, socio-economic aspects, and various strategies to ensure sustainable use and conservation of sheep and goat in Africa are discussed in Sects. 17.3 and 17.4. The final sections of this chapter (Sects. 17.5 and 17.6) present an overview of external factors that influence breeding structures and opportunities for adopting new technologies in sheep and goat improvement in Africa. An important recommendation is the need for governments in Africa to invest in human and institutional capacity development, encourage public–private partnerships, and embrace technological innovations in small ruminant production.

17.1 Background and Context

Across the continent of Africa, breeding programmes are dependent on the environment, the culture of the people raising the animals, available breeds, market demands for the products, and the prices offered for different goods. African countries are highly vulnerable to changes in climatic conditions because their economies and agricultural production systems heavily depend on rain. As a result, there is huge diversity in the adoption and implementation of livestock breed improvement programmes across the production systems. The continent hosts 33% of the world's sheep and 48% of the world's goat (FAOSTAT 2023). The regional distribution and trend in populations of sheep and goat—available through the FAOSTAT database from 2000 to 2021—are presented in Tables 17.1 and 17.2, respectively. Details on the characteristics of the sheep and goat populations and the use of the animals in different countries are outlined under Sect. 6.1 of Chap. 6 (African sheep genetic resources, diversity and unique features) and Sect. 5.1 of Chap. 5 (African goat genetic resources, diversity and unique features).

The sheep and goat populations in the different regions continue to increase over the years (Tables 17.1 and 17.2), except in Southern Africa, where the number of animals shows a decline over the years. West Africa hosts the largest numbers of both sheep and goat, followed by East Africa. Notably, the number of goats in North and Southern Africa is 50% less than the number of sheep in the same regions (Tables 17.1 and 17.2).

The large number of animals comprises an estimated **363** different breed types of sheep and **289** breed types of goat distributed across the regions, as illustrated in Table 17.3 with details on specific sheep and goat breed types available under Sect. 6.4 of Chap. 6 and Sect. 5.5 of Chap. 5, respectively. Most breed types are indigenous or local to the regions.

[a]Data is adapted from AU-IBAR (2019)

There is no better way to conserve a breed for future generations than to consistently keep the breed viable.

The sheep and goat are reared in production systems that vary from very low-input large-scale extensive pastoral production systems to high-input small-scale intensive production, as outlined in Sect. 2.3 of Chap. 2 on African Livestock production systems. In most systems, animal offtake rates are low <20% due to the slow growth rates of animals. Notably, 76% of the countries in Africa have no protocols established for monitoring their livestock genetic resources (James 1998; Haile et al. 2019).

In 2015, as part of the Agenda 2063 of the African Union (AU), the first 20-year Livestock Development Strategy for Africa (LiDESA) was endorsed under the Comprehensive Africa Agricultural Development Program (CAADP) (AU-IBAR 2015). Details on LiDESA are outlined in Sect. 30.3.5 of Chap. 30 (Policies, frameworks, strategies, and action plans for conservation and sustainable use of African animal genetic resources).

Economic and structural reforms have impacted market demands for different livestock products across the continent. A shift towards urban dwelling centres rather than country living means that the demand for livestock products is changing. In urban settings, the quality of products and the presentation of products affect their uptake and will have a long-term impact on how the products are produced at the farm level. Understanding the existing livestock populations, interventions undertaken to improve their productivity and learnings through past experiences is critical to devising options for harnessing desired productivity gains through breeding programmes.

Definitions See Box 15.1, Chap. 15, Defining Breeding Goals and Breeding Strategies

Breeding goals must be futuristic. Breeding goals generally include a combination of traits specified according to their relative importance. The outcome from breeding using defined breeding goals is realized many years after selection decisions are made. Hence, in developing goals, one must anticipate the demands and needs of future generations.

A Breeding programme is aimed at generating the next-generation animals aligned to the overall breeding goal.

Breeding strategies integrate the components of a breeding programme into a structured system for genetic improvement in order to maximize an overall objective.

17.2 Defining Breeding Goals for Small Ruminants in Africa

17.2.1 Components for Breeding Goals for Small Ruminants

For any livestock species, breeding goals should have a long-term perspective in line with national development plans (see Sect. 15.1.1 of Chap. 15). Such goals are key to addressing challenges in food production and determining incomes accruable from different product lines obtained from the targeted resource. Breeding goals should thus integrate characteristics aimed at improving productivity and efficiency of production, reproduction, health, and survival, and increasing resilience while reducing negative impacts on the environment. Before defining the breeding goals, it is important to understand the production environment, the purpose of keeping the animals, as well as the course for different products from the animals. Through mapping production systems to develop an outline of the activities and distribution channels involved in producing specific products, a better understanding of the opportunities for the breeding goal is obtained.

Breeding goals can be defined at the individual animal level or at the system level (see Sect. 15.1.3 of Chap. 15). Generally, breeding goals for small ruminant production in Africa are defined for production systems both in quantitative and qualitative terms. Economic values for different traits, though deemed important, are not routinely used in indexes for breeding sheep and goat in Africa (Bett et al. 2009a; Kosgey et al. 2003; Gebre et al. 2012). Due to limitations in data on animal performance in different production systems found in Africa, breeding goals are outlined in terms of the anticipated products or outcomes as follows:

> Approaches to improve sheep and goat productivity in Africa must be contextualized to consider the potential of indigenous breeds, the environmental constraints and the socio-economic demands (Philipsson et al. 2011).

- Increase meat production
- Increase milk production
- Increase both meat and milk production
- Improve resilience to diseases
- Enhance adaptability to different environmental conditions
- Preserve unique morphological attributes

Breeding goals usually involve a change in more than one trait simultaneously; see Sect. 15.1.2 of Chap. 15. To ensure progress is achieved in the desired direction, the relationships among traits need to be well understood and quantified. The magnitude and direction of correlations between breeding goal traits determine the rate of progress towards the overall objective. A breeding programme is normally designed and implemented to achieve the defined breeding goals. Outcomes from the breeding programme are realized several years after selection decisions are made in line with the breeding goal.

Sustainable breeding programmes in developing countries comprise several different components, as outlined below (Philipsson et al. 2011; Hutu et al. 2020):

- Characterize the production environment: existing policies, markets, socio-cultural values of communities, and the different farming systems
- Define the breeding goal
- Collate phenotypic information on the populations: the sheep and goat breeds, population characteristics, and productivity levels
- Develop infrastructure and institutional arrangements to support animal performance
- Adopt relevant breeding tools and appropriate technologies: selection criteria, reproduction methods, and evaluation methodologies
- Determine strategies for breeding: structure of the breeding programme and dissemination of genetic gains

Details on the production environments and systems under which sheep and goat are produced in Africa are outlined in Chap. 2 (Production Systems), while the breed types available and characteristics of the different populations are presented in Chap. 5 (African goat

genetic resources) and Chap. 6 (African sheep genetic resources).

17.2.2 Local and Conventional Products from Sheep and Goat

The large populations of local indigenous sheep and goat breeds are used for several different products, generally produced in low quantities per individual animal when compared with exotic product-focused breeds found in temperate environments. The main motivation for sheep and goat production in Africa is to obtain meat and milk for human consumption and blood in some pastoral communities (Kahi and Wasike 2019; Muigai et al. 2018). Milk from sheep and goat is more readily digestible by infants and immune-compromised elderly people. The skins of sheep and goat are also important by-products in several countries (Wilson 1992). These skins are used to produce various leather products and are exported to specialized niche markets in different countries. Sheep and goat skins from Africa contribute up to 17.7% and 21.1% of the global production, respectively (FAOSTAT 2021). Sheep and goat also provide a source of employment and income for both men and women in addition to fulfilling different socio-economic roles within communities (Verbeek et al. 2007; Kosgey et al. 2008; Solomon et al. 2014).

The most desirable traits associated with the different products derived from sheep and goat are presented in Table 17.4.

Table 17.4 Traits and performance indicators associated with different products from sheep and goat

Category	Product	Traits and performance indicators
Production	Milk	Milk yield and quality
	Meat	Weight at different ages: birth, weaning, yearling
		Growth rates, e.g. average daily gain
		Carcass quality and yield
		Fat deposition/ marbling
	Hides/skins	Coat colour
		Skin quality
		Wool quality Sheep
	Manure	Quantity of manure
	Lambs/Kids	Mothering ability
Reproduction	Lambs/Kids Yearlings	Age at first lambing/ kidding
		Lambing interval
		Lambing/kidding rates
		Litter size
		Weaning rate
	Yearlings Mature animals, Yearlings	Survival to yearling
		Survival longevity
Resilience	Mature animals, Yearlings	Disease resistance
		Adaptability to environments

17.2.3 Infrastructure and Institutional Arrangements

In most African countries, breeding programmes have been initiated by national governments in collaboration with bilateral donor organizations. However, the involvement of relevant stakeholders and adequate investments in appropriate infrastructure tend to be limiting (Philipsson et al. 2011). Critical infrastructure includes finance, trained personnel, breeding facilities, market channels, credit facilities, resources for data systems to enable animal data collection, monitoring and evaluation, and management structures that enable integration and inputs from different stakeholders, including governments, private sector service providers, investors, and farmers (Ayalew et al. 2003; Zonabend et al. 2013). The FAO reports on The State of the World's Animal Genetic Resources for Food and Agriculture of 2007 and 2015 (FAO 2007a, 2015) and the report on the state of animal genetic resources in Africa (AU-IBAR 2019) highlights the need for enhancing infrastructure for animal genetic resources at different levels across the continent of Africa.

Over the years, there have been several efforts to develop capacity in animal genetics and breed-

ing in Africa (AU-IBAR 2019; Ojango et al. 2011),resulting in an increased awareness of the critical role of animal breeding in the livestock sector and increased efforts in the development of relevant policies (see Chaps. 27 and 28 on Capacity development in Africa). A greater impact of the capacity developed is evident in dairy cattle production and is expanding to small ruminant production systems at individual country levels as demonstrated in various community breeding programmes instituted recently (Mueller et al. 2015a; Haile et al. 2019; Kaumbata et al. 2020).

Additionally, interest groups are an important organizational component in developing breeds with specific traits. These comprise breeding organizations, breed societies, or different types of community innovation groups. The success of such stakeholder groups in developing and adopting breeding goals is evident in the development of the Dorper sheep and Boer goat in South Africa (Ramsay et al. 2000; Milne 2000),and of the improved strain of Djallonke sheep in Côte d'Ivoire (Yapi-Gnaore 2000).

17.2.4 Technologies Adopted in Sheep and Goat Production

Different technologies have been introduced to enhance the success of targeted small ruminant breeding programmes. These are generally implemented through pilot projects in institutionally owned flocks with limited prospects for expansion to the larger sheep and goat populations. Reviews by different authors on small ruminant breeding projects implemented in different countries of Africa illustrate the adoption of different breeding methodologies and tools. In Eastern Africa, overviews on successes and challenges in small ruminant breeding programmes are documented by Kosgey et al. (2006) and Nwogwugwu et al. (2018), while Bett et al. (2009a) and Solomon et al. (2014) reviewed different small ruminant improvement projects implemented. A review of the indigenous meat goat of Southern Africa and its genetic improvement was carried out by Visser (2019). The various reviews also highlight the need for focused and targeted genetic improvement programmes for indigenous sheep and goat populations in Africa.

The main technologies adopted to support the breeding interventions are (i) recording and monitoring of animal performance, (ii) genetic evaluation of performance in different traits with the selection of better performing animals based on the resultant breeding values, and (iii) crossbreeding. When adopting technologies, crossbreeding is generally used to introduce new breeds into the environment. In some regions, automated systems for monitoring feeding, optimizing the temperatures within housing environments, and monitoring animal health have been introduced on a small scale (see Sects. 21.3.2 and 21.4 of Chap. 21).

Technologies to enhance reproduction in small ruminant populations include artificial insemination AI, oestrus synchronization, and embryo transfer (Menchaca and Ungerfeld 2018). Although AI is the oldest reproductive technique available (see Sect. 20.4 on reproductive technologies to enhance meat and milk production in Chap. 20), its use in small ruminant populations of Africa is not widespread. In Eastern Africa, AI in goat is commercially available in different areas of Kenya to propagate improved dairy goat, while in other countries, AI has been used to introduce new temperate breeds into populations through specific donor-funded projects (Kifaro et al. 2007). Embryo transfer ET is not widely used in small ruminant production in Africa (AU-IBAR 2019).

The heritability of different traits is key to the possible response achievable in a selection or mating programme. Heritability provides information on the 'transmitablility' of a trait from one generation to another and is necessary for predicting the breeding values of animals. Estimates of heritability for different traits vary with populations, breeds, and environmental parameters as the additive genetic variance depends on gene frequencies, levels of inbreeding, and selection (see Chap. 15). The estimation of genetic parameters on a large scale in different small ruminant populations in Africa has been

limited by the absence of data on the performance of animals across diverse environments and human and institutional resources. Published genetic parameter estimates for sheep and goat from select indigenous breeds are presented in Table 17.5. Parameter estimates obtained from the documented populations within a country are generally extrapolated to reflect the expected parameter estimates for animals with no performance information available that are reared under low-input systems. A review of genetic parameter estimates from sheep and goat populations in different environments across the world was presented by Shrestha and Fahmy (2005) while Jembere et al. (2017) presented a meta-analysis of genetic parameter estimates for goat populations around the world. The data highlight a paucity of parameter estimates for goat breeds of Africa. More recent estimates of genetic parameters for growth traits in indigenous small ruminant breeds in Africa are presented in Table 17.5.

Genomic tools have been used to characterize genetic diversity within small population clusters of sheep and goat in Africa. In a review of studies implemented, Visser (2019) noted that indigenous goat show moderate to high levels of genetic variation and relatively low inbreeding. The African Goat Improvement Network (AGIN) developed protocols for sampling goat in characterization studies and demonstrated the use of the Illumina goat 50k SNP panel in distinguishing indigenous African goat populations (Huson et al. 2014). Genetic diversity directly influences possible selection strategies and genetic progress achievable through breeding programmes. Using molecular markers, Yaro (2017) demonstrated substantial genetic similarities between Djallonke and Sahelian sheep breeds in Ghana. Using SNP

markers, Huson et al. (2014) showed clear differentiation between populations from South Africa and North Africa, resulting from geographic isolation. The sequencing and analyses of diversity in indigenous sheep and goat breeds in Africa are however not complete (AU-IBAR 2019).

17.3 Breeding Strategies and Key Considerations in Small Ruminant Breeding Programmes

17.3.1 Breeding Strategies Adopted for Small Ruminants in Africa

Animal breeding involves selection within and across breeds and populations, and the mating of the selected individuals in order to obtain specific products. Breeding strategies generally involve using these two principles in various combinations. Differential breeding strategies tend to be adopted in line with the existing animal breeds, the resource endowment of the livestock keeper, and the type of production system. Concerted efforts have been made to document information on the characteristics of the diverse sheep and goat genetic resources of Africa, see Chaps. 3 and 4 in anticipation that the information generated will be used in defining breeding strategies for their sustainable use.

Selection (see Chap. 15) has been implemented differentially across sheep and goat populations in Africa. Ideally, parents for a breeding line are identified based on the assessment of the breeding values of individual animals with the aim of maximizing the response to selection in line with the breeding goal (Van der Werf 2000). Cognisance of the ancestry patterns of the parents involved is required in order to prevent the build-up of defective genes and inbreeding through the mating of closely related individuals. Decisions on which animals to be mated are often made in relation to dominance effects, which are significant particularly when the selected breeds are of different genetic lines.

Selection within specific breeds enables the maintenance of inherent traits in local populations, notably those related to adaptation and resilience to the prevailing environment. A major challenge in implementing selection programmes in Africa is the lack of appropriate data to make evidence-based decisions (Kosgey et al. 2006). Examples of breeds developed through selection within local indigenous sheep and goat populations in the different regions of the continent are presented in Table 17.6, and average performance in growth traits for the different breeds is presented in Table 17.7. Select case studies on the development of indigenous breeds through targeted selection that have achieved broad use across the continent are presented in Sect. 17.4.

> The best way to conserve a genetic resource is to ensure it is useful

> In addition to striving to obtain marketable products from animals, breeding strategies for sheep and goat production in Africa seek to address both environmental and socio-economic challenges in different regions.

Cross-breeding (see Chap. 15) has been utilized in many populations as a quick means of transferring genes and traits between breeds. Cross-breeding is generally practised between tropically adapted indigenous breeds and high-yielding breeds from more temperate zones in order to utilize heterosis in the offspring. Cross-breeding among sheep and goat populations in Africa has yielded mixed results. Technical aspects of cross-breeding as outlined in Chap. 15 are well understood, however, results from long-term cross-breeding in different sheep and goat populations tend to be highly variable. The choice of parental breeds or populations for cross-breeding depends largely on the availability of

Table 17.6 Indigenous breeds characterized and developed through planned breeding programmes

healthy animals of appropriate breeding age and fiscal constraints, which usually result in the purchase of a limited number of unrelated animals for crossing, mostly sires.

The most successful sheep breed on the continent developed through cross-breeding is the Dorper Sheep in South Africa (Ramsay et al. 2000; Milne 2000) (Box 17.1). Dorper sheep are hardy, single-purpose hair sheep that are tolerant of harsh environments. Their adoption by livestock producers in many environments across the world emanates from their hardy nature, lower labour requirements, and high production efficiency (Knights 2010).

Box 17.1: Cross Breeding: Dorper Sheep in South Africa (Ramsay et al. 2000; Milne 2000)

The Dorper sheep was developed through crossing the indigenous fat-tailed Blackhead Persian with the British Dorset Horn following a series of cross-breeding trials by the South African Department of Agriculture from 1933 to 1946. The composite breed development was led by the Grootfontein Research Institute of the department, with the breeding goal to develop a breed able to survive in unfavourable conditions, reproduce regularly under local conditions, and produce lambs able to grow rapidly to a marketable size.

Critical to the successful development of the Dorper was the formation of a breed society in 1950 that defined and bred for the desired characteristics and popularized the breed in markets for mutton production.

Over the years, the Dorper has spread to different countries of Africa, with different strains popularized in different environments. A shorter legged more compact breed is popular in areas of higher rainfall, while a longer legged more hardy strain is found in more arid environments (Fig. 17.1).

Fig. 17.1 Strains of Dorper sheep found in Kenya and South Africa

Cross-breeding practices using indigenous breeds have also led to improved productivity in the resultant cross-breds. In the hot and humid climatic conditions of southwest Nigeria, significantly higher milk production was recorded in cross-bred West African Dwarf WAD X Yankasa YAN sheep 273–385 ml day^{-1} than in either of the pure breeds (Adewumi and Olorunnisomo 2009). The daily milk production of WAD sheep ranged from 146 to 217 ml day^{-1}, while that from YAN sheep ranged between 210 and 327 ml day^{-1}. The higher milk yield in WAD x YAN reflects the ability of the crosses to combine the advantage of large body size in YAN with the adaptability of the WAD sheep to the environment (Adewumi and Olorunnisomo 2009).

Different cross-breeding programmes have been implemented for sheep and goat, targeting multiple traits in resultant populations through donor-funded projects. Through such projects, more productive animals have been developed at different scales for smallholder farming systems with mixed results. The smallholder goat improvement programme implemented across different countries in Eastern Africa by FARM Africa (2003) is illustrated in Box 17.2. Though the cross-breeding programme was successful, its small scale of implementation meant that there were too few improved cross-bred dairy goat to meet the demand. The farmers who managed improved animals sold the parent stock as the prices of improved animals were greatly inflated (Peacock et al. 2011; Ojango et al. 2010).

The degree to which the indigenous breeds within regions are interrelated is demonstrated in studies that seek to characterize populations using genomic tools (Huson et al. 2014; Yaro 2017).

Box 17.2: Cross-breeding for smallholder farming systems; *The FARM Africa Goat improvement programme*

A community-based goat improvement project that aimed to breed a dairy goat for smallholder farms was implemented in five countries through FARM Africa: Ethiopia, Tanzania, Kenya, Uganda, and South Africa. The genetic improvement model adopted to improve goat productivity evolved over 20 years of implementation across the countries (Peacock et al. 2011). The breeding strategy adopted involved cross-breeding local goats with Toggenburg bucks in community-managed buck stations, as illustrated in Fig. 17.2.

Central to implementing the breeding was community development to improve the livelihoods of smallholder farmers, improve family nutrition and incomes for poor farmers, create employment within target communities, and enhance market access by the poor. All key inputs were in the hands of the farmers, supported by private animal healthcare providers, who

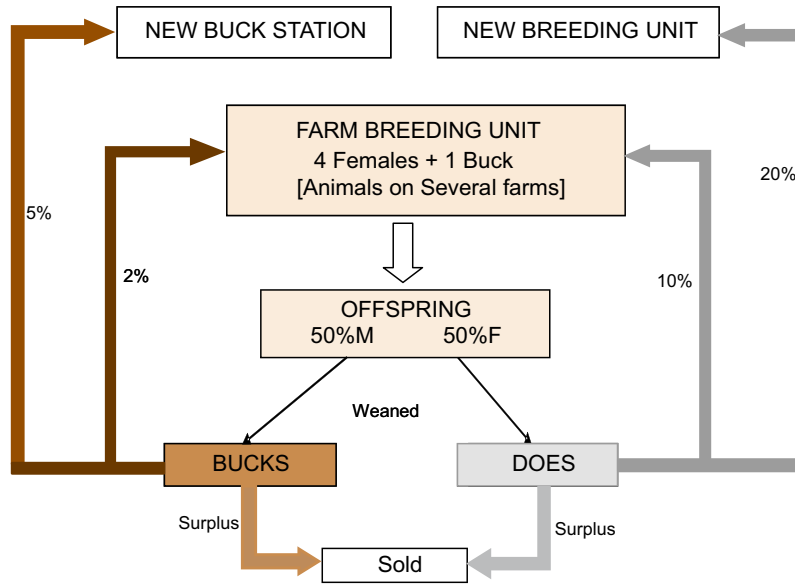

Fig. 17.2 Illustration of the FARM Africa farmer-based breeding strategy for goat improvement. Adapted from Ojango et al. (2010)

formed a breeders' association to manage the breeding of the improved goat genotypes identified. Successful development of a 'dairy goat' with requisite marketing of goat milk through project activities greatly contributed to transformation in dairy goat milk production in Eastern Africa, resulting in an increased demand for 'dairy goats'.

A high demand for breeding stock led to high off-take rates through sale of young goats at high prices. The smallholder farmers had to make choices of whether to maximize benefits through the lucrative sale of breeding animals or engage in a longer-term genetic improvement programme of their flocks. Their need for financial resources resulted in the first option, and animals were sold. This hindered continued genetic improvement of animals in the communities. Subsequent performance records of the animals that were sold were lost as the new owners generally did not follow up on keeping pedigree and performance records.

Composite Breeds Sheep and goat breed types that have been developed and stabilized as a result of crossing two or more breeds are referred to as 'composite breeds'. These are generally new breeds developed to meet the need to increase productivity while retaining the desirable characteristics of local breeds. An example mating scheme to develop a composite breed is presented in Fig. 17.3. Initially, producing the F1 cross-breds is undertaken in a base population while select female crosses with above-average performance are mated to produce the next-generation F2 of breeding females (Leymaster 2002). The composite breeds exhibit heterosis in different traits both at the maternal level and at the individual animal level. Animals selected to be parents should be screened to ensure their performance is above average for target traits in line with the breeding objective. Measures of performance should be routinely recorded and evaluated based on data collated within the flocks participating in the breeding programme.

17.3.2 Genotype x Environment Interactions in Breeding Interventions

African sheep and goat genetic resources have over time adapted to their production environments and acquired unique traits that enable them

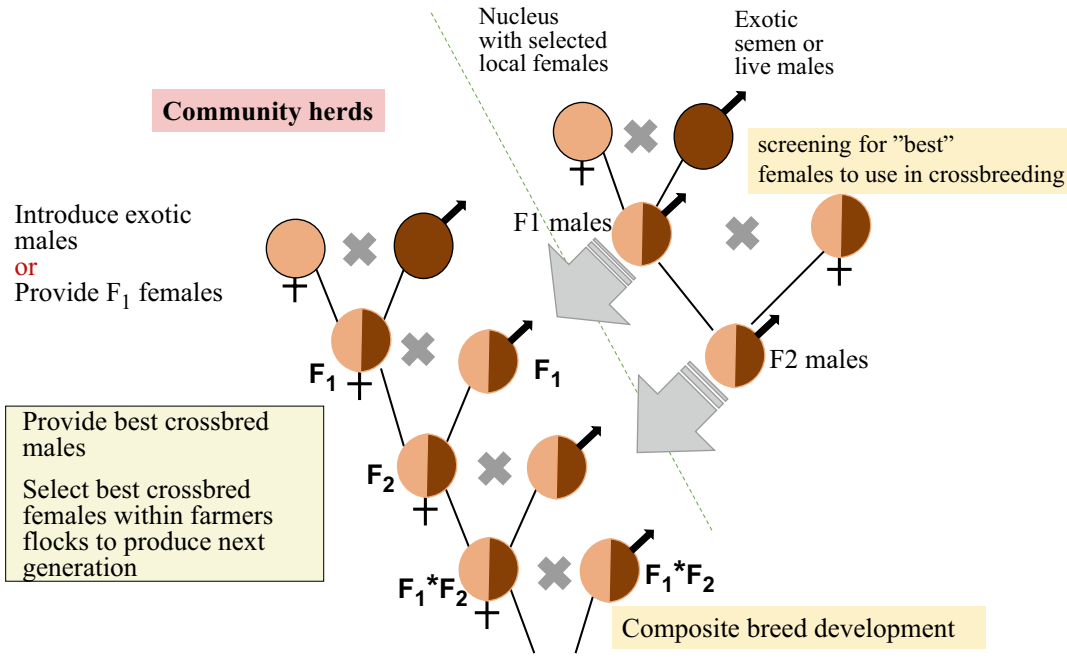

Fig. 17.3 Example of cross-breeding to develop a composite breed

to produce outputs with little inputs or modification of the environment. When importing external small ruminant genetic resources to the different production environments, genotype by environment interactions must be considered. Breeding strategies that involve the introduction of animals from more temperate environments have had varying levels of success under better managed more intensive production systems operational on national research stations and institutional farms.

The failure to incorporate Genotype by Environment GE interactions alongside long-term support for the establishment of breeding programmes has resulted in a variety of cross-bred animals in different production systems of Africa. Bett et al. (2009a) reviewed nine dairy goat breeding interventions implemented in East and Central Africa that were initially aimed at reducing poverty and improving nutrition and health for women and children in households. Both two-way and four-way cross-breeding strategies were adopted for upgrading local goat breeds to performance levels of European breeds. Offspring from the two-breed crossing of indigenous and exotic breeds that demonstrate considerable potential for improved productivity are perceived by livestock keepers to be more productive under local conditions. It is notable that none of the projects included economic evidence on the performance of the different breed lines in the target environments prior to introducing cross-breeding. With the limited scale and the short term of interventions implemented, follow-up on performance, and breed development at the end of donor funding has not been available—the bane of many livestock improvement projects in Africa. This has resulted in a mosaic of cross-bred animals with differential performance levels being reared across the smallholder farming systems from unplanned cross-breeding. In some populations, important characteristics of indigenous breeds such as adaptability, fecundity, and disease resistance have been lost or diluted by exotic germplasm.

17.3.3 Socio-Economic Aspects in Breeding Sheep and Goat

The sustainability of breeding programmes in different communities is highly influenced by

socio-economic factors. These greatly affect access to resources and the use of the resultant products by men and women in communities. This is demonstrated through the level of adoption of breeding interventions. The impact of breeding interventions is dependent not only on their suitability to the bio-physical environment but also on the pathway for adoption which is greatly influenced by the way the breeding goal impacts gender norms and dynamics in a household. When the breeding goal does not suit the socio-economic context of the communities, its successful adoption will be limited. In many instances, little attention is given to the way the system of gender norms and dynamics at the household and community level affect the livestock enterprise in a household (Njuki and Sanginga 2013). For example, gender norms that reduce women's benefits from live animals that are controlled by their husbands or their male counterparts may reduce women's willingness to adopt a technological intervention because it would result in more work for the women who look after the animals with no commensurate benefits. The failure to align emerging technologies in livestock production, including breeding goals to gender constraints and opportunities, limits their adoption leading to low impacts on breeding in livestock systems. A study on gender dynamics in sheep and goat production (Kariuki et al. 2022) illustrated the influence of gender dynamics on flock management practices in pastoral production systems of Kenya. Results from the study demonstrated that despite women's contribution to sheep and goat management in the pastoral systems, men were perceived to exercise a greater variety of ownership rights, especially regarding decision-making over sheep and goat breeding. Prioritization of traits in animals differed between men and women depending on the division of labour and decision-making regarding the flocks. This would greatly influence the adoption of a breeding programme if implemented without considering gender dynamics. Strategies to ensure that sheep and goat improvement practices are compatible with the preferences of men and women are more likely to improve technology adoption rates (Kariuki et al. 2022; Marshall et al. 2014).

Involvement of women in setting the agenda for small ruminant breeding programmes is critical, as women are estimated to comprise 66% of the 752 million poor livestock farmers (Kristjanson et al. 2010). Women engage in livestock rearing so as to produce food, generate income, manage risks, and build assets; hence, their interests and concerns should be considered when developing livestock breeds. The idea of gender-responsive breeding of agricultural commodities in Africa has been of interest in recent years, and significant effort has been put into tooling and re-tooling of African researchers in approaching agricultural research from a gendered perspective. This involves conceptualizing and identifying relevant gender research questions, and the implementation of breeding programmes that are more appropriate to the needs of both women and men farmers. Gender-responsive breeding research must involve commitments of time, financial resources, and personnel (Mangheni et al. 2021) so as to cause long-term impacts for all actors.

Culture and beliefs across different communities tend to influence the type of livestock species raised and the breed preferences. Communities living side by side have been reported to either prefer sheep or goat in line with the use of the animals for cultural and religious ceremonies (Zonabend König et al. 2016; Ojango et al. 2016). During funerals and religious celebrations, such as *Eid-il Adha*, Christmas, and Easter festivities, either sheep or goats are slaughtered depending on the household's socio-cultural practices and preferences.

In pastoral communities, responsibilities for animals are assigned by age groups. For instance, young children are responsible for herding and grazing small ruminants, while more mature men herd the larger animals. The need for young children to attend school leaves the tending of small ruminants to women in households with less labour available to tend separated flocks. This has resulted in higher rates of inbreeding among sheep and goat in

arid areas as mating is random in the mixed flocks (Oyieng et al. 2021).

17.3.4 Strategies That Enable Conservation of Indigenous Genotypes

Maintaining the diversity in African small ruminant populations through their sustainable use is an important aspect of the management of Africa's small ruminant genetic resources in line with the Global Plan of Action GPA (FAO 2007b). Indiscriminate cross-breeding and neglect of local small ruminant genetic resources lead to both the loss of important adaptive traits and of breeds unique to the diverse agroecologies in Africa. A conservation model for small ruminants that has shown the greatest traction in African production systems is the Community-Based Breeding Program CBBP approach (see Sect. 25.3.2 in Chap. 25).

Community-based breeding programmes typically target low-input systems, working with farmers within limited geographical boundaries who have a common interest in terms of improving their livestock genetic resources (Mueller et al. 2015a; Haile et al. 2011). In community-based breeding programmes, the livestock keepers in target areas are encouraged to engage in community meetings through which training and support are provided in relation to determining and adopting breeding objectives and strategies in raising sheep and goat genetic resources. Engagements with communities are aligned to a targeted impact pathway built around the African traditional concept of 'Ubuntu' understanding one another and working together for the common good. Various impact pathways adopted in communities are illustrated in a number of publications (AU-IBAR 2019; Mueller et al. 2015a; Ojango et al. 2018).

The breeding of improved animals through CBBP is implemented using a dispersed nucleus design such that better performing animals in different flocks are selected as potential 'sire-seed' animals for the larger community. When implementing CBBP, the technical expertise of scientists, extension workers, and other service providers is important for facilitation, capacity development, and adoption of critical breeding management practices such as performance recording, evaluation, and ranking of animals (Lamuno et al. 2018).

An overview of CBBP and their implementation processes is presented in the State of Farm Animal Genetic Resources in Africa by AU-IBAR (2019).

Through the African Goat Improvement Network AGIN under Feed the Future supported by USDA/ARC with USAID funding https://portal.nifa.usda.gov/web/crisprojectpages/0427456, two CBBP were implemented in goat in Uganda and Malawi from 2015. These CBBP followed the successful implementation of CBBP in sheep in Ethiopia supported by ICARDA (Mueller et al. 2015b; Gutu et al. 2015). Critical protocols in implementing CBBP as outlined by Haile et al. (2011) are as follows:

- Identify the breeding objectives at the community level
- Establish a system of selection over time and adopt objective measurement and recording of critical traits and performance measures
- Establish structures to support the implementation of the selection system determined
- Characterize the sheep and goat in the target communities
- Select the best animals within the flocks to provide 'seed sires'
- Manage the breeding and regularly evaluate the population in line with the breeding objectives
- Document progress
- Engage critical partners and out scale the breeding to other communities

CBBP have been shown to improve the productivity of goat within local populations in Malawi by 10–15% for growth and meat traits (Kaumbata et al. 2020). In Ethiopia, CBBP have been used to improve the productivity of various indigenous breeds of sheep under smallholder production systems (Weldemariam and Mezgebe 2021).

17.4 Examples of Indigenous Small Ruminant Breeds Developed or Improved Through Targeted Selection

Except for a very few cases, the implementation of breeding programmes for small ruminants in Africa over the years has mainly been driven by external funding, implemented at a small scale mainly at the institutional level with some community integration, promoting strategies geared towards traits that are perceived to be economically beneficial for the producers with little inputs from producers at the outset. In the absence of data, a large number of studies are based on questionnaires, obtaining information on trait preferences and characteristics valued by livestock keepers in the different regions.

There have been several programmes implemented to improve sheep and goat production in the different regions of Africa over time, with variable levels of success. For many small ruminant populations in Africa, records on relevant phenotypes are limited. The most common breeding system adopted to develop and disseminate improved genetics in small ruminant populations in Africa is an Open Nucleus Breeding system. Conventionally, animals in the open nucleus system belong to one of three tiers: nucleus-based animals that are used for generating the best animals of the selected breed, multiplier flocks that are used to multiply numbers of the improved animals derived in the nucleus for use in the larger community, or village flocks dispersed in different regions. Movement of improved genetic material across the tiers is generally through improved male animals. Animals in multiplier and community flocks with above-average performance in pre-defined traits can qualify as nucleus flock animals based on stringent selection measures. Examples of popular indigenous breeds of sheep and goat developed in Africa using variations in nucleus breeding schemes are presented in Boxes 17.3, 17.4, 17.5, 17.6, and 17.7.

The ability to select and improve traits in livestock populations generally relies on recording and access to clearly defined, accurate phenotypes

17.4.1 Select Indigenous Sheep Breeds

Box 17.3: Improved Djallonke Sheep: Côte d'Ivoire Adapted from Yapi-Gnaore (2000)

Djallonke sheep also known as West African Dwarf sheep are thin-tailed hair sheep popular across several countries in West Africa for their prolificacy and disease tolerance http://agtr.ilri.cgiar.org/djallonke. Following a drought in the Sahel from 1972 to 1973, the government of Côte d'Ivoire prioritized livestock development and promoted a national sheep programme for the country. In 1977, a within-breed selection programme was instituted on two state-owned farms and select private farms across the country for the Djallonke breed. The objective of the programme was to improve the growth and liveweight of the animals. The programme involved centralized performance recording of rams in nucleus flocks, with breeding ewes retained in the select farmers' flocks. Ram lambs for the nucleus flocks were initially selected from farmers' flocks based on their individual performance. Ram lambs not earmarked as breeding animals were castrated and reared for mutton production.

Through a well-resourced and trained extension service, the capacity of the livestock keepers was enhanced, and the smallholder farmers adopted new and improved techniques for managing their sheep populations. Over time, the top select sire rams from smallholder farms were purchased for

the nucleus flocks, while the second category of sire rams was sold to other commercial farmers for the production of animals for mutton. The base population of the improved sheep grew from 12,000 breeding ewes on 71 farms in 1992 to 17,000 breeding ewes on 143 farms in 1999. Key traits selected in the improved Djallonke sheep are fertility, growth rate, and trypanotolerance.

Box 17.4: D'Man Sheep in Morocco

Selection in D'Man sheep was implemented following a breed conservation effort by Institut National de la Recherche Agronomique INRA in Morocco in 1970. Prolific D'Man ewes with good growth potential were selected from populations retained in three research stations. Later in 1986, a national sheep development plan was instituted to enable planned use of the improved D'Man both as a pure-bred animal and in cross-breeding programmes with other indigenous sheep in farmers flocks. The INRA research station in Errachidia maintains a flock of 80 breeding D'man ewes under an accelerated reproduction system of three lambings in 2 years (Boujenane et al. 2015).

Key traits in selecting D'Mann sheep are ewe fertility prolificacy and growth performance.

17.4.2 Select Indigenous Goat Breeds

Box 17.5: The Boer Goat: South Africa (Malan 2000; Visser and van Marle-Köster 2018)

The best example of a new breed of meat goat that has demonstrated considerable promise for increased productivity is the 'Boer breed' developed in South Africa. In the early 1920s, the South African farmers from the Eastern Cape developed this breed by selecting and cross-breeding indigenous goat kept by the Hottentot and Bantu tribes in South Africa with imported Nubian and Indian goat. Successive years of recurrent selection for size and conformation resulted in a well-documented new breed of goat selected for commercial meat production supported by the South African Boer goat association that was founded in 1959. Key traits of Boer goat: High fertility and fecundity, adaptable and disease resistant, and good meat production.

Box 17.6: West African Dwarf WAD Goat

The WAD goat is known for its hardiness, prolificacy, and good mothering ability, making it the breed of choice among smallholder livestock farmers in West and Central Africa. Ghana's Ministry of Food and Agriculture has a breeding station at Kintampo in the Bono East Region aimed at improving the growth and reproductive performance of WAD goat. Ayizanga et al. (2018a) reported an average preweaning growth rate of 35.78 g/day and post-weaning daily gain of 26.49 g for the WAD goat in Ghana. Liberia Karnuah et al. (2018) reported two major ecotypes of WAD goat, corresponding to the humid zone and the savanna zone, with the latter being generally heavier with larger body size. The main coat colour types of the WAD goat are black and white 40%, white 14%, black 9%, black and brown 5%, and several other mixtures that gives a strong indication of admixture as a result of the uncontrolled random mating in the free-range extensive husbandry systems (Fig. 17.4).

Fig. 17.4 West African Dwarf Goat in Ghana

Box 17.7: The Galla Goat: Kenya

The Galla goat occupies an important economic and ecological niche in the Arid and Semi-Arid Lands ASAL of Kenya. Female Galla goat has a long productive life and continue to breed and rear kids up to 10 years. The Galla are rarely culled due to loss of teeth and have a very strong compensatory growth after long dry seasons (Skea 1989). Since 1972, several projects have been implemented in Kenya to improve indigenous goat in different production systems (Fig. 17.3). The Galla goat has been a breed of focus as it is the most popular indigenous breed used in cross-breeding and upgrading initiatives. The cross-breeding programmes implemented have resulted in a mosaic of cross-bred Galla goat with varying levels of imported genes (Muigai et al. 2018; Bett et al. 2009b). Long-term strategies sustaining Galla goat in Kenya are implemented through the Dairy Goat Association of Kenya, which follows up on the registration and recording of pedigree and performance of the animals in the Kenya Stud book in line with breed standards defined in 1982. Key traits of the Galla goat: milk production, growth rate, drought resilience (Figs. 17.5 and 17.6).

17.5 Key External Factors That Influence Small Ruminant Breeding Structures in Africa

The improvement of animal genetic resources with genetic gains in production and productivity requires available genetic resources, technical know-how, collection and management of animal information, selection methods, estimation of breeding values, and organized mating systems. These should have an organizational structure with a financial resource base for long-term sustainability. Additionally, livestock breeding structures require individual, community, and public institutional buy-in.

The importance of public sector support through national government systems in providing functional and durable infrastructure, sup-

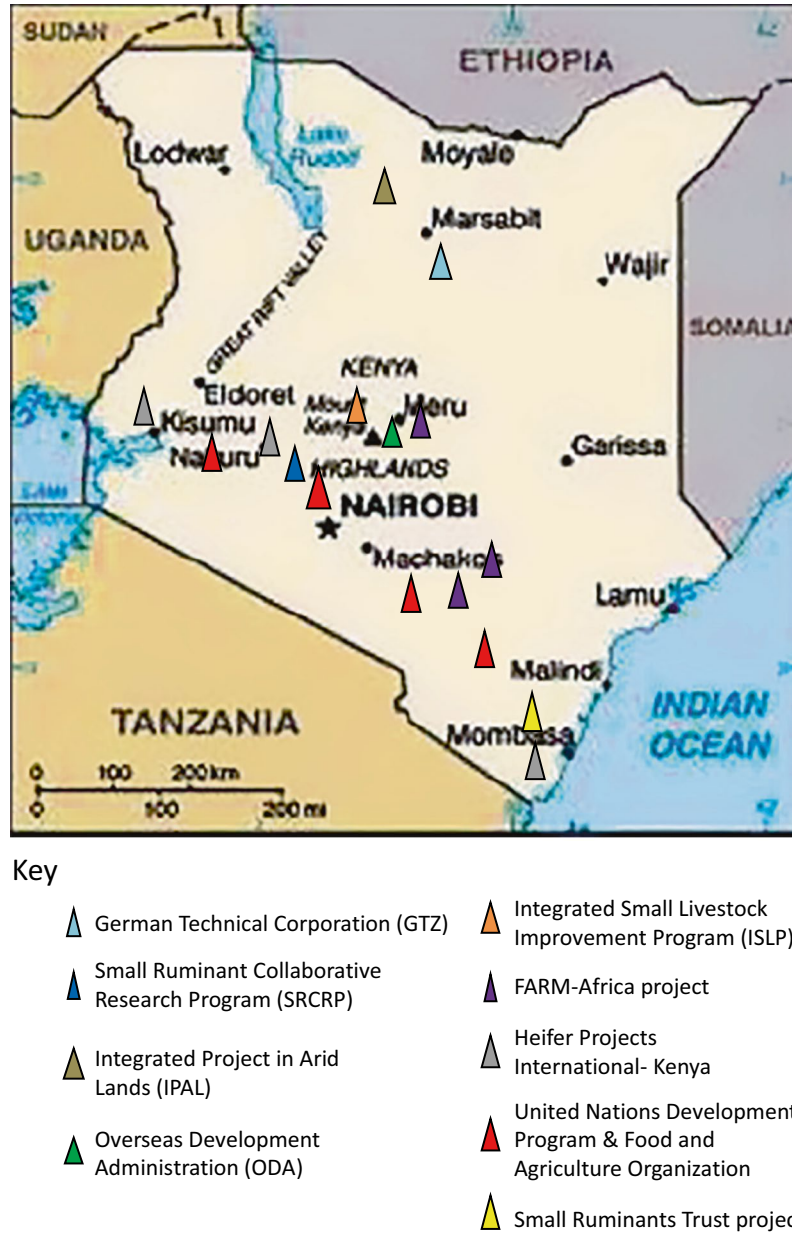

Fig. 17.5 Map of Kenya indicating the location of main goat projects from 1972 to 2010

portive policy, financial resources, and investment in training and capacity development of local expertise in animal breeding and management cannot be over-emphasized (Okpeku et al. 2019). Breeding structures should be set up to make good operational decisions and be able to model different options for strategic and informed decisions (van der Werf and Kinghorn 2017). The process of optimizing breeding structure across systems should strive to produce the best marketable product without adversely affecting genetic diversity within and between breeds and populations.

Optimizing breeding structures has to do with the choices made regarding a given species in a specified production system. Small ruminant breeding structures in Africa are, to a large extent, operationalized by livestock keepers with few

Fig. 17.6 Galla Goats in Kenya

animals under variable management conditions. Recommendations and simulations of optimizing breeding in these systems in line with pre-defined breeding objectives are documented in the literature; however, relatively little progress has been achieved in the larger small ruminant flocks found in rural agricultural systems of Africa (Okpeku et al. 2019).

With strengthening trade links across the African continent, it is important to identify livestock product demand drivers in different regions, taking cognizance of the differential production environments. Through inter-regional engagements, product exchange based on the relative advantages of production in different regions should be adopted. Relevant breeding structures could then be adopted based on demand and marketing structures. Livestock markets are vital for cost recovery and distribution of finished products.

17.6 Opportunities in Adopting New Technologies in Sheep and Goat Breeding Programmes of Africa

New genomic technologies such as high-density SNP microarrays (see Chap. 20 and 21 on the role of modern technologies) can be used to determine the breed composition in individual animals as well as, to some extent, the functional variation between breeds (Rupp et al. 2016; Kim et al. 2015). Genome-wide studies in small ruminant populations of Africa could provide valuable information on the diversity across the indigenous breeds, and possible populations in which genes associated with resilience and adaptability play an important role. Studies on possible identification of major genes associated traits in populations of Africa are limited, yet in different populations across the world major genes are being identified in populations and used in breeding programmes (Rupp et al. 2016). Incorporating genomic selection in small ruminant breeding programmes could allow countries in Africa to benefit from the on-going SNP discovery projects around the world (Kalds et al. 2019),and would contribute good-quality phenotype data on existing populations. Additionally, the use of Artificial Insemination (AI) for breeding across small ruminant populations is very limited, resulting in animals with unknown pedigree information in naturally mating populations. SNP technology could help to infer pedigree information that would guide the selection and use of unrelated males in breeding across populations. The adoption of SNP technology alongside the recording of animal performance data in small ruminant

populations using hand-held information and communication technologies ICT could greatly ease the implementation of breeding programmes for improved productivity and resilience under low-input systems.

17.7 Conclusion and Future Perspectives

Breeding structures to sustain genetic improvement in different sheep and goat populations of Africa are either very weak or absent. The availability of improved breeding stock and infrastructure to support and guide productivity monitoring and improvement in most production systems is also limited, and in a few instances, where available, is inadequate to support upscaling of the monitoring. The adoption of ICT-based platforms with mobile phone technologies for learning and information exchange across the continent, however, offers a great opportunity to generate information from widespread sheep and goat populations in Africa. Such information, once harnessed, should be innovatively used to design and influence targeted breeding strategies for animals while providing relevant and strategic feedback to the producers based on the evaluation of the collated data.

There are also new opportunities emerging with the expanded use of more cost-effective genomic technologies for sheep and goat breeding programmes in Africa. Genomic tools that enable rapid characterization of populations enhance the ability for breeders to source relevant adaptive and productive animals from different environments that can better boost the performance of indigenous breeds without eroding their inherent adaptive capabilities.

It is notable that the use of reproductive technologies to disseminate superior genetics across small ruminant populations is rare, and most genetic improvement is based on natural mating programmes. Evolving reproductive technologies that enable the production of surrogate sires for different environments could bridge the gap in mating practices that promote desired genotypes for different environments.

With changing land ownership and use patterns across production systems in Africa, the formation of interest groups to promote and retain desired characteristics within breeds, either as communities or as breed societies governed through supportive policies, with adequate resourcing for breed development and capacity development of various stakeholders, is critical to successful breed improvement programmes. Enhanced capacity within African countries is required to adapt and contextualize evolving technologies for improved sheep and goat productivity.

Acknowledgements The authors acknowledge the support provided through the CGIAR Research Initiatives on Livestock, Climate and Systems Resilience (LCSR) and Sustainable Animal Productivity for Livelihoods, Nutrition and Gender Inclusion (SAPLING) in drafting this chapter. CGIAR research is supported by contributions to the CGIAR Trust Fund. CGIAR is a global research partnership for a food-secure future dedicated to transforming food, land, and water systems in a climate crisis.

18 Defining Breeding Goals and Breeding Strategies for Chicken Production Systems in Africa

Sunday O. Peters, Michael O. Ozoje, Adeyemi S. Adenaike, Blaise A. Hako Touko, Christian K. Tiambo, Matthew A. Adeleke, Oluyinka Opoola, and Tadelle Dessie

Abstract

This chapter defines breeding goals and strategies for chicken production systems in Africa. Sections 18.1 and 18.2 introduces this chapter and highlight types of breeding goals at different trait levels, and critical components for breeding goals in different input systems of production. Sections 18.3 and 18.4 cover traits of economic importance with examples of various breeding programs for low-input systems (e.g., in Ethiopia as an example). Breeding objectives and strategies for adaptability and resilience for optimal productivity in low-input systems are covered in Sects. 18.5 and 18.6. Furthermore, the current practices for chicken breeding systems and the opportunities for the incorporation of omics technologies are discussed in Sects. 18.7 and 18.8. Also, strategic approaches toward integrating environmental, structural, and socioeconomic factors for chicken production to ensure effective multiplication, distribution, and delivery of improved chicken strains to end-users are extensively covered in Sect. 18.9. Lastly, a conclusion and future perspectives are presented in the last part of Sect. 18.9. Several attempts made to develop poultry production and productivity in Africa have concentrated on the introduction of exotic birds, improving management systems, and disease man-

agement through vaccination among others. These strategies only contributed marginally to the increase in overall productivity among the exotic-indigenous chicken crossbreds which could not be sustained because of several environmental stressors. Indigenous chickens are crucial components of the sustainability of the African poultry industry. Selection pressure in African indigenous chickens is different compared to introduced exotic commercial breeds because selection footprint is associated with adaptation to local prevailing environmental conditions. Balancing characteristics related to growth with that of reproduction is a vital consideration in the development of African indigenous chicken breeds. In some traits, unfavorable genetic correlations, also called genetic antagonisms, cause a decrease in genetic merit when single-trait selection is practiced. In the same way, failure to consider selection response in correlated traits not directly under selection when selection is practiced also decreases genetic merit. The ability of improved chicken strains to thrive and benefit farmers in harsh environments serves as a success indicator to breeders in Africa. Indigenous and tropically adapted breeds were not given due attention until recently when the African Chicken Genetic Gains (ACGG) group (also recently known as Tropical Poultry Genetic Solutions; TPGS) encouraged the selection and use of indigenous chicken strains with high productivity in semi-scavenging systems in the tropics. Genomic selection is considered the most appropriate standard breeding method in livestock. It is particularly advantageous as it can be used for the selection of breeding animals at an early stage of life without reference to their own breeding or production records. The developments in omics technologies also made the estimations of breeding values (BVs) more accurate, increasing genetic gain by aiding in the selection of genetically superior, disease-free animals at an early stage of life for enhanced productivity and profitability.

18.1 Introduction

A wide range of actors influences poultry breeding, as the needs and priorities of several interest groups must be balanced. Poultry breeding is a continuous process where future developments must be anticipated, and planning must be done carefully to establish effective breeding programs. Breeding programs are designed to generate genetic improvement in a population, which aims to use genetic variation available within and between breeds effectively. Its goal is to improve production, quality and output using breeding principles and technological means to optimize the input of resources per unit of the output. A key factor in any breeding program is the estimation of breeding values (the predicted genetic values of an individual determined by the genes of its parents) and a well-structured breeding program is required to improve productivity without exhausting genetic variability. Modern poultry breeding programs constantly evolve with changes and advances in breeding theory, biotechnology, and genetics. A modern breeding program combines the recording of selected traits, estimation of breeding values, selection of potential parents, design, and implementation of the mating program for the selected parents with the aim of generating genetic gain that will lead to more economic value. A comprehensive review of specific goals and strategies targeted for poultry breeding has been covered in Chap. 15.

Directional progress in the genetics of animals in subsequent generations is the focus of any genetic improvement that aims to produce desired products more efficiently in a future social, economic, and ecological production environment. The direction of improvement is formalized in a "breeding goal" which is the first step in the design process of genetic improvement strategies. The definition of breeding goal is therefore an important area of decision-making, although it shifts over time in response to the changing requirements of poultry producers and consumer demands. Breeding goals should both be market and demand-driven, in direct connection with the preferred chicken types (meat, eggs, or dual purpose).

Breed improvement strategies are important in realizing developmental objectives because the state of the future generation depends partly on the state of the current one. The development of effective improvement strategies is therefore of great importance for the management of animal genetic resources (see Chap. 7 on poultry genetic resources). Furthermore, Chap. 7 covers extensively the various domestic poultry breeds, genetic diversity, and the unique characteristics that enable their adaptation and resilience in their diverse environments. The increase in the rate of genetic progress achieved in production traits in poultry today is attributable to the methodological revolution in poultry breeding. This has modified the physiology of birds and the genetic architecture of the traits in chicken population at an unprecedented rate.

From the mid-twentieth century, meat-type (broiler) chickens have been subjected to intense selection for juvenile growth rate, feed conversion ratio, and body composition. These entries describe how the production and functional traits of the individual bird and accompanying management practices have responded to this unremitting selection and this suggest what the future might hold for other agricultural animal species (Hutu et al. 2020; Gowane et al. 2019).

This chapter discusses breeding goals, programs, and strategies in chicken production systems. The main components of structured breeding programs and strategies with relevant traits using performance records and data analysis to identify superior birds and the use of superior birds to produce the next generation of chickens.

18.2 Breeding Goals

The poultry breeding process involves the development of breeding objectives described by a profit function that takes genetic values as inputs and profit as outcomes. It starts with setting goals to identify traits that deliver necessary improvements to significantly impact poultry performance. The development of a new generation of birds that will produce desired products more efficiently under a future farm's economic and social circumstances is the main goal of poultry breeding (Hutu et al. 2020; Rivero et al. 2013).

A breeding goal defines the (combination of) specific trait(s) with their desired direction of change over generations. Each new generation is a small step toward the ultimate goal. Breeding goal is a list of traits and their relative importance targeted by a breeding program and it includes a description of how they should be changed genetically (increased, decreased, or maintained) from time to time. It is a linear combination of traits that influences the profitability, weighed with their respective economic values of a given species (Ponzoni 1988). The list of traits in a breeding goal is normally based on the objective of the agricultural production system and the specific characterization of the animal production system (see Chap. 15). They could be extended to include consumer behavior regarding preferences of animal origin or societal wishes (Amer et al. 2015). However, a breeding goal should involve traits that can be cheaply collected. Their characteristics should be amenable to exact measurement or evaluation, such as egg (size, quantity, and color), body weight, shank (length and color), and comb type. To maximize egg and meat production, commercial poultry breeders create unique lines with varying breeding goals and then cross the different lines to produce the best possible offspring. Significant gains can be realized in each generation since just a handful of breeding goal features are in a targeted line. The breeding goals achieved to a high level in each line are integrated through line breeding. This approach is more fruitful than selecting all desirable phenotypes in a single breeding population. In the chicken production system, a four-way cross is commonly used, with the first two generations consisting of hens from a line selected for egg production and a cock from a line selected for size. Secondly, hens from a crossbreed are bred with cocks from a line bred for their high-quality meat production. Many healthy, strong offspring are produced as a result.

Typically, breeding goals include more than one trait. In addition, traits of economic importance in poultry species have been previously covered (see Chap. 7). However, balancing the emphasis on each trait in a breeding program is also part of the goal. It focuses on saving the inputs of resources, achieving sustainability, dynamic genetic improvements, and accommodating local production environments. Although breeding goals shift over time in response to the changing requirements of livestock producers and consumers' demand, genetic change is likely to be in the wrong direction, when the focus is put on the wrong traits or when important traits are left out of the breeding goal (Amer et al. 2015; Ponzoni 1984).

18.2.1 Types of Breeding Goals

Regardless of the species, the breeding goal focuses on the improvement of gross efficiency by improving productivity (higher yield), feed conversion, reproduction, health, and survivability. The traits in a breeding goal can either be quantitative or qualitative. Meat/egg production traits, body measurement traits, and performance expression traits are some examples of quantitative traits measured in units of gm or kg. Quantitative methods are used when breeding for desired characteristics. Product traits such as

scores for body conformation, disease incidences and/or performance traits, meat quality, plumage color, and comb type are all examples of qualitative goals that might guide chicken breeding and be measured in classes. Some breeding goal traits cannot be measured when needed; for example, meat quality is an essential trait in meat production, but carcass composition cannot be measured when it is considered helpful. It can only be measured after the bird is slaughtered, breeding with that bird is impossible, but indicator traits obtained by scanning live birds for body composition before breeding decisions are made can aid in the prediction of carcass composition. Many underlying traits also complicate breeding goals. For example, overall reproduction capacity results from both male and female reproduction traits. In males, sperm quality and insemination results are part of their reproductive capacity, while age at first egg, egg size, and clutch size are underlying reproductive traits in females. The inclusion of reproductive capacity will therefore complicate the breeding goal (Okeno et al. 2013).

Traits in a breeding goal can be evaluated at four different levels:

1. Individual level: At the individual level, the focus is on how the improvement of a trait would affect the profitability of a bird.
2. Crossbreeding system level: At this stage, the focus is on the effect of selection in the grandparents on the profitability of the crossbred grand progeny in producing the final product.
3. Farm level: At the farm level, the interest is the effect on income per farm.
4. Production chain level: The effect on production and processing levels is the focus.

Each level generates different outcomes. When a producer of broilers obtains a contract to supply a fixed kilogram of broiler meat annually, selection for daily gain will result in heavier carcasses. When a producer subsequently keeps fewer animals than needed, there will likely be a surplus of feed that cannot be converted into valuable carcasses. As such, the profit from a higher daily gain will be lower at the farm level (Amer et al. 2015).

18.2.2 Key Elements of Appropriate Breeding Goals for Various Input Systems

A breeding system specifies how genetic resources are combined to attain the breeding goal by outlining the mating strategies and breeds or strains that will be used. Other higher levels include the farm, but a production system is an association of a finite number of parts analyzed and their interaction with the environment. The production system is defined by husbandry, feeding, and management practices. Two types of farmers work within the chicken industry: those raising chickens for sustenance and those raising chickens for profit. Due to the low costs and low risk involved in the subsistence system, it has been determined that aversion to risk is a major factor in the decisions made by farmers. Regarding input costs and final product pricing, marketing systems detail the channels via which items are sold to customers (Rivero et al. 2013; Ponzoni 1988).

Breeding objective denotes a profit function that takes genetic values as input and produces profit as outcome. It requires consideration of all potential income and expenditure. This is because an overestimation of genetic improvement's monetary value could occur from disregarding expenses that impair selection efficiency. Costs in commercial poultry operations are primarily attributable to inputs, while earnings directly result from the sale of outputs or products. A flock's fixed costs are unlikely to vary even if output levels increase, while the variable costs do alter. Growing a business to a larger size may increase fixed costs. Cost and revenue models from various agricultural businesses show that different systems typically rely on different sets of inputs. Each manufacturing system has its own set of costs from various places. Therefore, it is essential to analyze them individually. It may be challenging to put a price on the various economic benefits that the subsistence system provides. A chicken's biological features significantly impact the system's profitability (Okeno et al. 2013; Hietala et al. 2014).

18.2.3 Unintended Consequences of Breeding Goals

In recent times, modern farming technologies, including quantitative selection and breeding methods, have significantly increased the efficiency of production in many poultry species. However, selection for an increase in production output has trade-offs and negative outcomes often more pronounced in intensive systems of production (Berry and Evans 2014).

In the last century, the formulation of breeding objectives and their applications have dominated quantitative genetic selection practices. Adoption of a data-driven approach to the formulation of breeding goals resulted in the development of animal recording systems. However, Garrick and Golden (2009) emphasized the potential dangers associated with the use of only traits that are easily recorded, such as growth with moderate to high heritability estimates in selection programs because they result in relatively fast genetic progress.

The aim of the poultry industries is to maximize profitability with genetic progress in production traits (Miglior et al. 2017). This goal is, however, associated with a decline in other traits correlated mainly with reproduction and welfare. Historically, the driving force behind the setting of breeding objectives, and thus selection progress, is the profitability of the operation. The focus of the breeding goal on productivity in combination with a data-driven selection approach has resulted in unintended outcomes in several traits (Dawkins and Layton 2012). In all production systems in the poultry industry, fertility is considered the most important economic trait (Cammack et al. 2009), although, intensive selection for production traits in the past has unintentionally led to selection for impaired fertility as a result of the unfavorable genetic relationships between these components (Dawkins and Layton 2012; Berry et al. 2014). The emphasis of selection on increased muscularity and meat yield in the past had also inadvertently led to conditions of double muscling which has adverse effects on fertility (Dawkins and Layton 2012). As such, most breeding companies now increasingly incorporate health and welfare goals alongside economic ones in their breeding programs because animal health and welfare is now becoming a major concern in the different production systems.

18.3 Breeding Programs for Chicken Production

A breeding program is a set of actions outlined to achieve specific breeding goals and create a new animal generation. It is a set of systematic actions designed and implemented to enhance desired phenotypic and/or genotypic characteristics in the target breeding population (Ponzoni 1988; Declaration 2007).

To begin a breeding program, one must first establish a target for the program's offspring and then create a plan to achieve that target through genetic improvement. Structured breeding programs are comprised of a breeding goal with the required traits, collection of performance data, analysis of the data for the identification of superior chickens, and the use of superior chickens to produce the next generation (Fig. 18.1).

A breeding program is designed to create genetic progress that will lead to increased productivity and improvements in other areas with a strong environmental impact. All individual groups and activities contributing to the transformation process are regarded as elements of the breeding program (Ponzoni 1988; Simianer et al. 2021). The economic benefits of the genetic progress generated are generally difficult to quantify since the potential for monetary returns depends mainly on factors outside the breeding program (Dekkers and Shook 1990). The economic benefits of the genetic gains in a breeding program can be calculated for a nation's economy, a sector of a national economy, or different institutional actors in multi-action breeding programs (Hayes et al. 2009).

Generational shifts in breeding objectives do not lead to noticeable gains in overall success. Economic benefit and heritability are two factors that should be considered when deciding whether a trait should or should not be included in the

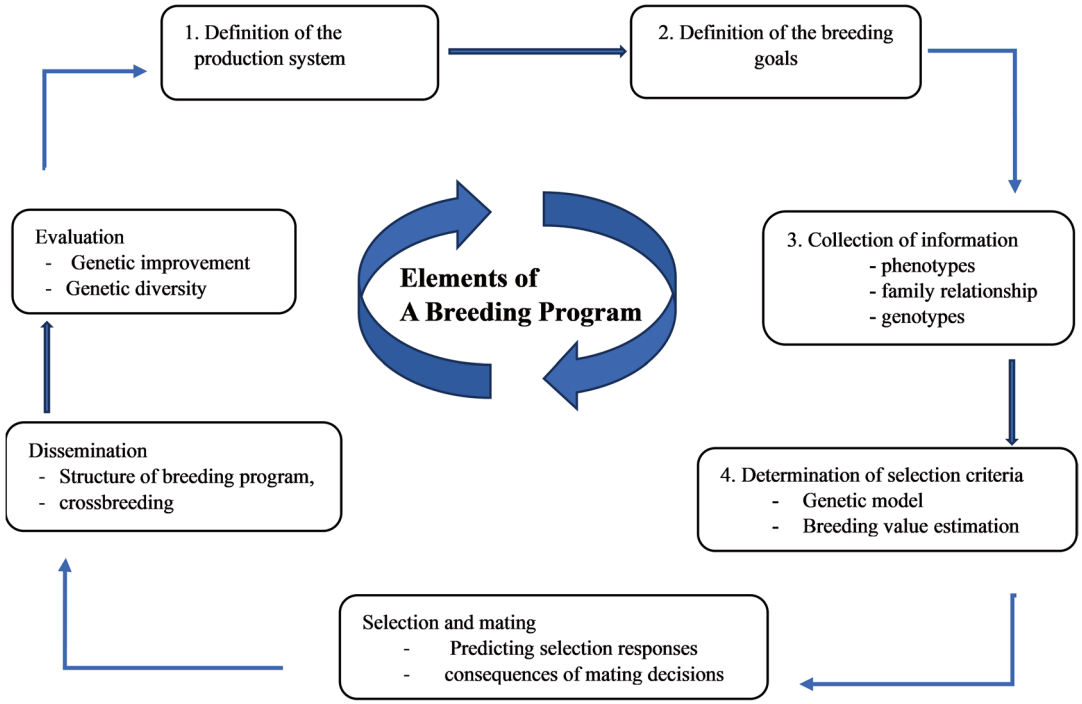

Fig. 18.1 The cycle of a breeding program

breeding goal. Both can be used to express breeding goals. The traits selected for breeding could be limited to the breeder's desires, the needs of the producers and processors, or the preferences of the general public. However, including more traits in the breeding goal will result in slower improvement of each trait with each successive generation. A breeding program's selection decisions usually take a long time (multiple generations of selective breeding) to bear fruit, therefore, emphasizing the importance of considering long-term financial benefits during the breeding goals' establishment. The success of a breeding program resides in solid plans, without frequent to no revisions.

With advances in animal breeding theory, biotechnology techniques, and genetics, modern poultry breeding programs consistently evolve. They are set up to sustainably exploit the existing genetic variation between and within traits (Harris et al. 1984). Both genetics and reproduction techniques tend to influence the optimal design of the breed improvement and dissemination program. Breed improvement programs are designed within and between breeds, enhancing the sustainability and competitiveness of animal production. A key factor in any breeding program is the estimation of breeding values, which is the genetic merit of an individual (Simianer et al. 2021; Kessner and Novembre 2014). Relevant tools and methodologies utilized in bringing about genetic improvement in poultry breeding have been extensively discussed in Chap. 23.

Breeding programs are natural stochastic processes with implicit randomness. A systematic and comprehensive approach to the design of breeding programs, described by Harris et al. (1984), consists of nine steps that begins with the analysis of the production system. Other steps include the definition of breeding goals, the choice of the breeding system and breeds to be used, data recording (both phenotypic and genomic data), estimations of heritability and genetic associations, breeding value estimations including large data sets using genomic information, selection of reproducing animals, mating of reproducing animals, and evaluation of the effects selection practice and its consequences. The

design also addressed the need to compare alternative forms of breeding programs with respect to genetic progress and costs. Kinghorn et al. (2000) differentiated between two variant procedures of designing breeding programs: the bottom-up and the top-down approaches. In the top-down approach, the different steps are defined and implemented by rules, but in the bottom-up approach, available animal material and technologies are made use of in a beneficial manner. It is also called "tactical implementation of breeding programs," in that all available technologies are used and combined optimally. However, in many real-life cases, implemented breeding programs are a mixture of both approaches (Simianer et al. 2021).

To fully design a breeding program, according to Simianer et al. (2021), both the breeding environment and the structure of the breeding program are needed. The founder population(s) must be defined along with the relevant traits in the context of performance testing and the estimation of breeding values included in the breeding goal. For a joint set of traits, phenotypic mean and variance in the founder population, heritability, repeatability, and genetic and phenotypic correlations, which are all the required parameters must also be defined. If the objective of the breeding program is to make genetic progress, the breeding goal, which can be implicitly formulated in an economical manner by providing marginal economic values per natural unit or genetic standard deviation of each trait, must be defined also (Simianer et al. 2021; Faux et al. 2016; Greenbaum and Fefferman 2017; Schlather 2020).

There are typical phenotyping and selection scenarios in many breeding programs at certain stages. For example, a specific set of traits may be recorded for a particular group of individuals, which may depend on combinations of data that can be own or relatives' phenotypes, genotypes, etc. This must be well defined together with the type of breeding value estimation method applied at a given stage. Once the breeding environment has been properly defined, the breeding program structure can then be represented as a graph that is composed of nodes, made up of elementary objects and edges linking the nodes in a directional way (Schlather 2020; Pook et al. 2020).

An elementary object in a breeding program is the smallest unit to be addressed. It can exist in different types, either as "individual" or "gamete" with a certain set of attributes (e.g., "sex," for individual or "age," for "phenotype"). A group of elementary objects of the same type is called a node which can also have two attributes; size, a positive integer, and duration, which reflects the time allocated to its "lifespan." A node can either be a founder node or a derived node, resulting from one or several other nodes.

Edges exist in different classes. For example, it can be "aging," "selection," or "reproduction." It is a directed link from an origin node to a target node. A given edge class has a specific set of attributes. For example, selection as an edge can have the attribute of selected proportion and selection type that can either be random or phenotypic. An edge of a specific class defines the transformation rule of the set of elementary objects in the node of origin. The transformation rule is applied uniformly and in a probabilistic way to all elementary objects of the node of origin to prevent systematic discrimination between the elementary objects in that node (Simianer et al. 2021; Faux et al. 2016; Pook et al. 2020).

The genetics of the founder populations in addition to the correlations (genetic and phenotypic covariances) among traits critically determines the success of any breeding program since the founder population genetics provides the range of genotypes that can be selected. This is a particularly important consideration in breeding programs involving broilers because many generations of selection for a narrow range of traits may have eliminated the variation necessary for breeding for a broader range (Dawkins and Layton 2012).

In a formal assessment of a breeding program, an essential requirement is that one can predict genetic progress achieved through the program by regressing average phenotypic and breeding values on the year of birth. In addition, regular internal and external performance testing can be performed by the breeder which must cover various production environments to ensure that

selected animals perform well under various conditions. Other sources of information for regular assessments are field results and customer feedback, which are probably the most important. The impact of a breeding program depends on the dissemination of genetic progress to customers (Simianer et al. 2021; Pook et al. 2020).

18.3.1 Breeding Programs for Local/Native Chicken in Low-Input System

To improve the productivity of native chickens with respect to egg production, growth rate, and feed efficiency without compromising on crucial genetic features like product quality, disease resistance, or adaptation, well-structured breeding programs are required. Determining specific breeding objectives that meet the needs of the production systems that will use indigenous chicken is essential when establishing breeding programs. According to Hazel (1943), breeding objectives are a linear collection of qualities that impact profitability weighed with individual respective economic worth. Therefore, genetic change is likely to be in the wrong direction or worse than none when the focus is placed on false attributes or when crucial traits are left out of the breeding aim. Most African countries lack indigenous chicken breeding schemes due to unclear breeding goals (Manyelo et al. 2020). Selecting native chicken requires the development of sustainable breeding goals.

The chickens' end-use and users' preferences heavily influence the breeding objective and plans. Many questions about the production system must be answered before defining the breeding aim. Why do you have chickens? How do you advertise your chickens and other products? What factors are most critical for husbandry and management practices? How regulated are the breeders? Is there a plan in place to start a breeding program? How observable are the characteristics? Because of this, the potential for breeding programs and the selection of breeding goal traits is determined by these aspects of production systems.

The first stage in starting a breeding program is selecting the best breed to use in the target environment or production system, focusing on the breed's adaptive performance. There have been failed attempts to transplant high-yielding chicken breeds (such as Rhode Island Red) to tropical regions. Lack of adaptation to the heat means the chickens have trouble reproducing, and that heat stress makes it difficult to raise high production rates. There is also a significant death rate due to various tropical diseases.

18.3.2 Examples of Breeding Programs in Low-Input System

Over 90% of Ethiopia's chicken meat and egg production comes from local poultry systems using indigenous breeds (Dana et al. 2011). Characteristics of this system include keeping a small flock size per household, maintaining birds in scavenging conditions, not providing any supplementary feeding, not providing any separate shelters other than night enclosures in the family house, and not providing any medical attention to the flock. A survey examined the socioeconomic aspects of the production system to determine and rank the breeding goals and trait preferences of village poultry producers. The breeders' primary traits are disease and stress resistance, the ability to evade predators, scavenging vigor, and live weight development and egg production. Hereafter, they will consider reproduction potential, hatchability of eggs, or size and color. In addition, the study found that villager poultry breeders preferred local poultry breeds over a reference modern breed for various traits, including resistance to disease and stress, ability to avoid predators, minimal care requirements, scavenging tendencies, egg hatchability, and meat flavor. These results resulted in adopting a breeding program utilizing mass selection live weight at 16 weeks for males, age at first egg, and egg production up to 45 weeks for females. The productivity considerably increased in just five generations, demonstrating that a "complex" breeding program may be unnecessary. It must be

adaptable to regional conditions (small holdings) and contribute to the existing value structure.

18.4 Economic Traits in Chicken Breeding Programs

The principles of population genetics through quantitative selection practices have been in use since the 1940s for improving the productivity and efficiency of production in poultry breeding programs (Hunton 2006). Developing genetically superior stocks capable of higher production has transformed poultry production, and the poultry industry has grown exponentially over the years. Increased genetic selection pressure for economically important traits and traits associated with carcass-processing characteristics in broilers and egg-laying characteristics in layers have contributed significantly to the productivity and efficiency of the poultry industry. The development of high-yielding layers (310–340 eggs) and broilers (2.4–2.6 kg at 6 weeks) largely attributed to a combination of crossbred and purebred selection practices have significantly contributed to spectacular growth in poultry production (Rajkumar et al. 2021; Saxena and Kolluri 2018). Nevertheless, traits' response to selection depends on population size, gene frequency, mutation, allelic fixation, random drift, and physiological limits. The development of effective breeding strategies for improved productivity depends heavily on the magnitude and direction of correlated responses (Rajkumar et al. 2021; Chatterjee and Rajkumar 2015).

Through a unique selection program, specialized sire and dam lines for different traits have been developed over the years. The dam lines were developed through intense selection practice for reproductive traits, for example, egg production, egg size, egg weight, shell quality, age at sexual maturity, and hatchability besides juvenile growth. In contrast, the sire lines were developed and selected for improved growth rate, body confirmation, feed conversion ratio, carcass quality, and fertility. Mating of these genetically diverse lines resulted in several kinds of gene recombination, producing heterotic effects in the progenies for different economic traits. Increased selection pressure within pure lines and crossing those that are genetically diverse has been the most characteristic feature of the broiler breeding program (Saxena and Kolluri 2018).

Layer breeders have improved over 30 traits of commercial importance for egg production through the application of selection pressure over time. This intense selection for egg production has significantly reduced genetic and phenotypic variations in egg production traits. Peak production is now very close to the biological limit of one egg a day per bird. However, genetic variation at early production (at sexual maturity) and late production (persistency) is still high (Thiruvenkadan et al. 2010; Schmidt and Figueiredo 2005). Nowadays breeders select for age at sexual maturity, laying rate, livability, egg weight, body weight, feed conversion, shell color, shell strength, albumen height, egg inclusions (blood and meat spots), and temperament (Saxena and Kolluri 2018). Residual feed consumption has been used as the major selection criteria for improving feed efficiency because of high heritability and the absence of any significant negative effects on production parameters (see Chap. 23 for modern technologies used in the improvement of feeds, targeted feeding, and poultry nutrition).

The breed improvement program has concentrated more on rapid growth and carcass traits in broiler chickens. Selection at a commercial weight in broiler birds applies selection pressure at a weight that matches the market weight. As such, the age at selection becomes progressively earlier as growth potential increases (Tavárez and Solis de los Santos 2016). As research in genetics and breeding continues, productive performance in the broiler industry also continues to evolve. The industry has, therefore, been characterized as an age-for-weight market industry with the slaughter at a fixed target weight; thereby, emphasizing rapid growth and early carcass development (Zuidhof et al. 2014; Makanjuola et al. 2021a). According to Tavárez and Solis de los Santos (2016), it is difficult to accept that genetic improvement in broiler chicken has not reached a biological threshold. By the recent projections

from Agri-Stats, Inc., broiler body weight of 2.34-kg (5-lb) will be attained at the end of a 28.8-day growing period in the year 2034. This will result from genetic improvement programs. The growth period is therefore projected to reduce at a rate of 0.56 days/year and the main benefit of selecting birds for faster growth will be improved feed efficiency.

Maternal effects also play an important role in the development and expression of economic traits as a result of genetic or environmental differences between dams or by the combination of both genetic and environmental differences (Mohammadi et al. 2018). Maternal effect is a situation wherein the genotype and environment of the mother influence traits. Egg weight is a major factor resulting from maternal effects on body weight. Other traits, such as hatch weight, incubation conditions, and nutrition, may also play a role. Correlations of egg weight on hatching weight and the subsequent body weight of chicks also reflect maternal effects. Therefore, including maternal effects in breeding programs will reduce bias and increase the precision of genetic parameters (Rajkumar et al. 2021; Ghorbani et al. 2012).

18.4.1 Trait Antagonism

In livestock production, selection decisions often impact traits that may not necessarily be under selection. These unintended consequences result from genetic correlation between traits. Genetic correlation provides information on whether two heritable traits share genes, and this means that selection for one will cause changes in the other. When selection is carried out for a trait that is highly correlated with another, substantial changes can be expected in the other trait, simply because of the strong genetic correlation between them. A negative genetic correlation indicates that the other trait tends to decrease as one trait increases. When selection for one trait produces a desirable outcome in another trait, then the genetic correlation is said to be favorable. As such, a trait can either have a favorable positive correlation or a favorable negative correlation. Unfavorable genetic correlations are sometimes referred to as genetic antagonisms. In some traits, when single-trait selection is practiced, genetic antagonisms can cause a decrease in genetic merit. Similarly, when one fails to consider selection responses in correlated traits that are not directly under the selection, genetic antagonisms can also result in a decrease of genetic merit (Tavárez and Solis de los Santos 2016). In poultry, two of the most important reproduction traits are clutch length and broodiness. Clutch length refers to the number of eggs laid in a single brood, while broodiness is the behavioral tendency to sit on a clutch of eggs to incubate them (Ohkubo 2017) Broodiness is negatively correlated with egg number, and clutch length is also negatively correlated with the body weight of females. This is an undesirable genetic correlation between production traits in poultry according to Jambui et al. (2017) and Makanjuola et al. (2021a). Similarly, some low-fitness traits have emerged over generations of breeding programs in broiler birds where early growth is considered a priority. Slower skeletal development has put immense pressure on broiler birds' gait quality and leg integrity as compared to the rapid growth of breast muscles and this has led to well-documented disorders such as tibial dyschondroplasia, bone deformities, and valgus-varus deformities (Avendaño et al. 2017). In these birds, cardiovascular efficiency has also been compromised, leading to the rise in myopathies causing defects in meat quality. There is also reported antagonism between early growth and reproduction traits in broilers (Tavárez and Solis de los Santos 2016). With osteoporosis in commercial layers, several "unfavorable trends" have also emerged because of "major pressure put on calcium metabolism and bone remodeling by eggshell synthesis." Bird selection has also been linked with injurious feather pecking, with one of the hypotheses stating that the trait for total bird egg numbers is linked to social dominance (Makanjuola et al. 2021a). According to Jambui et al. (2017), the antagonistic relationship between productive and reproductive traits has consequently changed the breeding program goals over time to a more balanced approach that considers production and reproductive traits without trading off on animal health and welfare

(Avendaño et al. 2017; Makanjuola et al. 2021b). However, several individual traits, including egg production, hatchability, and fertility, affect overall reproductive performance.

Increasingly, breeders had to deal with antagonisms between different traits as breeding objectives expanded. Selecting one trait can bring a correlated beneficial response in the other trait when the genetic correlation between two traits is favorable. Nevertheless, selecting one trait will lead to an undesirable response in the other when traits are antagonistically correlated. It is common practice in such a case to include both traits in the selection objective and select animals with desirable attributes for both traits. This is a strategy that allows all traits to be improved over time (Neeteson-van Nieuwenhoven et al. 2013). Typically, combining traits in a "selection index" is the most efficient way to select multiple traits (Phocas et al. 2013). In a selection index, traits are weighted according to index coefficients that consider the economic importance of such traits and their genetic relationships and in addition, maximize the correlation between the selection index and the breeding goal (see Chap. 15). However, the outcomes of breeding programs are realized many years after selection decisions are made. A genetic change implemented in a breeding nucleus in poultry will take at least 3 years to have a noticeable effect at the commercial level, which underlines the need to anticipate future demands when defining breeding goals. The development of specialized male and female lines in layer and broiler stocks was a result of negative correlations realized in production and reproduction traits. These specialized lines developed in both meat-type and egg-type stocks usually have very different foundation genetic sources (Chambers 1990; Crawford 1990; O'Sullivan et al. 2010).

18.5 Breeding Strategies in Chicken Production Systems

Breeding objectives address the question of the direction of production, but breeding strategies describe "how to get there." (Kinghorn et al. 2000) The breeding strategy is made up of five building blocks, namely, trait measurement, estimation of breeding values, reproductive technologies, selection, culling, and mating. These building blocks are divided into three major categories: selection between breeds, selection within breeds or lines, and crossbreeding. The production system characteristics and the available animal type determine the choice of strategy to pursue (Declaration 2007).

The domestication of the jungle fowl and identification of superior birds based on performance or phenotype marked the beginning of selective breeding in poultry. This practice was, however, carried out without knowing of the underlying principles of genetics until 1866 when Mendel reported that the inheritance of traits from parents is governed by particles of inheritance later called genes and the "law of heredity" gave the scientific basis for their inheritance (Saxena and Kolluri 2018; Singh n.d.).

As knowledge and needs increased, selection and breeding programs have evolved with time in the poultry business. The concept of two- or multi-way crosses has transformed the poultry breeding output, resulting in high-yielding modern layer and broiler strains. This concept was adopted in the 1980s, from a maize improvement program. In addition, commercial hybrids have replaced pure breeds as terminal crosses, while specialized egg and meat-type birds replaced dual-type birds. Specialized male and female lines in layer and broiler stock with different foundation genetic sources were also developed because of the negative relationships in production and reproductive traits (Chambers 1990; Crawford 1990; O'Sullivan et al. 2010).

The inheritance pattern of quantitative traits is multigenic with minor allelic and additive effects in addition to substantial environmental influence. Identifying or selecting superior individuals for these traits required different procedures based on the theories and principles of quantitative genetics. Chicken breeds show a range of traits that encompasses body size, egg production, and egg color. Large-scale industrial poultry breeding started with the hybridization of selected pure breeding lines. Different breeding and

selection technologies for genetic improvement were introduced at different times. Techniques, such as mass selection, hybridization, pedigree selection, artificial insemination, Osborne index, family feed conversion testing, selection index, individual feed conversion testing, BLUP breeding value estimation, and DNA markers have been used over decades (Saxena and Kolluri 2018).

The development and utilization of synthetic lines from specialized selection programs and crossbreeding processes were vital for the progress made in poultry production over the years. The inclusion of performance record information on pure and crossbreds in selection criteria helped improve responses to selection (Baumung et al. 1997; Uimari and Gibson 1998). Therefore, estimated breeding value (EBV) for crossbreed performance can be determined using the knowledge obtained from both pure and crossbred animals, which may also be used as the basis for selection in a strategy known as "combined crossbred purebred selection (CCPS) strategy" (Uimari and Gibson 1998). Genetic correlation between the heritability of crossbreds (h^2_C) and the performances of pure and crossbreds, especially when combined crossbred and purebred selection method is applied to achieve genetic progress in crossbreds, are important parameters for optimizing and evaluating crossbreeding systems (Bijma and Van Arendonk 1998; Wei and van der Werf 1994). When crossbred performance is the breeding goal and the genetic correlation between purebred and crossbred performance is low, the EBVs of selected candidates will be dominated by the information obtained from the crossbred half-sibs (Bell 1982). Low or negative estimates of crossbred performance indicate a nonadditive genetic effect that suggests a more effective reciprocal recurrent selection (RRS).

Both pure-line selection (PLS) and crossbreeding in a combined crossbred and purebred selection (CCPS) program are used in modern poultry breeding. Purebred and crossbred performance are treated as genetically correlated traits assuming the infinitesimal model (Bell 1982). Depending on estimated genetic parameters (e.g., heritability and correlations) involved, the phenotypic selection method is primarily adopted for improving body weights. The selection index (Osborne index) method is adopted in PLS to improve egg production. Several traits are now being included in the selection program for poultry birds. However, modern breeding programs rely on breeding value estimation with an animal model of the best linear unbiased predictor (BLUP), whereas genetic evaluations based on traditional BLUP utilize average relationships based on animals' pedigrees. Genome-enhanced BLUP utilizes the actual genomic relationship between the animals, which allows for a more précised estimation (Meuwissen et al. 2001).

The maximum number of saleable eggs per hen housed at a low feed cost per egg is the main breeding goal for laying birds. In addition, the eggs should have optimal internal and external qualities, and the stock should have a low mortality rate and high adaptability to different environments. Through the application of selection pressure, layer breeders have improved over 30 traits of commercial importance egg-producing birds. Age at sexual maturity, rate of lay, livability, egg weight, body weight, feed conversion, shell color, shell strength, albumen height, egg inclusions (blood and meat spots), and temperament have been included in selection programs by modern poultry breeders. The strategy for the improvement of egg production also included part-time egg production records, persistency of lay, clutch length, FCR/Residual feed consumption (RFC), and skeletal problems (Saxena and Kolluri 2018).

Selection strategies for broilers concentrated on rapid growth rate and carcass traits. "Selection at commercial weight," is the most practiced strategy in pure line selection. This method employs selection principles at a weight that matches the market weight and the age at selection becomes progressively earlier as growth potential increases. The other strategies practiced are the multi-stage selection strategies and selection at the commercial age (Saxena and Kolluri 2018; Thiruvenkadan et al. 2010). Breast muscle weight, meat quality, and FCR are traits considered. Selection based on breast area determined by measuring the length and width of the breast

using a pachymeter and body weight resulted in a genetic gain of about 277% per generation while keeping feed conversion and fertility in their actual levels (Glasbey and Robinson 2002). Recently attention has also been given to skeletal abnormalities, metabolic disorders, and welfare.

Within 30–35 years, the development of genetically superior poultry birds capable of higher production, even under adverse climatic conditions, revolutionized poultry production and transformed it from a rural farming system to a full-fledged industry. The increase in production volume and productivity per bird were largely attributed to the method of "combined crossbred and purebred selection (CCPS)." Constant evaluation of the superior purebred lines for nicking ability and best nicking male and female lines by a specialized crossbreeding program was used for the development of four-way commercial crosses. DNA marker technology emerged as a finer tool for assessing genetic variability with advances in molecular biology techniques. Genome-wide scans identified quantitative trait loci (QTL) for use in marker-assisted selection (MAS). The discovery of single nucleotide polymorphisms (SNPs) in addition to "next-generation sequencing" technique led to the development of high-density SNP arrays as a powerful tool for genetic analysis. The prediction of genomic estimates of breeding value (GEBV) of individuals using SNPs across the whole genome paved the way for conceptualizing "genomic selection," which has emerged as the most advanced technology that revolutionizes animal production (Saxena and Kolluri 2018; Meuwissen et al. 2001).

18.5.1 Breeding Strategies for Low-Input Systems

Though breeding and genetic improvement of local chickens are complex processes, they are crucial components of sustainability of the African poultry industry (Manyelo et al. 2020). Breeding strategies are based on the careful selection of breeds or genes to be used and require a good understanding of the specific attributes or phenotype of each contributing breed, as well as its input to the general objective of the local poultry industry development.

The general aim of poultry breeding strategies should be to obtain generations of animals in the future that will produce more efficiently under future production, market, and consumption circumstances. For a breeder, this will mean firstly designing tactics to adopt and integrate new technologies and/or to improve old local proven ones to maximize the performance of the existing stock, and secondly integrating the components of a breeding program into a structured system for genetic improvement, mating the best to the best, to optimize the overall objective.

The basic components of a successful poultry breeding strategy for Africa can be structured and integrated, as illustrated in Fig. 18.2.

18.5.1.1 Defining Chicken Breeding Objectives in African Input Systems

In Africa, poultry production is carried out in a wide range of production systems which vary in both scale and resource utilization. Each system performs a valuable role in people's lives so that they will co-exist rather than transit from one to another. Africa, therefore, requires a breed or breed of chickens that will perform in these different production systems (Crawford 1990). Breeding objectives need to be clearly defined with specific and measurable selection criteria to ensure genetic improvement (Garrick and Golden 2009; Crawford 1990). The definition of breeding objective should be market-led and demand-led, directly connected with the preferred types of chicken (meat, eggs, or dual purpose). Still, it should also consider economic productivity, conservation needs, or other sociocultural considerations that could ensure the sustainability of the systems. All these parameters are interdependent with the local policy and other support mechanisms from the local governments. According to Olori (2012), the success of a global leader like Aviagen has resulted in a thorough understanding of the requirements in each of the very diverse production systems and environments that a global market entails and the capacity to meet the

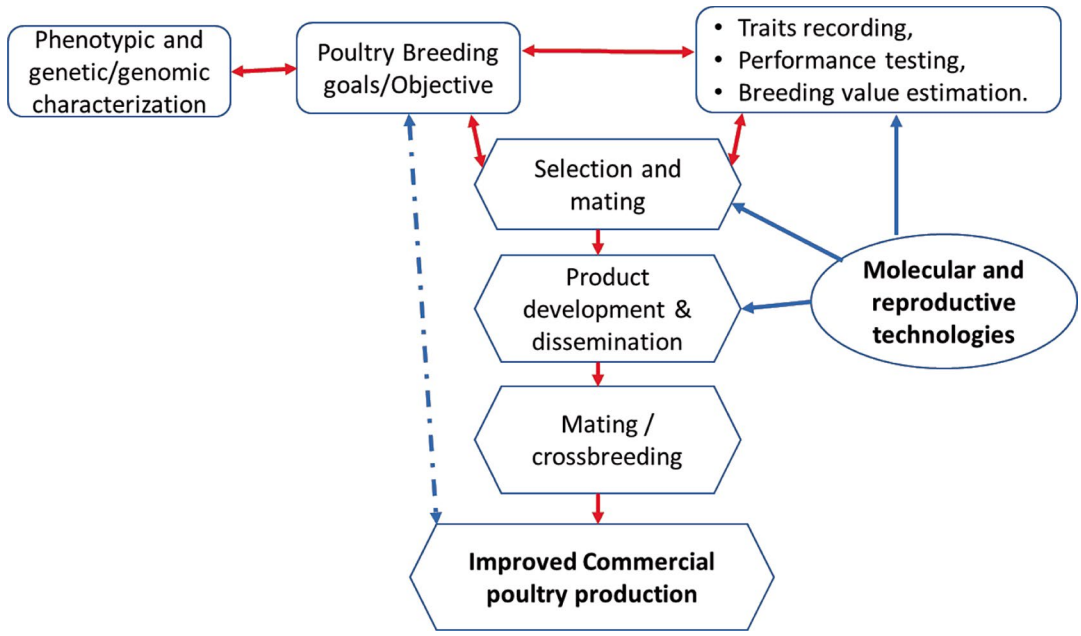

Fig. 18.2 Basic components for a successful poultry breeding strategy for Africa. (Adapted from Jack Dekkers 1990)

challenges of producing a suitable product for each market. This also applies to the future African poultry industry.

Trait Recording, Performance Testing, and Breeding Value Estimations

Trait recording is the ground for identifying animals with the "best" genetics in relation to the breeding objectives. Figure 18.3 shows some breeding objective traits normally included in a typical broiler breeding program of a breeding company (Olori 2012; Laughlin and MIBiol 2007).

Data recording is the primary objective for breeding and genetic improvement within breeding populations with pedigreed records in dispersed facilities that comprise the breeding nucleus (Olori 2012). Precision breeding robustness that will meet the needs of the future African poultry industry has been facilitated by the impact of technological advancement, especially on data recording and genomic selection which has provided poultry breeders with additional tools for breeding program efficiency and accurate selection decisions on a broad range of traits. Animal identification and traceability remain major hindrance to livestock and poultry development in Africa. This is the most basic and important information in genetic evaluation because of the need for accurate pedigree registration.

Population-specific parameter estimates require pedigree and performance recording, which is one of the biggest challenges in developing countries owing to small flock sizes and lack of commitment by smallholder farmers (Wasike et al. 2011). Performance testing will provide the essential precondition for breeders to improve economically important traits in African poultry. An on-farm performance testing was recently conducted by Abegaz et al. (2019) on tropically adaptable chicken strains under smallholders management in three countries of sub-Saharan Africa under ILRI's African Chicken Genetic

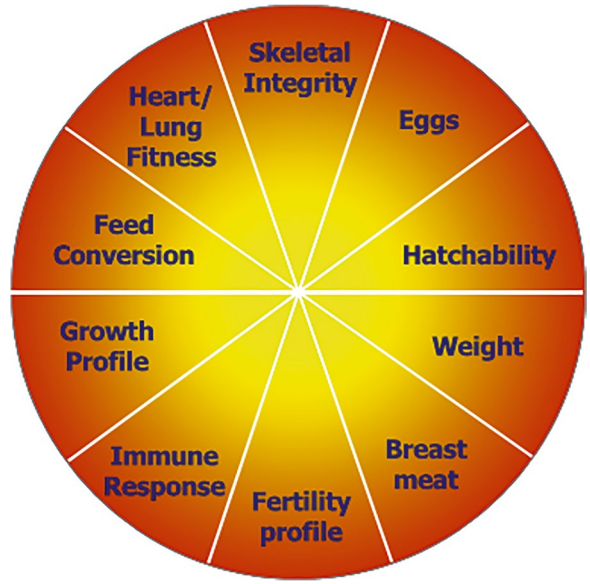

Fig. 18.3 Breeding objective traits in a typical broiler breeding program. (*Source*: Olori (2012))

Gains (ACGG) Project. This can potentially define the chicken breeds, phenotypes, and genotypes preferred by African smallholder farmers in terms of bird color, body conformation and temperament, egg and meat productivity, and overall tropical adaptability under low-input production systems. The design of this chicken performance test was informed by the ACGG Producer Level Baseline Survey (PLBS). The information generated from the performance tests prepared a roadmap for long-term chicken genetic gains programs in the respective environment or countries (Dessie 2018). A similar study in Nigeria by Bamidele et al. (2020) identified FUNAAB Alpha and the Noiler chicken breed as more suitable for dual-purpose functions (egg and meat). In contrast, Sasso and Kuroiler (meat) and Shika-Brown (egg) were reported to be better suited for a single-purpose function. These findings could guide the introduction of smallholder poultry-specific hybrid germplasms for developing a smallholder poultry production system in Nigeria.

Accessing farmers' and breeders' data for recording and performance testing should generally lead to the development of estimated breeding values (EBVs), resulting in genetic improvement in most of the preferred production traits with high heritability. The lower the heritability of a trait under selection, the slower the herd will improve (Wolc 2014).

Selection Approaches

Breeding of indigenous chickens in Africa, in general, has mainly been done by smallholder farmers who raise the birds in extensive and scavenging systems characterized by low inputs, high disease pressure, and adverse climatic conditions (Ngeno 2015). This has resulted in natural selection with the development of specific genetic adaptations for challenging environments. Natural selection is most likely a major factor that shaped the genomic variation of the rural African indigenous chicken, driving the development of their genetic footprints (Elbeltagy et al. 2019). Expectedly, selection footprints are associated with adaptation to locally prevailing environmental stressors, including high altitude, disease resistance, poor nutrition, and oxidative and heat stresses.

Although artificial selection driven by human needs has resulted in phenotypic, physiological, and behavioral changes in chickens (Rubin et al. 2010), the selection pressure has been different in African local chicken compared to the commercial breeds.

Identification of superior animals on the basis of performance for breeding has been in practice

for ages (Saxena and Kolluri 2018). Phenotypic selection allowed for the creation of native breeds from wild breeds. Selection strategies for improving egg production traits in African chicken should include part-time egg production records, persistency of lay, clutch length, FCR/Residual feed consumption (RFC), and skeletal problems (Thiruvenkadan et al. 2010). For meat-producing chicken, selection strategies should concentrate on rapid growth and carcass traits. In developing African poultry breeds intended to be dual-purpose and tropical adaptation, geneticists must consider a balance of characteristics related to growth and reproduction (Table 18.1).

At different periods of time, contrasting selection and breeding methods that gradually led to the exploitation of quantitative and molecular selection methods were employed for the genetic improvement of poultry. Some of these include mass selection, trap nesting, hybridization, artificial insemination, Osborne index in layers, family feed conversion testing, selection index, individual feed conversion testing, BLUP breeding value estimation, and DNA markers techniques.

Table 18.1 Characteristics to be balanced when selecting for dual purpose and tropically adapted chicken breeds

Growth and meat-related traits	Reproduction and egg-related traits
Growth rate	Acceptance laying in nests
Weight-for-age	Adaptation to heat distress
Feed efficiency	Aggressiveness
Meat (breast) and carcass yield and body conformation	Feed conversion per kg of egg
Livability	Disease resistance
Skeletal integrity	Egg number
Feathering-cover rate and color	Marketable egg produced per bird
Adaptation to heat distress	Egg size
Daily gain weight	Egg weight
Growth (body weight at different ages)	Fertility
Feed efficiency	Hatchability
Viability	Internal egg quality (Haugh units)
Bone density	Absence of itching
Feather: coverage	Libido
Heat adaptation (heat tolerance)	Mature weight and age
Disease resistance	Persistence of laying without broodiness
	Sexual precocity
	Shell quality (strength and thickness)
	Visual sexing

Utilization of Molecular Information and Tools Relevant to the Various Input Systems

Molecular information and techniques has been used in the selection and utilization of specific genes that affect the anatomical development of breast and/or calcium metabolism in hybrids, to the point of reaching the limit of pathological situations (Castellini et al. 2008). There are, however, limited studies involving molecular tools with high genomic coverage that will perform genome-wide scans of genomic variations and also reveal how these genomic variations can be associated with variability in resistance and susceptibility of African local chickens to rusticity and adaptability. Several first, second, and third-generation genomic markers (RFLPs, ESTs, SNP, RAPDs, micro- and minisatellites, AFLP, etc.) have considerably contributed to the development of poultry breeding (Mpenda et al. 2019; Vaarst et al. 2015; Oldenbroek and van der Waaij 2014; Oluyemi et al. 1979). Today, SNPs have become very popular with various genetic applications, including quantitative trait loci (QTL) identification and genome-wide scans. Candidate gene and high-density SNP genotyping for whole-genome selection are also in use and according to Mpenda et al. (2019), the genetic/genomic selection of resistant chicken to viral infections is a promising strategy currently in use. Reports have revealed that African local chickens are highly genetically diverse and adapted to harsh tropical environmental conditions. In the context of climate change, therefore, the African local chicken can be a potential candidate chicken population for selection of resistance to disease infections (Vaarst et al. 2015).

18.5.1.2 Chicken Breeds Development and Dissemination

The choice of breeding goals, selection criteria, the design of the breeding scheme, identification of objective traits, derivation of appropriate

selection criteria, and accurate genetic evaluation are some of the core activities of the primary breeder, which determines its effectiveness and the program's success. For its sustainable and independent development, it is critically important for African livestock, in general, and the poultry sector, in particular, to be structured as recommended by FAO (Declaration 2007) and create specialization along the value chain (Fig. 18.4). However, the sustainability of such a system will require an understanding of the intrinsic and extrinsic factors that affect poultry production and productivity in Africa, such as the climate, production systems, and available feed resources.

Considering the proportion of farmers in the low-input production system, Africa will have hardy, robust poultry breeds that can resist or survive disease outbreaks and cope with harsh weather conditions and should be resilient to climate change.

The dissemination aspect following product development entails programs for marketing and distributing superior genes into the commercial sector as parental stock. Prerequisites to successful dissemination include an efficient progeny test, applying practical breed multiplication tools, and installing trusted multipliers. The selection response dissemination depends on the breeding program's structure (Oldenbroek and van der Waaij 2014). Various intervention programs including crossbreeding/upgrading, breed substitution, and selection within the population intended to enhance the productivity of African chickens have been attempted in the past.

Mating/Crossbreeding

Crossbreeding/upgrading of indigenous chickens with exotic chickens through cockerels or pullets exchange was another genetic intervention method implemented in several African countries at a time. These interventions started in 1937 in Tanzania, in the 1950s in Nigeria and Malawi, and 1956 in Sudan, and were extended to many other African countries where local chickens were mated with such breeds as Rhode Island Red (RIR), Light Sussex, and Black Australorp chicken (Ponzoni 1984; Oluyemi et al. 1979). According to these authors, crossbreds demonstrated superior performance, but their survivability was poor. The intervention was therefore categorized as unsuccessful.

Breed Substitution

Intensification of African chicken replacement by exotic breeds started around the 1960s and has culminated with the most recent introduction of the Kuroiler chicken. In principle, the main objective of the substitution was to have chickens with better growth and superior egg production

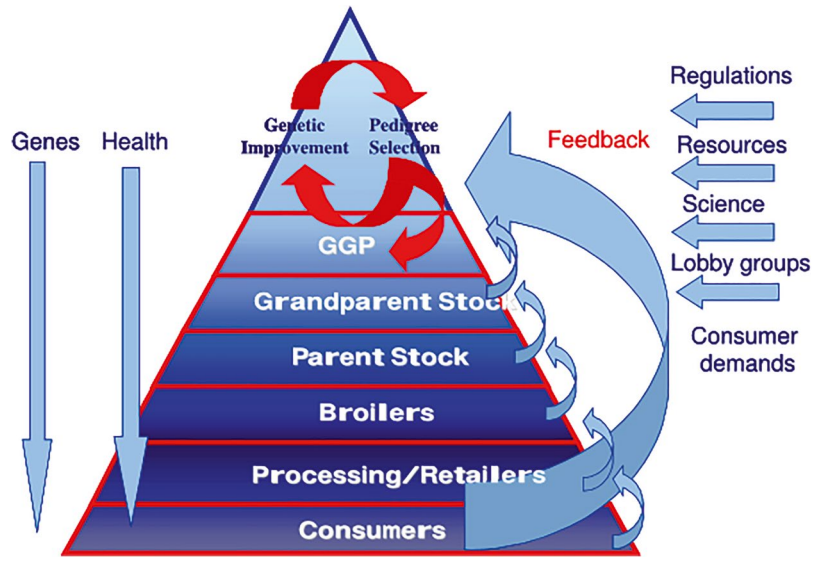

Fig. 18.4 Pyramidal structure of poultry breeding. (*Source*: Olori (2008)

performances. However, the adaptability of the exotic chickens was poor and could have been improved under the prevailing tropical conditions of production systems before distribution. Moreover, substituting locally adapted breeds with exotic breeds that are more susceptible to the different environmental stressors, though more productive was contrary to the global trend on the conservation of indigenous genetic resources because it was threatening the existence of the indigenous breeds (Kosgey et al. 2006; Hanotte et al. 2010). The only way to prevent local poultry breeds' substitution from occurring would be to make them more valuable to farmers. This can be realized by genetic improvement through careful within-breed selection.

Within-Breed Selection

Within-breed selection has been one of the major strategies used in some African countries, like Egypt, Nigeria, and recently Ethiopia, for the genetic improvement of indigenous chicken (Hossaryl and Galal 1994; Wondmeneh et al. 2014). In Egypt, this strategy was successful as it created two pure lines strains of the Fayoumi breed of chicken with a 60% higher egg production rate when compared with the original indigenous breed (Hossaryl and Galal 1994). In Ethiopia, the selection of Horro local chicken started in 2000 at the Debre Zeit Research station. This program has successfully increased the egg production rate by 123.5% to 75 eggs at week 45 and reduced the age of the first egg from 203 to 148 days by the fifth generation. It also led to an increase in the body weight of the birds (Wondmeneh et al. 2014). The within-breed selection is a promising strategy for improving the productivity of African chickens compared to crossbreeding or upgrading systems. As a baseline consideration, the lessons from the failed crossbreeding/upgrading programs should be put into consideration when initiating breeding programs for within-breed selection. These failures demonstrate that success in any crossbreeding/upgrading program requires proper planning, infrastructural development, sustainable funding, and an understanding of the production environment.

Under the smallholder farming system, functional breeding programs remain a big challenge. Earlier native chicken genetic improvement efforts mostly failed for the following reasons among other things: (i) dependence on breed replacement and/or indiscriminate crossbreeding with exotic breeds that had no sustainable replacement plan and no intentional selection on the dam line; (ii) incompatibility between the exotic genotypes and the producers' breeding objectives, management practice, and environmental conditions; (iii) adoption of complex breeding programs that require and technological development and many logistics; and (iv) insufficient/ no systematic breed evaluation studies that ensure a fair comparison of the relative merit of the indigenous and the exotic breeds that considers the role of genetics × environment interactions (Wurzinger et al. 2014). Smallholder production systems are normally characterized by small population size, single-sire herds/flocks, lack of animal identification, absence of performance and pedigree recording, illiteracy, poor infrastructure, and ill-functioning institutions. These in addition to the mobility of pastoral flocks pose additional difficulties in data recording and selection practice.

18.6 Increasing Productivity Without Sacrificing the Adaptability of Traits to the Production Environment

The success or failure of a breeding program is profoundly affected by obstacles encountered during the breeding process. Chicken farmers, chicken consumers, the food business, and, increasingly, the general public all have a hand in setting these standards. Finding that sweet spot between competing needs is an ongoing effort that calls for forethought about the future and systematic planning of breeding initiatives. In chicken breeding programs, beyond the apparent

breeding objective features, other traits, such as the chickens' health and welfare and their ability to adjust to the feed of lesser quality and harsh climates, play a crucial influence in the birds' ability to produce and reproduce. Robustness in performance, according to Niyas et al. (2015), is "the ability to combine a high production potential with resilience to stressors, allowing for the unproblematic expression of a high production potential in a wide variety of environmental conditions." Robustness and disease resistance have improved significantly through selective breeding programs that use both genomics and new quantitative genetic theory to improve the response of birds to environmental changes as well as predicting adaptation responses (Burrow 2012).

The major environmental stressors affecting productive and reproductive traits are heat and nutrition related. Heat stress is the result of high ambient temperature which adversely affects both production and reproduction. The effect of heat stress on livestock is reflected by reduced feed intake, poor growth performance, panting, increased rectal temperature, respiratory rate, and water intake (Augère-Granier 2019). Changes in hematological parameters, electrolytes, metabolites, increased mortality and morbidity, and reduced immune function also result from the effect of heat stress (Sejian et al. 2010). Fitness and adaptation, which determine an animal's tolerance to adverse conditions, are influenced by individual genetic makeup. Adaptability measures the potential or actual capacity to adapt (Hoffmann 2010). Many breeds have developed adaptive traits that increase their survivability in harsh environmental conditions (Mirzaie et al. 2018; Barker 2009). The range of unique adaptive characteristics of poultry birds which evolves in stressful environments enables them to survive and be productive in adverse environmental conditions.

Initial steps in a breeding program should focus on selecting the most adaptable breed for the target environment or production system. If this information is disregarded, the animals' fitness will decline. An increase in the susceptibility of birds to environmental challenges resulted from the selection for high production, according to (Gaughan and Cawsell-Smith 2015). Although optimum production is easier to achieve under controlled environmental conditions, which is common in poultry production, it is not necessarily the most economical. Adaptation involves trade-offs that must be considered when selecting animals for use in breeding programs. Broadly, adaptation is a short-term, long-term, or generational (genetic) response to challenges (stressors). Short-term responses to a stressor encompass reduced feed intake and increased respiration rates when birds are exposed to high ambient temperatures. However, short-term responses also have a genetic basis, with some animals able to cope better than others when exposed to the same stressors. Inherent genetic variation is the primary factor that determines the ability to adapt as measured by survival and reproductive rates which interact with the constraints of the environment creating phenotypic variation (Mirzaie et al. 2018). Adaptation is often at the expense of performance, and survival rate is often better in animals with "low" performance because their input needs (mainly feed) and internal heat production are lower (Gaughan and Cawdell-Smith 2015). However, the issue of whether to directly select for adaptive traits, and production, reproduction, and growth traits in harsh environments is debatable. Generally, favorable correlations suggest that adaptive traits would not be compromised when selection is emphasized for performance traits (Burrow et al. 1991). Indications exist to suggest that selection for better performance traits (e.g., reproduction, survival, and growth) in stressful environments will lead to selection for the most suitable animals (Turner 1984).

One of the most cost-effective tools for achieving a permanent change in bird tolerance to heat stress is the application of genetic principles of selection. Although its implementation strategies are challenging because of the complexity of responses to heat stress and the antagonism between heat tolerance and productivity. Variability in the population is the basis

for any genetic improvement which is primarily determined by response to selection in the trait under consideration and other correlated traits of economic importance. The magnitude and the direction of correlated responses play a major role in the development of effective breeding strategies for improved productivity (Hassan et al. 2009; Boki 2000; Hill and Mackay 2004). However, as the number of traits in a selection program increases, the amount of genetic progress that can be made in the improvement of any one trait slows down unless the traits are highly genetically correlated (Bamidele et al. 2020). The use of genetic tests based on single nucleotide polymorphisms to identify genetic markers that predict thermotolerance (Dikmen et al. 2008) in addition to genomic selection offers new opportunities for commercial breeders to produce better breeds and manage their birds in the future (Niyas et al. 2015; Burrow 2012).

There is, however, the need to duly emphasize environmental effects when selecting breeding stocks and planning breeding strategy since the phenotype depends on genotype and environment. Most breeding companies need to pay more attention to the impact of the genotype x environment (G × E) interaction because having a selection environment that accounts for the traits of importance is inconvenient (Sørensen 2005). A breeding scheme should evolve animals that perform optimally under specific climatic conditions. The chance for a G × E interaction increases as the difference between the environments grows, and the genetic distance between the breeds is large (Sørensen 2005). Therefore, every breeding animal must be evaluated under specific climatic conditions before being released for commercial use. The success of a breed or strain in a particular environment depends on its ability to adapt and perform in that environment/climatic zone. The available evidence for genetics × environment interactions in performance analysis of poultry birds in various suboptimal conditions emphasizes the need for breeding programs to improve performance in a particular environment.

18.7 Breeding Systems

Regardless of the character involved, the kind of progeny (young ones) produced determines whether a male or female will be kept for breeding purposes. When a male mated to a female with a high egg production record is a progeny of a high egg-producing dam, the daughters frequently produce a high number of eggs. The results obtained from a given mating are largely determined by the genetic contribution of the birds that mated. Breeding systems can, therefore, be classified depending on the aim, which can either be to increase homozygosity or heterozygosity in random mating, inbreeding, or outbreeding (Saxena and Kolluri 2018).

18.7.1 Random Mating

This involves individual mating that does not involve any form of selection. It is used to develop a control population for comparison and measuring the effects of other breeding systems. Controlling population also helps in the estimation of the effects of the environment, which in turn, aids in the estimation of true genetic gain through any breeding method.

18.7.2 Inbreeding

Inbreeding is the mating between individuals more closely related than the average relationship between all individuals in a population. Inbreeding has its own benefits and can be consistently carried out for several generations with benefits, although the consequences can be damaging.

There are three distinct ways inbreeding and be practiced. These are as follows:

1. Close inbreeding: This is mating between siblings, parents, and progenies.
2. Strain formation: This involves developing small groups within a breed for a special desired character. It is usually regarded as a mild form of inbreeding.

3. Line breeding is a form of inbreeding with an ancestral line where an attempt is made to concentrate the inheritance potential of a common ancestor (usually a male) on an individual. It is backcrossing to the same parent for several generations in succession, an intensive form of back-crossing.

18.7.3 Outbreeding

Outbreeding is the opposite of inbreeding, and it is the interbreeding of individuals that are relatively unrelated as compared to the average relationship of individuals within the population. Mating between strains/inbred lines is a form of outbreeding (Hutu et al. 2020).

The methods of outbreeding (crossbreeding) include the following:

(a) Single or two-way cross: When two populations of the same or different breeds are crossed to produce an F1 generation not intended for breeding purposes, the progenies usually exhibit hybrid vigor, especially when inbred lines are involved. When two inbred lines of the same breed are crossed, the progeny is said to be crossbreds.
(b) Three-way cross: In a three-way cross, F1 crossbred females or males are mated to males/females of a third line to obtain an F2 progeny.
(c) Four-way cross: In a four-way cross, two different single crosses (AB and CD) are made to obtain ABCD. Four-way cross is usually practiced in poultry breeding program between inbred lines of low viabilities since only a relatively small number of animals of lines need to be maintained.
(d) Crossing for a new breed: To produce modern-day breeds of poultry birds, different breed types have been crossed to combine desirable traits from many sources. The foundation crosses were subjected to inbreeding combined with selection practice to consolidate them into true breeding populations to meet desired needs (breeds) (Singh n.d.).

18.7.4 Mating Methods

Mating is the act of pairing a male and female for the purpose of reproduction. Different methods of mating are commonly practiced in poultry.

1. *Pen mating*: It is a mating system where a male is mated to a group of females in a pen during the breeding season. It is sometimes described as a mass mating system where two or more males are mated with several females in a single pen. Male to female ratio is generally high in pen mating. It ranges from one male to 12 to 15 females in egg-type chickens and 10 to 12 for meat-type chickens.
2 *Stud mating*: In this case, the males are usually confined to individual pens (studs) within a large laying pen and the females are held in the stud for a known period of time, till they are mated. They are then replaced by other ones. In this method, mating at least once every 5 days or twice a week is desirable for optimum fertility.
3 *Artificial insemination*: Artificial insemination (AI) is the technique where semen collected from a male is introduced or deposited in the female reproductive tract using a pipette. It is usually a three-step procedure that involves semen collection, semen dilution, and insemination. However, undiluted semen can be used directly within 30 min of collection. On average, one cock yields about 0.5–1.0 ml of semen, depending on the body weight. Usually, about 0.05–0.10 ml of semen is enough to inseminate one hen.
4 *Flock mating*: In this mating type, large numbers of hens are kept with all the breeding males in a single flock at a ratio of approximately 10 hens per cock. Record keeping is minimal in this mating system as the lineage of individual chick is relatively unknown. Because of the large number of birds per unit, flock mating reduces the costs of operation and it is preferred where pedigree records are not maintained (Singh n.d.).

18.8 Omics Technologies in Selective Breeding for Economic Traits in Chicken Production

Genetic selection and breeding are crucial breed development tools that have resulted in genetically superior and disease-free animals with improved productivity and efficiency in various livestock species (Rexroad et al. 2019; Erasmus and van Marle-Köster 2021). Conventional animal selection and breeding methods were based on observed production trait characteristics and the estimations of the breeding value (BV) of economic traits included in genetic improvement programs (Brito et al. 2021). However, there are limitations in these methods, particularly for traits that are sex-limited, traits with low heritability, and traits expressed later in life (e.g., carcass traits). The consequence is that their genetic gain is slow because of high generation intervals. However, with the onset of high-throughput omics techniques, discoveries and availability of multi-omics technologies, and development of sophisticated analytic packages, several promising tools and methods for the estimation of the actual genetic potential of animals have been developed. In the last two decades, landmark developments in omics technologies have revolutionized genetic selection for animal breeding. It has now become possible to collect and access large and complex datasets which provides new opportunities for a better understanding of the mechanisms regulating actual animal performance. Large and complex datasets comprising different omics (genomics, transcriptomics, proteomics, metabolomics, and phonemics) data as well as animal-level data (such as longevity, behavior, and adaptation) can now be easily accessed and studied to provide a better understanding of the regulatory mechanisms of animal performance.

Better and more accurate breeding values (BVs) can now be estimated with data generated through omics technologies to increase genetic gain by assisting the selection of genetically superior, disease-free birds at an early stage of life for enhancing productivity and profitability. Selection and breeding programs utilize omics-generated data to estimate more accurately breeding values for early selection and to achieve reduced generation interval and increased rate of genetic gain (Krassowski et al. 2020; Chakraborty et al. 2022). Several omics tools have been developed in the last two decades for the collection and analysis of high-throughput data in proteins (proteomics), mRNA transcripts (transcriptomics), gene sequences (genomics), microbial diversity (metagenomics), epigenetic regulation of gene expression (epigenomics), metabolic profile (metabolomics), etc. (Chakraborty et al. 2022). Omics technology applications allowed for extraordinary progress in the study and understanding of many quantitative traits in broilers (see Chap. 23). The approaches used in transcriptomics, proteomics, and metabolomics have been successfully applied for investigating the molecular basis of complex traits, such as feed efficiency and muscle myopathies, and for the assessment of the molecular responses to nutritional treatments and evaluation of important aspects relating to immunity and disease resistance (Zampiga et al. 2018).

18.8.1 DNA Markers and Genomics Selection

Tremendous advancements in molecular genetics have provided a better understanding of quantitative economic traits in animal production, ever since Chang et al. (2003) reported that DNA markers is advantageous in animal breeding to foretell genetic makeup and animal performance. Several genes and gene combinations have been found to be directly associated with animal performance and production efficiency (Rexroad et al. 2019; Ruan et al. 2021). In addition, many quantitative trait loci (QTL) responsible for trait diversity have been identified for various production and reproductive traits and are in use for selection and breeding decisions (Zhang et al. 2021). Several genetic markers have also been discovered and used in marker-assisted selection (MAS) of breeding stock (Ma et al. 2021). Marker-assisted selection (MAS) uses genomic

and phenotypic information to increase reliability in the selection process for the genetic improvement program. Identified quantitative trait loci (QTLs) and candidate genes were crucial for producing chickens with more desirable meat characteristics.

The decoding of the genomic sequence soon after releasing the draft chicken genome sequence (Hillier et al. 2005) showed that there are millions of places within the chicken genome where poultry birds differ from each other at a single nucleotide (Wolc 2015). The search for differences between individuals in their DNA sequence and differences in observed phenotypic traits resulted in the identification of single nucleotide polymorphisms (SNPs). In the chicken, 2.8 million SNP markers have been mapped and are available for evaluation. The first "high-density" panel of genetic markers for chicken 6000 single nucleotide polymorphisms (SNPs) was released in 2007 (Andreescu et al. 2007), and a 600,000 SNPs panel (Kranis et al. 2013) was released in 2013. Genome-wide association studies (GWAS) demonstrated the link between SNPs and QTLs Field 105 using high-density SNP chips. Whole-genome sequencing (WGS) was a breakthrough in detecting molecular signatures for selecting and breeding animals (Bovo et al. 2020). The genome is a complete set of genetic material present in an organism.

The paradigm shift in QTL- and candidate gene-based approaches for genetic selection leveraged on the landscape of genome sequence. In genomic selection technology, a sample DNA can be used to calculate the breeding values of animals. Meuwissen et al. (2001) initially proposed the method, which involves scanning entire genome-wide genetic markers to generate the breeding value of the selected candidates. This method is based on certain assumptions such that linkage disequilibrium between the markers and the polymorphisms causes variation in important traits (Meuwissen et al. 2001). In genomic selection, the underlying principle is that information generated from many markers can be used to predict genomic estimated breeding values (GEBVs) without understanding the specific location of the gene on the genome length. In the selection of traits of economic importance relatively governed by many genes, sex-limited traits (such as egg production and egg quality), and traits with low heritability (such as disease resistance), this method has shown higher reliability and efficiency when compared to the traditional method (Khare and Khare 2017). This technique also increases the accuracy of selection for new breeding animals by selecting beneficial genes. The availability of genomic information has recently permitted the simultaneous combination of pedigree and genomic relationships in a single-step genomic evaluation method (ssGBLUP). Using a random regression model, an increase of about 23% in heritability estimates for fertility and hatchability was obtained using this method. In addition, the ssGBLUP method resulted in higher prediction accuracy when compared with the traditional pedigree method (Makanjuola et al. 2021b).

Genomic selection is considered the most appropriate standard breeding method in livestock. Poultry breeders have taken a huge interest in its application and execution after numerous successful validation studies (Wolc 2015; Wang et al. 2013) with the main aim of yielding rapid genetic progress in its selection program. Increased accuracy in genomic prediction is the main advantage exploited by implementing the genomic selection program in the poultry industry (Kaisa et al. 2020). The revolution of genomic selection has already been described as an efficient technology in poultry improvement programs, justified by its increased rate of genetic gain.

Genomic selection is considered particularly advantageous as it can be used to select animals for breeding at an early stage of life without reference to their own breeding or production records (Fig. 18.5).

Genomic selection has become widely accepted for selecting animals for breeding with advances in high-throughput omics technologies which help in the identification of functional SNPs and their priority to increase the accuracy of the genetic selection (Chakraborty et al. 2022; Tan et al. 2017; Chang et al. 2019). Further, population-level omics (e.g., population genom-

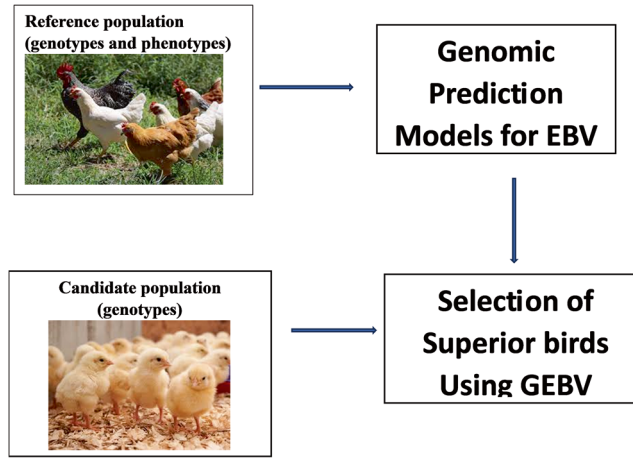

Fig. 18.5 Genomic selection in poultry

ics) hold tremendous potential for classifying individuals based on allelic diversity and the identification of genetically related individuals (Lippert et al. 2017).

18.8.2 Biomarkers

Biomarkers are quantifiable biological molecules representing specific physiological states' characteristics that reflect the molecular changes caused by the interactions between organisms and environmental factors. The identification and validation of biomarkers (genes, transcripts, proteins, and metabolites) associated with fertility have shown great potential for the improvement of reproductive efficiency in poultry. Biomarkers play key roles in the definition of animal diseases, although, some have poor diagnostic specificity and are not pathognomonic for diseases (Ali et al. 2020). The biomarker technique is a post-genome technology induction. It acts precisely on a specific biomarker in a pool of molecules inside a tissue or fluid. In the biomarker field, the development of omics is a remarkable discovery in the assessment of animal health (Ali et al. 2020; Moore et al. 2007; van Ginneken 2017). The rapid advancement of post-genomic technologies in transcriptomics, proteomics, and metabolomics has allowed for the development of strategies that help to identify biomarkers from the thousands of molecules in a tissue or biological fluid (Moore et al. 2007). Based on the analysis of RNA-level gene expressions, the occurrence and change of rules of the transcriptome in biological cells is what is generally called transcriptomics (Oskoueian et al. 2016; Wang et al. 2009; Lockhart and Winzeler 2000). Large-scale gene expression profile techniques, qRT-PCR, and biostatistical methods such as principal component analysis (PCA), hierarchical cluster analysis (HCA), and partial least squares discriminant analysis (PLS-DA) (Oladokun and Adewole 2022) are used for the determination of transcriptional biomarkers on the transcriptomic platform. The use of biomarkers will increase the rate of genetic improvement due to more accurate selection. Biomarker techniques have been successfully applied in molecular medicine, disease diagnosis, and prediction. Current biological processes can be diagnosed and monitored promptly by identifying and monitoring biomarkers (Oskoueian et al. 2016; Su et al. 2022). Blood biomarkers enable an early-warning system in poultry, detecting health challenges like coccidiosis and heat stress. Biomarkers are also currently being used in precision nutrition studies in broilers to identify amino acid imbalance and monitor intestinal health in poultry birds (Hassan et al. 2009; van Marle-Koster and Nel 2000; van Marle-Koster 2008; Ramadam et al. 2012)

Along with platform sensitivity and data analysis, technological advances in extraction and fractionation techniques have enabled the discovery of next-generation biomarkers with high sensitivity, specificity, and precision that are useful

for monitoring the health and well-being of poultry birds (Al-Dawood 2016). These biomarkers are also used for surveillance against pathogens, assessing pharmacologic responses to therapeutic and directing genetic selection and breeding. A number of proteomic biomarkers, for example, have been identified and used for the diagnoses of gastrointestinal, respiratory, diseases, and heat stress in poultry (van Marle-Koster and Nel 2000; Ramadam et al. 2012; Al-Dawood 2016). The acute phase proteins (APPs) are blood biomarkers associated with innate immune response and they are responsible for systemic reactions to inflammations. Increases in the concentrations of APPs are valuable biomarkers of inflammation in the body (van Marle-Koster 2008). When physiological parameters deviate from normal, biomarkers are useful in determining the degree of physiological imbalance and early detection reduces disease risk and improves production and reproduction performance (van Marle-Koster 2008; Ramadam et al. 2012).

18.9 Strategic Approach to Sustainable Use and Genetic Improvement

18.9.1 Accounting for Major Environmental, Structural, and Socioeconomic Differences Among Production Systems

Although the FAO recognizes four poultry production systems, clear differentiation can be made between the commercial/intensive systems and the extensive system. The poultry production system in Africa and elsewhere in the developing world includes both commercial (broilers and layers) and traditional birds relying mainly on indigenous and improved dual-purpose breeds kept primarily in a free-range system. Commercial poultry production is mostly practiced in urban and peri-urban areas, while the traditional poultry system is confined to rural areas. The traditional production system, however, contributes most of the flock and supplies the bulk of poultry meat and eggs consumed in both rural and urban areas. Poultry production's impact on the environment is less problematic compared to other livestock species. Structurally, most commercial setups are more vertically integrated than the extensive production system, including breeder farms, hatcheries, layer and broiler farms, traders, and processors. Intensification demands keeping big flocks of chickens, whose feed and water consumption remains high. Commercial or intensive poultry production systems are mainly profit-oriented and have a less direct socioeconomic contribution to individual households like the smallholder or the extensive poultry production system.

18.9.2 Ensuring Participation of End Users (the Chicken Keepers)

End users (both men and women) should have access to relevant information and be involved in policies formulating policies and planning with ample opportunities to give personal opinions. Women comprise most of the world's poor and poor livestock keepers (Bagnol 1998), who generally own and manage village chickens. Village chickens are normally the most essential assets for female-headed households, who have the power to control the income generated from them (Guèye 2000; Donadeu et al. 2019; MacVicar 2020). They are easier to manage and place little or no additional burdens on these women. Apart from the provision of household food scraps, these birds find their feed and require little supervision (Donadeu et al. 2019; Alders et al. 2010). Rural poor women livestock keepers in low- and middle-income countries (LMIC) are more likely to own chickens and goats as assets that generate income, provide high-protein food, accumulate wealth, confer social status, protect against economic shocks, and act as financial reserves for the family (McKune et al. 2021). The poorest smallholder farmers in developing countries tend to own only chickens, and as they progress out of poverty, pigs and small ruminants (goats or

sheep) are added, with cattle, camels, or buffalo being the most desirable animals (Donadeu et al. 2019). Most of the household men, head the households. Although decisions are expected to be made in consultation, women often accept the decisions of their spouses. In villages, men get interviewed about the poultry intervention, while women responsible for poultry are not given a chance. Women might prefer technologies that do not require much hard work, which would not burden their already heavy workload.

18.9.3 Multiplication and Delivery of Improved Strains

One of the main tasks of breeding programs is the distribution of the improved chicken strains to users across broader geographies. The ability of the improved chicken strains to strive and benefit farmers in harsh environments serves as a success indicator for breeders and farmers alike. Commercial chicken strains or exotic breeds introduced in Africa failed to bring the expected result due to high feed, veterinary, and energy costs (Sonaiya and Swan 2007). Exotic birds were not adapted to the local conditions and demanded high feed investments, veterinary support, and housing conditions. Local and tropically adapted breeds were not given due attention until recently. A good example is the BMGF-funded, ILRI-led African Chicken Genetic Gains project. ACGG blends new chicken strains, enhancing delivery systems to support the adoption of highly productive birds in semi-scavenging systems in the tropics. The strains were selected based on their previous history of being used in harsh environments. Brooded and vaccinated birds 45 days old were widely tested in Ethiopia, Nigeria, and Tanzania (Marshall et al. 2019). The key to the success of such projects or sustainable distribution of improved genetics will be its ability to deliver more productive chickens on a large scale and reach the users whenever demanded. The poultry industry is a private domain whose motivation is essentially profit. Distribution models differ from location to location depending on the existence of the performing value chain. However, sustainable distribution should be identified after several models have been tested. Prior identification of the right and preferred chicken strain traits and strategically supporting actors along the value chain will help reach the poultry producers effectively. Transfer and adoption of livestock technologies are particularly limited because most entail very high costs and require institutional linkages and partnerships to bridge this gap and transform traditional subsistence production into new production objectives targeting the market (Dana et al. 2006). Poultry development programs were possible through the support of donors. The programs reached out to several households in different geographies. The sustainability of such programs can be possible if there is a buy-in from the governments.

18.9.4 Promote Step-By-Step Development and the Sustainability of the Actions Implemented

Several attempts were made in Africa to develop poultry production and productivity. The intervention involves improving the management of chickens, introducing exotic blood, vaccination, and so on. Most of the interventions have contributed to the overall productivity level but could not sustain (Kitalyi 1998; Boki 2000). The results observed in limited locations or research stations may indicate the potential of the interventions but can only bring about a change if scaled out in huge numbers. Different interventions need to be brought together into a package. Most technological interventions should be supported by coordination, planning, marketing, etc. Scaling out of a particular technology can best be promoted in a public–private partnership model involving local agriculture businesses as paid technology and input agents. An institutional mechanism needs to be established to arrange accessible credit facilities for the farmers and local entrepreneurs to scale up proven technologies.

18.9.5 Conclusion and Future Perspectives

Africa is home to a diverse poultry population. Indigenous poultry resources have never been fully utilized, although they remain the primary source of chicken meat and eggs. Farmers have never been given a chance in the formulation of development policies that led to the introduction of commercial chicken breeds from overseas. Commercial chicken production has not benefited smallholder farmers due to their need for management inputs that remain challenging in low-input systems. Breeding companies can design products for specific ago-ecologies in Africa. The approach is expensive as agro-ecologies are quite diverse, and the demand shifts every time. The logical path is to consider breeding programs by countries involving indigenous chickens. Breeding programs require proper planning, understanding, and execution capabilities. It will be essential to understand the production environments. The necessary steps need to be followed, and modern technologies should be considered at the right time and stage.

Several attempts were made in Africa to develop poultry production and productivity. The interventions involved improving the management of chickens, introducing exotic chicken genetics, vaccination, and so on. Most of these interventions contributed marginally to overall productivity, especially among the crossbreds which could not even be sustained. An institutional mechanism must also arrange accessible credit facilities for farmers and local entrepreneurs to scale up proven technologies. Locally developed indigenous chicken can be important in poultry development under low-input production environments.

Poultry production systems in Africa and other developing parts of the world include both commercial (broilers and layers) and traditional birds relying mainly on the indigenous and improved dual-purpose breeds primarily kept on free-range. End users (farmers) should have access to relevant information, be involved in policy formulation and planning, and be given ample opportunities to air their opinions. The ability of the improved chicken strains to strive and benefit farmers in low-input environments serves as a success indicator. Breeders/farmers will be able to design products specific to each low-input agro-ecology. This provides room for countries to develop their breeds involving indigenous chicken. Commercial chicken strains or exotic breeds introduced in Africa failed to bring the expected result because of high feed, veterinary, energy costs, and the need for specific infrastructure. These birds were not adapted to local environmental conditions and demanded high feed investments, veterinary support, and housing conditions. Transfer and adoption of new livestock technologies are limited because most entail very high costs and require institutional linkages and partnerships to bridge the gap and transform traditional subsistence production into a market-oriented production system.

This chapter extensively covers breeding goals, strategies, and breeding programs relevant for chicken production systems in Africa. This approach therefore presents the opportunity to harness the potential of poultry genetics resources that could adapt efficiently to the tropical environment while enhancing food security, farmer livelihoods, and income opportunities to those that need it the most.

19 Defining Breeding Goals and Breeding Strategies for Pigs in Various African Production Systems

Donald R. Kugonza and Richard Osei-Amponsah

Abstract

Pigs (Sus scrofa) are an important animal genetic resource in Africa with many different genotypes adapted to various environments and production systems. Sustainable animal breeding programmes seek to correctly evaluate breeding candidates and select the ones most appropriate to be parents of the next generation in order to achieve desired breeding goals and objectives. This chapter presents an overview and significance of pig production in Africa as well as components of sustainable breeding programmes in the context of farmer-preferred traits. Cognisant of genotype–environment interactions, there is a need to select appropriate genotypes for specific breeding objectives and production systems. Additionally, we discuss the changing environmental conditions and market demands and make a case for the need to breed more productive, resilient pigs for both current and future generations. However, this must be done in consonance with available genetics, feed, housing, healthcare and the targeted markets. The importance of indigenous and locally adapted pig breeds and their sustainable utilisation and conservation as important players in protein-source food security, livelihoods and wealth creation are presented. The need for all stakeholders to be actively involved in defining objectives for pig breeding, human and institutional capacity building as well as sustainable government policies cannot be overemphasised. Finally, we posit that any pig breeding programme aimed at improving the productive and adaptive qualities of pigs in Africa should aim at conserving locally adapted genotypes while making use of emerging innovative technologies for greater efficiency.

19.1 Introduction

Pork production is an important animal protein food worldwide, accounting for more than two-fifths of all red meat consumed worldwide

© The Author(s) 2026

E. M. Ibeagha-Awemu et al. (eds.), *African Livestock Genetic Resources and Sustainable Breeding Strategies*, Sustainable Development Goals Series, https://doi.org/10.1007/978-3-031-92076-9_19

and in most African countries, a source of income, livelihoods and socio-cultural values. Pig husbandry has been an economic activity over the past seven millennia but has undergone transformation mainly driven by shifts in pig product valuation and processes to develop preferred pig genotypes. A host of pig breeds have been developed or evolved in and beyond Africa and each breed development process has focussed on a set of breeding objectives. Pigs are reared alongside a wide array of other livestock species in varying production systems and with different production goals and priorities, as well as management strategies. In all the production systems, pigs provide cash income from animal and pork sales, meat for home consumption and manure to enhance soil fertility, while in a few systems particularly in smallholder semi-intensive management, pigs are also used as a means to save the farmers' wealth and secure their livelihoods. A breeding objective specifies the ideal pig that a producer aims to breed and such a pig is often identified through selection based on the traits of interest. It is pertinent that all pig breeding enterprises establish breeding objectives and goals, and then implement selection processes that aim to meet the identified objectives as part of the general planning process of the business. The determination of the breeding goal is one of the most critical elements and foundation of breeding as it determines the direction, process and success of genetic improvement. Breeding goals have over time shifted from principally production-driven targets to more balanced breeding goals that target simultaneous improvement of production, efficiency, health, functional (Miglior et al. 2017) and adaptive traits.

The primary goal of genetic improvement is the selection of the best animals of each generation to be parents of the next generation. Selection is a major component of the breeding programme which describes the process of choosing individuals that meet the requirements of the breeding objective to enable them to pass traits of interest to their offspring within a breeding enterprise. The process considers both traits of a subjective nature such as visual assessment and objectively measured traits such as growth rate and genetic attributes including heritability.

19.2 What Are the Key Considerations/Drivers for Implementing Sustainable Pig Breeding Programmes in Africa?

19.2.1 Farmer-Preferred Breed and Trait Preferences

Breeding programmes should consider the breeding goals and objectives of the farmer. Commercial pig farmers normally focus on a few traits of economic importance, such as fast growth rates, larger carcasses and disease tolerance. On the other hand, goals for smallholders include aesthetic (colour and patterning), behavioural aspects (temperament, mothering ability, foraging behaviour, herd-ability and other aspects that minimise labour inputs), adaptability, in particular the ability to survive under low-cost management levels (e.g. inadequate feeding and housing) (Halimani et al. 2020). Traits of religious and socio-cultural importance are also of importance to local farmers. Therefore, participatory approaches to designing breeding programmes that involve livestock breeders and farmers at every stage of the planning and implementation of the breeding programme, including the definition of the breeding objective, are necessary (Roessler 2019). A programme that meets the need to develop a sustainable industry must consider the prevailing conditions of the piggery sector—the strengths and opportunities—as well as the challenges reflected in the weaknesses and threats (Table 19.1).

19.2.2 Genotype by Environment Interactions

These arise when the best genotype in one environment is not the best genotype in another environment or when genotypes differ in their

Table 19.1 A SWOT analysis of a typical piggery value chain

Strength	Weakness
A growing market for animal proteins due to the increasing human population and higher incomes	Relatively low knowledge level, especially on disease and farm management
Pig farmers getting more organised	Lack of practical education in livestock management
Government policies towards piggery are favourable in several countries	Few farmers trained in livestock management
Changing consumption patterns towards quality products for a growing middle class	Limited of rural veterinary and artificial insemination extension services
High domestic production of maize	Lack of independent testing facilities for feed and veterinary inputs
Growing awareness and interest in improved technologies by farmers	Limited of applied biosecurity on farms
Growing investments into piggery business	Lack of quality standards and enforced slaughter regulations
Growing consumption and demand for pork and pork products	Lack of specialised pig feed supply market
Increasing interest into piggery by youth farmers	Underdeveloped market for quality pork meat
Improving the quality of pig carcasses	Mostly practiced as non-commercial farming
Availability of prophylactic treatment options for pigs increasing	Lack of abattoirs
	Transport of pigs is not allowed by night according to laws, leading to informal fines
Opportunity	**Threat**
Great potential to become a strong export market due to relatively low cost of production	Seasonality in input prices
Increasing demand for pig products	High reliance on the domestic market
Increasing demand for value-added goods	High animal disease prevalence, especially African swine fever
Improvement in waste management practices can greatly benefit the sector	Pig farming is not a priority for some national governments
Sector growth allows for local feed production	Traders have excessive market power, leading to low farmer profitability
Genetics/breeding certification and registration agency exists	Market flooded with under-size piglets of non-descript genetics

response to environmental factors (Mulder and Rashidi 2017a). Given the wide variety of Sus genotypes and production systems (Chaps. 2 and 8), Africa needs to breed pigs that perform optimally in a wide range of environmental circumstances and meet the needs of stakeholders. The genetic correlation between the same trait across different environments (genotype by environment interaction) determines the robustness or sensitivity of the genetic potential of a specific trait to the environment to which it is exposed.

According to de Leon et al. (2016), genotype-by-environment interactions include the ability of genotypes to express different production potentials when subjected to different environments and production systems. Some pig breeds are most suited to perform in particular environments and suffer excessive stress when transferred to other environments. A common example is the improved performance of exotic and crossbred pigs raised at research centres or on government farms compared to their relatively inferior performance under local farm conditions. Most exotic pig breeds have been farmed in Africa but their full genetic potential is only achieved when they are kept under intensive husbandry conditions with adequate nutrition, healthcare and appropriate housing. Thus, it is important to ensure that the breeds or genotypes used in the breeding programme will be available for the foreseeable future and farmers can provide the minimum inputs for maintaining them. One should therefore carefully consider the production environment in terms of breeding infrastructure, feed and health services, and ease of accessing the targeted market as part of any pig improvement programme.

19.2.3 Conservation of Indigenous Pig Genetic Resources

In most African countries, indigenous pig breeds are generally kept under smallholder husbandry systems (see Chap. 2) and have slower growth rates than exotics. However, they have adaptive traits (such as reduced deposition of adipose tissue, adaptation to extreme weather conditions—hot and very cold, and ability to withstand heavy parasite load) that give them an advantage in low-intensively management smallholder systems. Invariably, these adaptive traits are constantly

threatened by genetic erosion caused by indiscriminate crossbreeding with exotic breeds (Halimani et al. 2020; Osei-Amponsah et al. 2017). Sustainable pig breeding programmes should therefore aim at improving indigenous pigs through selection and crossbreeding programmes that combine the strengths of indigenous and imported pig breeds. For selective breeding to happen, there should be concerted efforts to conserve the indigenous and the naturalised breeds and genotypes so that these are reservoirs for those special genes, particularly for given locations.

The Large black and Saddleback pigs for instance were introduced in Uganda over 70 years ago. Due to several management bottlenecks, the prevailing environmental conditions and genetic erosion, individual animals of these breeds are currently generally small in size and are grouped by farmers among native and or local pig breeds. The many small-scale pig farmers in Africa depend on the indigenous pig on account of its adaptive, disease resistance, ease of management, and various roles in sustaining livelihoods and socio-cultural practices. Therefore, all breed improvement programmes should ensure that indigenous pig breeds are conserved and protected from excessive genetic dilution and indiscriminate crossbreeding. National governments need to ensure that indigenous pigs are conserved in situ and ex situ in vivo on government and institutional farms. Additionally, pig breeding improvement programmes should target traits that will help conserve the unique adaptive traits of indigenous pigs and give them an upper hand on niche markets.

19.2.4 Feed Resources

For a breeding programme to be sustainable, there has to be a deep appreciation of ensuring that there is feed for the breeds being promoted/developed and this should be in synch with the circumstances of the farming communities and the environment. It is defeating to develop high-performing (fast-growing, very prolific) pigs to be distributed to smallholder farmers who have neither feed production capacity nor capital to invest in the procurement of processed feeds. The likely result would be high-performing animals that farmers cannot maintain, and such breeding programme(s) would ultimately become unsustainable. Purchased feeds can be a complete substitute for land and this can spur small and medium size intensively managed pig operations. In many ways, the production of feed resources and the availability of land on which to grow/produce the feed resources are almost inseparable. The exception is the intensive system that is designed to rely on purchased feeds that may be imported or locally sourced (Mwesigwa et al. 2013a, b). Systems that rely on this option are generally intensively managed and are almost exclusively driven by demand for pork. In many African countries, pigs are reared for income from the sale of weaned pigs for fattening or mature pigs for slaughter; significant income also comes from the sale of pigs for use in breeding. Despite this, most female and male pig farmers' rank the keeping of pigs as a saving/insurance asset (Babigumira et al. 2021), and such farmers may not invest in the best feeding options available. Research into alternative feed sources to replace important but expensive components in particular protein and carbohydrate sources should be encouraged in Africa.

19.2.5 Socio-economic Factors

Socio-economic factors like gender, religion, urbanisation, market, consumer preferences and labour availability are valuable elements in the pig production value chain. Female and male pig farmers have the same level of knowledge regarding available breeds and lines. A Ugandan study reported that 69% of female and 70% of male pig farmers are very familiar with local pigs, whereas their knowledge of exotic and crossbred pigs is very low. Women and men do not differ much in their pig breed preferences (Babigumira et al. 2021). Both women and men eat pork although the proportion of men is slightly higher; and pork

ranks second to chicken as preferred meat, mainly due to its special taste. The choice of pig breed is not necessarily influenced by the religion/faith of the farmer, notwithstanding that some faiths such as Islam, Judaism, and Seventh Day Adventist, Ethiopian and Eritrean Orthodox churches consider pigs and pork a taboo—not rearing them, associating with them or eating them. Urbanisation to a very large extent influences the choice of breed and invariably the type of pig breeding programme. In Uganda where a pig breeding programme supported by artificial insemination initiatives thrives, there is a clear distinction in breed choices. Urban pork consumers demand lean meat, whereas rural pork consumers prefer fatty pork and as result the trend is to rear more indigenous pigs in rural areas as these tend to have much fat. In urban and peri-urban areas, the market forces demand that farmers rear exotic breeds or crossbreds to produce lean carcasses that the market prefers.

19.2.6 Smallholder Versus Industrial Pig Production Systems

Smallholder farming of pigs is compatible with deliberate low-input production systems, whereas industrial-scale piggeries demand that the most productive systems are deployed to maximise growth, reproductive ability and overall performance. Farms that focus on economies of scale, maximum production efficiency per animal or per unit of land would choose pig breeds that can pay back the investment. Such breeds of high-payback potential would possibly not be well adapted to a low-input farming system. On the other hand, farms that focus on product quality, self-sufficiency and niche marketing are more likely to target breeds that are resilient to feeding systems and environmental conditions that are not necessarily top-of-the-range. Selecting pig breeds that are appropriate to the local environment safeguards animal health and welfare and leads to long-term and sustained production.

19.2.7 Partnerships that Enhance Efforts of Actors

Implementing sustainable pig breeding programmes in and for Africa will require partners-researchers, breeders, funders, promoters and other enhancers in all African nations to collaborate, and above others, share resources, expertise and lessons learned during their professional careers and demonstrated best practices (see Chap. 31). Collaboration with developing partners in human and institutional capacity building should help Africa take advantage of modern innovative breeding technologies (see Chaps. 20 and 21) for improved sustainable pig production.

Pigs, like other animal genetic resources in Africa, continue to suffer from both direct and indirect effects of climate change particularly global warming and heat stress. This is one of the several areas of pig production that should be targeted by partnership collaborations. Generally and as elaborated in Chap. 8, indigenous pigs such as the Ashanti Dwarf of Ghana, the Ugandese black pig and the Bakosi of Gabon and Cameroon are well adapted to their production environments compared to exotic breeds such as Large White and the Duroc. Other efforts that will deliver sustainable pig breeding programmes include molecular characterisation of indigenous pigs of Africa in order to identify the genes responsible for various traits of economic importance to help match them to appropriate genotypes in crossbreeding programmes.

Additionally, partnerships under the auspices of continental agencies such as the African Forum for Agricultural Advisory Services (AFAAS) and the Forum for Agricultural Research in Africa (FARA) should target pig farmers for training and support to stock and keep appropriate pig genotypes while ensuring the provision of adequate feed, housing and healthcare in order to increase their production levels. Pig breeding programmes in Africa should also include resilience as a trait of economic importance in order to breed more robust productive pigs for sustainable protein food security.

19.3 Definitions and Considerations for Pig Production

19.3.1 Definition of Breeding Goals, Objectives and Strategies

A breeding goal specifies the traits to be improved including the emphasis given to each trait as well as the desired direction of the improvement of the population. The breeding goal as defined by the breeder indicates what is considered important in the future including expected customer demands. The breeding goal should always consider the unique production environments, namely high-, medium- and low-input production systems in order to be sustainable and useful to stakeholders. In this regard, breeding goals set for some pig genotypes in intensive production systems in other parts of the world are bound to fail if implemented in extensive production systems in parts of sub-Saharan Africa.

The breeding goal and the corresponding selection index determine the direction of a genetic improvement programme. In all species, breeding goals have moved from primarily production-driven breeding goals to balanced breeding goals that aim for simultaneous improvement of production, efficiency, and health and functional traits (Miglior et al. 2017; Berghof et al. 2019). A breeding objective specifies those characteristics that mostly affect profit in a particular pig business, in addition to how each characteristic is important to the realised profit. Every pig breeding objective should be specific, measurable, realistic and must be time bound. Pig breeding objectives focus on traits of interest and their relative importance with the strategy of achieving them set out in the breeding programme (Merks et al. 2012). The breeding objective should thus be based on projected profits under future conditions of production, not merely on the potential to change traits genetically. It requires an idea about the expected developments in production systems and regulations; new developments related to housing systems, nutrition and how are they expected to influence the performance of selected animals; (inter)national government regulations that may limit the current production system.

Some critical considerations when developing pig breeding objectives include the following:

(a) Understanding the customer and market requirements, as each breeding objective is generally specific to a particular market.
(b) The economic importance of traits depending on the target market.
(c) Production performance of the breeding stock needs to be evaluated continuously while monitoring the prevailing market demands to adjust the breeding programme accordingly. More health-conscious consumers may, for example, lead to adjusting the breeding goal to include pig breeds which will produce leaner carcasses.
(d) Some of the target traits in pigs are highly heritable and these should be targeted to attain the greatest progress towards breeding objectives.
(e) The need to focus on traits that have economic value instead of traits that have more to do with personal preferences and cultural or traditional roles.

Whenever pig producers determine the requirements of the target pig and pork market, and have refined breeding objectives that are well aligned with market requirements, they can start the selection of pigs that meet their preferred breeding objectives, considering both subjectively and objectively assessed traits. This selection process is most effectively done when some records are available on the traits of interest. Farmer and extension service personnel's capacity for record keeping should thus be encouraged by national governments. At all times, one should embrace innovative data recording technology such as the use of weigh, or calibrated chest girth tapes (Marshall et al. 2024) to determine body weight, ultrasound to measure fat and loin eye area, computerised tomography scans for individualised primal yield of carcass components and sophisticated scoring methods for anatomical traits. Additionally, proper pig pedigree records help to avoid mating of relatives which will lead to inbreeding with its undesirable effects.

Subjective visual assessment involves assessing pigs on the basis of what can be physically seen, with a main focus on the conformation of the pig for instance the body condition scoring or body muscling; and on the pig structure for instance ear size, ear shape and sometimes hair coat colour. Objective genetic assessment makes use of real measurements to assess the worth of selection candidates relative to other pigs on the farm. Genetic evaluation is one of the available forms of objective assessment and it provides an understanding of the genetic merit of pigs being farmed. When boar acquisition for the improvement of a pig herd is based on the breeding objectives of the pig farm, objective assessments are necessary.

The definition of the best animal/breed is subjective, based on the function of the animal/breed, culture, market structure, production environment, legal framework, population structure and environment limitations. In this regard, the best animal may not necessarily be a high-performance animal for a particular animal product (meat or litter size) but could be an average performance animal with reasonable resistance to an endemic disease. Defining the best animal thus requires inputs from all stakeholders, including farmers, consumers, breeders and researchers. Additionally, there is a need for adequate data/records on candidates for selection to make objective assessments and then select the 'best' animals/genotypes. It is for this reason that any serious genetic improvement programme needs infrastructure for collecting data. Without data collection, it is almost impossible to undertake any form of tractable genetic improvement.

Based on the breeding goal, phenotypic data that can help to establish the value of selection candidates should be collected. For instance, when the fertility of pigs is in the breeding goal, litter traits should be recorded. Pig genetic improvement programmes should have the infrastructure for collecting data to trace genetic improvements. Involving animal keepers in a genetic improvement programme offers an opportunity to collect data on their animals. Additionally, a data repository centre with high storage and computing ability is essential in developing any improvement programme. Based on an appropriate genetic model and a statistical model including pedigree information, a breeding value for a trait is estimated. Estimated breeding value indicates the value of the animal with respect to the breeding goal: the lowest ones will have a negative effect on the breeding goal traits and the highest ones will improve breeding goal traits.

19.3.2 Pig Production Systems in Africa in Relation to Heat Stress and Environmental Impacts

The predominant pig production system in Africa is the smallholder system characterised by minimum housing made from locally available materials, scavenging for food with some supplementation from household wastes from time to time, and little or no veterinary care. Often the environment is harsh with little or no veterinary care exposing the animals to disease pathogens, bad weather and predation. The little veterinary care sometimes comes in the form of herbal concoctions. African indigenous pig breeds such as the Ashanti Dwarf pig of Ghana are generally adapted to the production environment, survive under poor management, are more resistant to heat stroke and remain more active than introduced exotic breeds across a range of environments (Osei-Amponsah et al. 2017). The increasing use of exotic genotypes in low-input pig production systems in Africa calls for strategic breeding to reduce the negative effects of heat stress on animal welfare, production and reproduction. Exotic pig breeds are often kept in medium- to large-scale production systems where they are provided with adequate housing, feeding and veterinary care.

A recent spatial analysis has identified heat stress hotspots in Uganda where pig production could be affected significantly (Mutua et al. 2020a), with some regions reporting severe heat stress conditions over 183 days per year (Fig. 19.1).

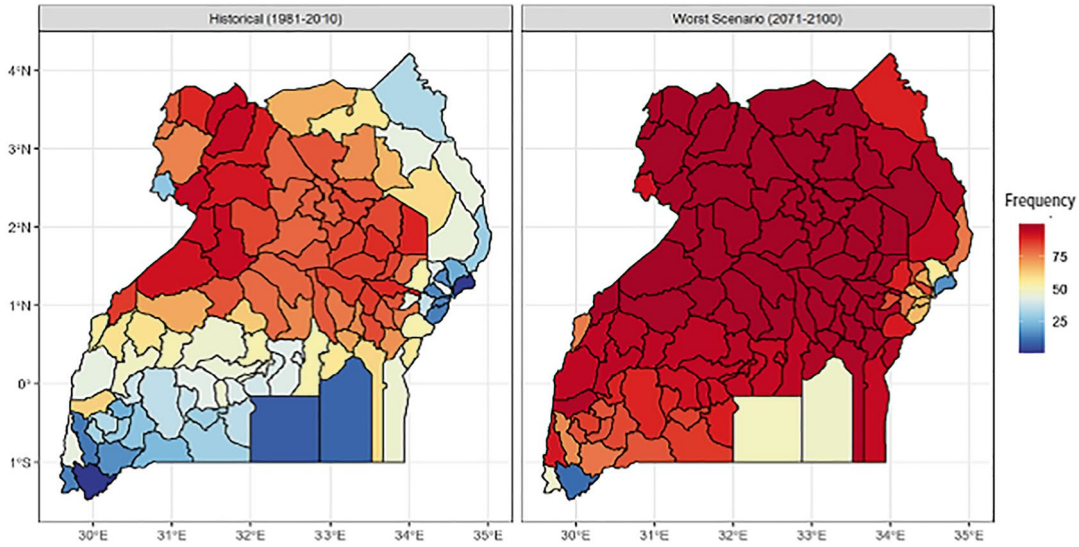

Fig. 19.1 Frequency of severe heat stress for past and future periods for pigs in Uganda. (From Mutua et al. (2020b), licensed under a CC BY 4:0)

Heat stress risk factors vary in impact and effect and include climate (air temperature, humidity), management system (specifically free-range pig management) and pig characteristics (age, lactation, stage, dark hair colour, overweight, breed, and pregnancy) (Fig. 19.2).

Resilience is the capacity of an animal to be minimally affected by disturbances or to rapidly return to the state pertained before exposure to a disturbance (Berghof et al. 2018; Colditz and Hine 2016) In the swine industry, economic losses associated with heat stress are mainly explained by reduced and inconsistent growth, decreased feed efficiency, decreased carcass quality, poor sow performance, increased mortality and morbidity, and decreased facility efficiency (Zaake et al. 2020; Baumgard and Rhoads Jr 2013). Reduced reproductive performance is characterised by anoestrus, increased wean-to-oestrus interval, decreased farrowing rate and reduced litter size (Ross et al. 2015). Similarly, poor semen production and quality occur in boars exposed to heat stress. Thus, heat stress compromises almost every economically important phenotype within the industry (Mayorga et al. 2019).

Selection for improved heat tolerance in pigs based on reproductive performance and temperature-humidity indices based on public weather station data is possible and should be encouraged in porcine breeding programmes. Heat susceptibility appears to be a heritable trait in finishing pigs, and therefore, genetics may offer a viable strategy to improve production during periods of high temperature–humidity indices. Heat tolerance based on reproductive performance indicators is a heritable trait and genetic progress for heat tolerance can be achieved through genetic or genomic selection and genomic regions and candidate genes with important biological functions have been identified (Tiezzi et al. 2020). Other heat stress management options that can be up-scaled are summarised in Table 19.2. One of these, the indigenous micro-organism (IMO) technology involves using a diverse mixture of beneficial native micro-organisms to enhance the natural processes that occur in the environment (Kumar and Gopal 2015; Yadav et al. 2020). The IMO is added to a natural bedding material such as sawdust, rice hulls and crushed corn cobs, and these are put on the pig sty floor. The set-up controls odours, reduces the spread of pathogens and provides a comfortable and safe environment for the pigs.

Current developments in big data collection give opportunities to determine new resilience

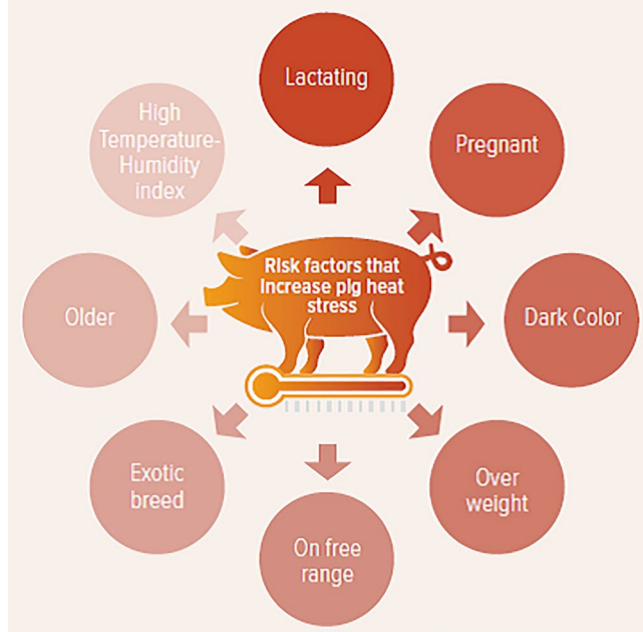

Fig. 19.2 Risk factors that cause heat stress in pigs. (From Mutua et al. (2020b), licensed under a CC BY 4:0)

Table 19.2 Current and futuristic adaptations to heat stress management for pigs (Mutua et al. 2020b)

Pig value chain node	Current adaptations	Futuristic adaptations
Input supply	Community water management committees for sustainable use of water resources	Farm-based water points
	Increased investment in water for production, solar use	Private sector-led investments in water for production
	Adoption of intensive management practices	Further research in pig house construction
	Provision of general extension services	Recruitment of specialised extension staff
On-farm pig production	Capacity development of farmers	Strengthen farmer-extension-research linkage
	Promotion of tolerant feed resource plant varieties and feed conservation	Emphasise capacity building among smallholder farmers on feed conservation
	Indigenous micro-organism (IMO) technologies	More research and capacity development in IMO
Transport	Day time transportation of pigs	Capacity building for transporters and policymakers to appreciate the benefit of transporting pigs at night
	Holding pigs under trees and other shades	Research in appropriate pig transportation and holding facilities
Output market	Increased establishment of pig market associations and farmer trade relations	More awareness of climate change information knowledge exchange with pig market actors
	Slaughtering of pigs in basic slaughter facilities	Increased innovation by the private sector on appropriate structures and abattoirs
	Implementation of animal movement and certification	Review of regulations to allow for animal movements at any time of day based on circumstances

indicators based on longitudinal data, which can aid the incorporation of resilience in animal breeding goals (Berghof et al. 2019). Many significant genomic regions in relation to heat tolerance have been identified in pigs (Riquet et al. 2017). This new genomic information could be used in the future to identify pigs capable of maintaining high levels of productivity during heat stress (Mayorga et al. 2019). Improving swine climatic resilience through genomic selection has the potential to minimise welfare issues and increase industry profitability (Tiezzi et al. 2020).

19.3.3 Pig Genetic Improvement and Conservation

In general, small-scale farmers dominate the pig production landscape in Africa. These farmers often keep indigenous pigs, and provide little or no housing, feed and veterinary care. Increasingly, commercial pig producers operating in the semi-intensive and intensive production systems utilise mostly exotic pig breeds and, in some cases, crosses between indigenous and exotic pig breeds. These commercial farmers have often been the targets of various pig genetic improvement programmes in Africa. The open nucleus breeding strategy is often employed to disseminate superior genetics to pig farmers and other stakeholders. Generally, the breeding of female pigs is organised into a three-step system consisting of breeding herds, multiplier herds and production herds. In the breeding herds, purebred sows and boars are selected and bred according to a specific selection criterion defined by the company's or producer's strategy (Pedersen 2018).

The government and other stakeholders often import exotic breeds and raise them in a nucleus herd on institutional or research station farms. The best-performing offspring from these pigs are distributed to grower farmers, who are carefully selected based on the availability of housing, ability to feed the pigs, keep records and provide significant veterinary care. The outgrower units multiply the stock supplied to them and the performance of the offspring is monitored regularly. Superior offspring are later given to other outgrower farmers or sent back to the nucleus station and the rest are sold for slaughter. Apart from such organised breeding programmes, there are many instances of indiscriminate crossbreeding between exotic and indigenous pig breeds.

Pig conservation (see Chap. 25) efforts have been very limited hitherto the establishment of the five African Union Animal Resources Seed Centres of Excellence (AU-ARSCoE). In most of Africa, pig conservation has been a preserve of the farmers who rear them. Whereas this in situ conservation strategy is practically the best, the lack of institutional support mechanisms means that farmers may change their production objectives and with that, the entire conservation effort. Recent efforts have seen the inclusion of pigs in the national strategies and action plans on the conservation and sustainable utilisation of indigenous animal genetic resources. For instance, in Uganda, the National Agricultural Research Organisation (NARO) is establishing a conservation scheme for the Ugandan local black pigs. This is to include a managed station herd and a registration of active farmers. The AU-ARSCoE gene banks will receive genetic material for all livestock species from the countries in the five geographical sub-regions of Africa and manage these collections on behalf of the countries in the various sub-regions. This ex situ in vitro conservation plan is expected to stave the real threat to African indigenous animal genetic resources that are continually threatened by a consistently changing animal agriculture landscape.

19.4 Defining Breeding Goals for Pigs for African Low-, Mid- and High-Input Systems

19.4.1 General Overview of the Pig Production System

The low input system, generally referred to as the smallholder pig production system (Table 19.3), is still dominant on the African continent (see

Table 19.3 Pig production system considering the scale of operation—the Uganda case

Parameter	Small-scale farming	Medium scale breeders and farmers	Large scale integrators
Source genetics	Free mating, NAADS[a], local breeder	Commercial farm or imported	Imported
Production system	Free range/wooden pens	Concrete pens or IMO system[b]	Indoor pens
Knowledge level	Very low	Low but increasing	High
Source of information	Other farmers, NGO[c] training	NGO training, other farmers	Foreign suppliers
Biosecurity	Non-existent	Low to medium	High
Disease prevalence	High	High	Medium
Veterinary service	None	Local veterinarians	Local veterinary/on-farm veterinarian assistants
Source of medicine	City market	City market	City market or imported
Feed type	Household waste or other waste products	Compounded or concentrate-based	Concentrate/ premix own feed production
Source of feed	Household or farm waste	On-site feed mixing or Private Feed Companiese.g. Devenish	On-site feed mixing
Harvest size of pig	30–60 kg	50–90 kg	80–125 kg

Adapted from: Larive International (2020)

[b]*IMO* Indigenous Microorganisms Deep Litter System—involves the use of litter such as wood shavings impregnated with bacteria to breakdown wastes

[c]*NGO* Non-Governmental Organisation

Chap. 2). A significant proportion of the pig herd on the continent is managed within this system. The small-scale pig production system is generally characterised by pigs reared outdoors, free range on pasture all the time or on a tether under a tree shade. This system also extends to the free-range scavenging type of pig rearing where pigs are left to freely move all over the home, the gardens, waste bins, wastelands and the entire neighbourhood searching for food. Pigs that are tethered may be kept on a leash during the day but very little is provided in the form of feed (such as kitchen and table leftover food, swill, crop residues and water) (Pezo and Waiswa 2012). The free-range system is practiced by extremely resource poor dwellers in peri-urban and rural settings. The pigs reared under this system are almost entirely indigenous breeds or non-descript types, and no formal breeding programmes exist for these producers. The sale of pigs is not systematic, being done when there is a need for cash to solve a problem; and not when the pigs reach market weight/size. In general, smallholder pig farmers typically keep 1–3 sows or less than 10 pigs of all ages at any given time. Many smallholder pig farmers operate under the low-input mode, but a significant number, particularly in peri-urban areas, do invest in some form of housing and feeding and in return, reap good levels of income by selling piglets, porkers and spent sows/boars to butcheries and pork-eating joints that are frequented by the low- and middle-class residents of these locations. Piglets are sold mostly to other smallholder farmers who specialise in growing and fattening pigs. Smallholder pig farming is also characterised by inadequate feeding regimes, below optimal reproductive performance, slow growth rates, relatively low-grade carcasses, and poor disease and parasite management, which is typically a precursor for rampant disease and parasite outbreaks and spread. African swine fever, porcine

cysticercosis and other major diseases tend to be rampant under this system since biosecurity measures are regularly below acceptable minimums.

In the medium/semi-intensive input system (Table 19.3), pigs are housed for part of the year and when they are dry or in gestation, they are put on pasture. The system is desirable in areas where the weather is not too hot for open air/paddocking of pigs and where there is land for putting the pigs on range. It is a system desired by some producers as it allows for keeping costs low for part of the year (savings on processed feed and labour); but it is also associated with the production of organic pork that relies much less on industrial processes inputs like feed, drugs and equipment. There is improved management and more investment in this system than in the low-input system—characterised by better feeding, better disease and parasite prevention and control and heat stress management leading to better growth rates, animal welfare and production. Farm income can be enhanced if marketing is strategically planned and sequenced to match high production levels with peak market demands. In this system, gilts and sows in late gestation and sows in lactation, as well as barrows and castrates under finishing are kept under intensive management, while boars, dry sows that have recently weaned piglets, and pigs in gestation are put on the semi-intensive component of the system so as to take advantage of the afore-mentioned benefits of keeping costs low and maximising on land utility.

The key feature of the high-input system is adequate and continual housing where pigs are provided with feed, water and protection from extreme weather (hot sun and rain showers) or from getting into contact with diseased/stray animals. The labour needs and other inputs, such as feed and water for both pig consumption and cleaning purposes, are high. Notably, the system provides the highest level of farm output compared to other systems and it is the most commercially viable. In much of Africa, this system accounts for a very small portion of pig production (about a tenth), partly because of the high investment capital needed, superior management skills and a well-connected marketing system. High-input systems invest in high-grade breeding stock (fast-growing and high carcass quality pigs) and also set up on-farm selection programmes. They are also characterised by effective disease and parasite control practices, good hygiene and low piglet mortality that mainly arises from poorly constructed farrowing pens in the other systems, and or starvation and cannibalism. Though of very low incidence, farms that use these systems occasionally experience devastating incidence of African Swine Fever (ASF), particularly when there is a gap in the year-round biosecurity system of the farms.

Industrial pig farms/large integrators are a type of high-input system (Table 19.3) that typically rear 500 or more pigs, mainly for the commercial sale of pork or breeding stock (Mutetikka and Kugonza 2009). These farms are near large cities and supply most of the pork produced to the formal sector, such as high-end butcheries, restaurant chains, supermarket chains and for processing into other pork products.

19.4.2 Production Characteristics, Breeds, Markets and Farmer Organisations for Pig Genetic Improvement

19.4.2.1 Production Characteristics for Pig Improvement

Identification of pig breeds, characterisation of the production environment, the definition of production objectives and a database on the production performance of animals is a foundational step in any pig improvement programme. In most African pig production systems, increasing the quantity and quality of meat is a primary breeding goal. This has been largely achieved through improved litter size at birth and weaning as well as litter weight at birth and weaning. Additionally, the emergence of educated and health-conscious consumers has created a market for lean carcasses, and thus, the breeding for lean meat. The diversity of pig genetic resources in Africa is enormous (see Chap. 8). There is thus a need for phenotypic and genetic characterisation of pigs in Africa using appropriate tools so that metadata

analysis across countries and regions can be carried out and data used as a base for informed decisions on breeding strategies. Advances in molecular biology and the availability of various genomic tools and technology provide greater opportunity for the characterisation, sustainable use and conservation of Africa's pig genetic resources (see Chap. 21).

19.4.2.2 Breeds Targeted for Pig Improvement

Although most indigenous pig breeds are valued on account of their adaptation to the production environments and their tastier carcasses, they do not produce as much meat as exotic genotypes (particularly under intensive production systems). Indigenous breeds are the most efficient under the prevalent traditional extensive systems of production on account of their better adaptation, ability to survive under harsh conditions and scarce feed resources, and resistance to various endemic diseases. Indigenous pig genetic resources are also superior in terms of some carcass and organoleptic attributes including taste, which makes them popular delicacies for consumers. These are important traits and attributes which call for an in-depth characterisation and utilisation of indigenous pig genotypes in breeding programmes to develop pig genotypes for specific purposes and for various production systems. A locally adapted exotic genotype such as the Large White is already useful under intensive production systems and may be considered in planned crossbreeding programmes with indigenous pigs for the development of pig genotypes with improved production and adaptability characteristics.

19.4.2.3 Markets for Improved Pig Breeds and Pig Products

Improved access to livestock genetics to international markets and the growth of world trade have enabled livestock breeding firms to sell their products worldwide. The increase in the size of the potential market strengthens incentives to invest in research to develop new animal production inputs. For example, several multinational companies have emerged over the past several years to become major developers and suppliers of improved pig breeds for producers including Babcock Swine (US), Cotswold USA (Heartland Pork Enterprises, UK), DeKalb Swine Breeders (Monsanto, US), DanBred (Denmark), Farmers Hybrid (US), Genetic Improvement Service (US), Genetic Porc (Canada), Nesham Hybrids (US), PIC-USA (London-Dalgery PLC, UK) and Seghers Hybrid (Belgium) (Narrod and Fuglie 2000).

Breeding schemes aim at utilisation of the between- and within-breed genetic diversity. Breeding schemes do not aim at a fixed target; breeding organisations are dynamically searching for improvements. Differences in economic, social and ecological production environments give rise to different desired directions of change. The desired direction of change of a particular breed might differ between regions and change over time. Changes over time are strongly driven by the needs of consumers and society. Breeding organisations are increasingly aware of this and are changing their breeding objectives by including traits related to animal welfare and the quality of the product. The reproductive capacities of animals put a major constraint on any animal breeding operation. Reproductive techniques like artificial insemination and embryo transfer can be used to overcome these constraints. These techniques play an important role in the activities of breeding organisations. In essence, the most basic effect of reproductive technologies is to increase fecundity. This means that fewer parents are needed to produce a given number of offspring. The application of reproductive techniques has had a major impact on the structure of breeding programmes, the rate of genetic gain and the dissemination of genetic gain in livestock production (Nimbkar and van Arendonk 2010).

Globalisation represents both an opportunity and a threat for developing countries' agriculture and in particular sustainable use of animal genetic resources. It offers the potential to serve markets beyond local and domestic ones, but at the same time exposes producers to the full force of international competition, including highly efficient low-cost producers from other developing regions. There is a real risk that poor, smallholder

livestock producers including the many pig farmers will lose out as they fail to compete in the 'free market' and will be replaced by either large-scale local operations or imported breeds (Rege et al. 2011). Therefore, there is a need for pro-poor animal breeding strategies to ensure that the many local small-scale farmers and their breeds and not disadvantaged as a result of global competition. In targeting markets for genetic improvement in Africa, therefore, sustainable intervention should be included to sustain use and conserve local pig genetic resources and their unique production systems.

Concerns about boar taint and aggressive behaviour are being addressed through breeding. To support the transition to the abandonment of castration and the rearing of entire males in pig production, genetic selection brings the medium- to long-term solutions to control the problems of boar taint and aggressive behaviour. Some breeds have been identified as a low-taint risk and can be used for crossbred pigs. Because of the knowledge developed over many years on the genetic determinism of skatole and especially androstenone, breeding organisations have recently developed selection strategies to propose improved lines for the breeding of entire males (Larzul 2021).

19.4.2.4 Farmer Organisations for Pig Improvement

Organised pig farmer organisations exist in many African countries such as Ghana, Kenya, Nigeria, South Africa, Tanzania and Uganda (see Chap. 31). Through these associations, farmers build capacity, get access to improved genetics, bulk purchase of inputs, and have a collective voice on issues germane to improved pig production, healthcare and marketing. Under the umbrella of an organisation, farmers can be easily consulted and their inputs taken into account on varied issues, including setting breeding goals, selecting breeding stock and determining appropriate breeding programmes based on their preferred traits. Breeding goals are also dependent on the targeted market and in some cases when value addition is to be considered. Furthermore, sensitisation of local farmers on the important adaptive attributes of indigenous pig breeds and the need to ensure that they remain an important/useful resource in their communities should remain on the agenda.

19.4.2.5 Future Perspectives

Officers will provide information on the most suitable pig genetic resource and important part of the production system will maintain/conserve pig biodiversity for future needs. Moreover, utilisation of exotic genotypes in crossbreeding with indigenous breeds must be well designed/planned to ensure that the unique and important attributes of indigenous breeds are not lost. The benefits of organised pig farmer organisations should be extended to countries where they do not exist. To start pig farming, and particularly a pig breeding company, it is important to formalise operations from the outset. The starting point is to contact the local government authority in charge of Animal Production. Often, Animal Production is a Directorate or a Unit under the Ministry of Agriculture in the different African countries. Animal Production information on service providers (feed millers, and veterinary practitioners and markets among others). Supply or access to the appropriate swine genetic resources in the intended environment as well as the market demands are vital aspects that must be carefully considered by potential producers.

19.4.3 Products from Pig Production Systems

19.4.3.1 Pork and Pork-Derived Products

Pork is the meat harvested from pigs and it is the most commonly consumed meat globally. Pork is consumed either as freshly cooked, or as preserved or cured meat. A 100 kg pig at a market age of about seven months yields about 70 kg of pork (70% dressing percentage). Fresh pork may be cooked by roasting, frying, stewing or steaming. Preserved pork-derived products on the African market include bacon, gammon, ham, hot dogs, salami, sausages, smokies, smoked pork, pork chops and others. Additionally, pork

and pork products are important components of many local and continental dishes creating a vibrant market for the industry.

19.4.3.2 By-Products from the Pig Industry

By-products from the pig industry include gelatin, wax, adhesive, bio-fertiliser, lard, soap, leather, hair, industrial lubricant and pet food. Lard, the fat harvested from the abdomen of pig, is particularly useful as a substitute for vegetable oils but its high price puts it beyond the reach of many households on the African continent. Lard is also a major ingredient in the manufacture of soaps, creams, beauty products, baked goods and other foods. Whereas most pigs reared in Africa produce fatty pork, consumer preference is shifting towards lean pork and, hence, the production of lard will eventually drop. Pig by-products are also used in the manufacture of water filters, insulation materials, rubber, antifreeze (used in various equipment), plastic, wax for flooring, crayon and chalk (USDA 2016). A growing sector that offers much promise for the pig industry is the human medicine organ and parts industry. In January 2022, the first whole heart transplant from a pig to a human was performed (www.floridatoday.com/story/life/wellness/2022/02/15). Although the recipient lived only two months post-surgery, history was made as the future of the pig industry now extends beyond food and general-purpose functions. Additional valuable products of direct human health importance harvested from the pigs include insulin for regulating diabetes and valves for human heart function. Pig genetic resources and their diversity in Africa therefore need to be sustainably used and appropriately conserved not only for protein food security and wealth creation but also for the future survival of humanity.

19.4.3.3 Manure and Biogas

It is estimated that a herd of 500 finishing pigs produces almost 84,950 litres of manure per month. This is a high-grade fertiliser for use in crop production. With the estimated 40 million pigs on the African continent, 6.8 million M^3 of manure are available to substitute for some of the millions of tons of imported inorganic fertilisers. To ensure efficient use of pig manure, there is a need to have innovative and cost-effective means of collecting, storing and transporting it to the point of use. This requires the education and training of pig farmers and the provision of appropriate technology. Additionally, end users or crop farmers also need to be sensitised on the value and importance of using pig manure on their farms instead of inorganic fertilisers.

19.5 Traits of Economic Importance in Pig Production

Traits of economic importance in pig breeding include litter size, growth rate, feed conversion efficiency and back fat thickness. The main breeding objective of pig production is producing large numbers of fast and efficiently growing lean progeny. Although this strategy has been highly successful and greatly increased the weight of lean meat produced per sow per year, negative correlated consequences with welfare traits have been recorded (Turner et al. 2018). The impacts of pig production on the environment call for attention to traits that ensure environmental sustainability in pig breeding and improvement.

19.5.1 Litter Size

Litter size is a major component of sow productivity, and it is the main driver of the profitability associated with pig farming. As litter size increases, the fixed on-farm production cost per pig is reduced to the point at which the entire enterprise first becomes economically neutral and then realises a profit (Zak et al. 2017). Reproduction traits such as litter size is heritable (h^2 = 10–15% across breeds) and can enhance the genetic gain within a population by improving selection intensity or reducing generation interval (Zak et al. 2017). Targeting litter size for improvement in a breeding programme requires the availability of the necessary infrastructure—

such as adequate housing and nutrition, improved management and veterinary care—to support larger litter sizes.

19.5.2 Number of Pigs per Year

This is directly related to litter size and also to the number of piglets born alive. A large litter size and more pigs in an operation per year enable farmers to make more economic use of labour and other production inputs, including veterinary care and high returns. In terms of breeding, sows bearing large litter sizes are preferred to enable farmers to increase the number of pigs in an operation per year. Moreover, the most appropriate genotypes or high-producing genotypes that are supported by the prevailing environmental conditions, availability of inputs and technical know-how are important considerations for having a high number of pigs per year.

19.5.3 Carcass Traits

Superior carcass traits like carcass yield will increase farm productivity. An increase in the average weight of carcasses will ultimately lead to the reduction of the herd size since fewer animals have to be slaughtered to attain the amount of meat demanded. However, on the contrary, with increasing urbanisation and population growth, demand for pork and pork products will ultimately increase and farmers will respond by increasing the pig population on the African continent. With better nutrition and disease management, carcass weights will keep improving as long as the quality of the carcasses is sustained. Superiority in carcass yield should translate into profit and create more wealth for the pig farmer. An important aspect of the carcass in terms of quality is the leanness of the carcass. Pig improvement programmes should target lean carcasses meaning that breeds with a high meat-to-fat ratio should be prioritised. Another important trait related to carcass yield is the palatability and organoleptic attributes. The breeding objective should therefore prioritise breeds which produce more tender and marbling carcasses to improve carcass quality.

19.5.4 Welfare and Resilience

The welfare of pigs is related to their ability to cope with their environment while resilience is the ability to cope with and quickly recover from stressors (Broom 1994). It is also regarded as the capacity of a pig to be minimally affected by disturbances or their ability to quickly return to normalcy following exposure to a disturbance (Berghof et al. 2019). Typical stressors for pigs include respiratory diseases, bacteria diseases, mycotoxins, heat stress, poor human handling, environmental pollutants (e.g. dust and ammonia) inadequate feeding and lack of water or poor water quality. The growing concern about pig welfare and hence the need to consider welfare traits in breeding programmes can be attributed to the increased cost of pig production that often leads to poor husbandry conditions resulting in extra stress to animals; decreasing the capability of pigs to cope with changing environmental conditions; increasing ethical consciousness of the human populace; and the increased availability of pig welfare information (Kanis et al. 2004). Breeding strategies that produce more resilient pigs increase the capacity of pigs to attain their full potential under commercial conditions and ensure efficient and sustainable production. In pig improvement programmes, it is important to incorporate indigenous genetics to ensure the adaptability of piglets, particularly in the face of the negative direct and indirect impacts of climate change on exotic pigs under African environmental and management conditions.

Growing attention on aspects of pig welfare and resilience is born from evidence showing that pig welfare aspects have a genetic basis and the selection of pigs for increased production can have negative side effects on animal welfare. Therefore, like other negatively correlated traits, considering them alongside production and health traits can lead to faster gains. Significant negative genetic correlations between leg quality and lean meat percentage, and between leg qual-

ity and daily pig growth rate are typical examples of how selection for one trait can affect another; and in particular, unfavourable genetic correlations between lean meat percentage and stress susceptibility (Rauw et al. 1998). Genetic selection for production and reproduction traits possibly results in welfare problems in pigs. For example, selection against nest-building behaviour before birth could lead to pigs with little or no oestrus behaviour (Wischner et al. 2009) and hence reduced fitness.

Several adaptation and coping strategies to welfare challenges in pigs have been documented and include a reduction in feed intake and an increase in maintenance energy among others (Mayorga et al. 2019).

Breeding for improved pig welfare requirements should be matched with improvements in productivity as well as address general society and ethical concerns. Other resilience-associated concepts for consideration include robustness, tolerance, resistance, genotype by environment interaction, genetic heterogeneity of environmental variance, plasticity, environmental sensitivity, canalisation and stability (Berghof et al. 2019).

19.5.5 Piglet Survival and Morbidity

Piglet survival is important to ensure increased profitability of the herd. Although breeding programmes have focused on improving the total number of piglets born, this has led to a concomitant increase in piglet mortality (Rutherford et al. 2013). Consequently, adjusting selection criteria to include neonatal survival, in addition to the number born, is a more sustainable strategy for improving piglet survival rates (Roehe et al. 2010). Closely linked to this is the need to breed for improved maternal behaviour to ensure piglet survival (Baxter et al. 2011).

Resistance is the ability of a host to restrict an invading pathogen's life cycle. An animal with greater resistance will have a lower pathogen burden (Mulder et al. 2013). Pathogen burden is the amount of pathogen in the animal's body. Tolerance is the animal's ability to minimise the detrimental impact of infection on performance. A tolerant animal maintains performance despite the pathogen burden (Mulder and Rashidi 2017b). Resistance and tolerance are both important components of resilience which in recent times have become an important trait on account of climate change and its adverse effects on production environments. Selection of the Expected Breeding Value (EBV) for resilience will target general disease tolerance and resistance rather than specific disease resistance or tolerance. Indigenous pig genetic resources are known for their resistance to most endemic diseases and their ability to survive under harsh environments including feed scarcity and heat stress (Osei-Amponsah et al. 2017). Therefore, in considering pig breeds for various improvement programmes, there is a need to consider indigenous pig genetic resources to ensure resilience and sustainability.

19.5.6 Feed Conversion Efficiency

Increasing feed efficiency is a major goal of breeders as it helps reduce production costs and energy consumption (Ding et al. 2018). Increasing feed efficiency not only reduces feed consumption while decreasing farming cost and energy use but also lowers manure production and the total amount of potential greenhouse gas emission. Feed conversion ratio (FCR) and residual feed intake (RFI) are two traits that have been used to evaluate feed efficiency (Lu et al. 2017). FCR (the ratio of feed intake to output) is widely used to estimate feed efficiency in pig breeding because of its simplicity in calculation and its correlation with growth rate and body weight (BW). Feeding behaviour is one of the most important factors affecting feed efficiency (Ding et al. 2018).

Selection for feed efficiency (*FE*) is a strategy to reduce the production costs per unit of animal product, which is one of the major objectives of current animal breeding programmes. In pig breeding, selection for feed efficiency and other traits traditionally takes place based on purebred pig performance at the nucleus level, while pork production typically makes use of crossbred ani-

mals. The success of such selection, therefore, depends on the genetic correlation between the performance of purebred pig and crossbred animals (*r*pc) and on the genetic correlation (*r*g) between feed efficiency and the other traits that are under selection (Godinho et al. 2018). Pig farmers in Africa and other stakeholders should be trained and given the right tools to enable them to monitor and take appropriate data on feed consumption and costs regularly. This will help in both breeding and management decisions.

Breeding schemes so far have focused on improving the performance of pig genotypes with little or no attention given to the feeding regimes in the selection environment and production environment (Nirea and Meuwissen 2017). Therefore, pig breeding programmes should target selection for robust animals that are genetically superior and perform best under lower-quality feed resources. The costs of feed can be reduced; therefore, any improvement in feed efficiency made will have a significant impact on economic return (Nirea and Meuwissen 2017).

19.6 Breeding Strategies for Pigs

19.6.1 Past and Ongoing Breeding Programmes in Africa or for Africa

19.6.1.1 Selection Programmes/ Initiatives

Indigenous pig breeds possess unique genetic characteristics that are crucial for the production of future breeds with production traits for survival in different geographical locations (Buckner et al. 2016). However, this genetic diversity is not well utilised since the majority of the smallholders' pig farmers in Africa are not engaged in well-defined pig selection programmes neither are they following concrete breeding programmes (Halimani et al. 2012). Lack of access to production information, poverty and/or resource constraints, ill-defined government policies and programmes coupled with low-input production systems have hindered the development of adequate breeding programmes in indigenous pig communities (Buckner et al. 2016; Halimani et al. 2012). In developing a regional strategy for the control of African swine fever in Africa, an FAO-ILRI-AU-IBAR consortium initiative has recommended selective breeding programmes targeting well-adapted animals and tailored for improved productivity, with adaptation to diseases being one of the lead targets of such an initiative (FAO/ILRI/AU-IBAR 2017).

19.6.1.2 Crossbreeding Programmes/ Initiatives

The ever-increasing market demands for pork and pig products have led to the commercialisation of the pig industry in the majority of African countries. The indigenous pig breeds, which are regarded as unsuited for intensive commercial production (Swart et al. 2010), are being replaced by exotic species that are fast growing and have high carcass weights (Buckner et al. 2016). Breeds such as the Landrace, Large White, Duroc, Comborough, and Pietrain (AU-IBAR 2019) have been introduced through various routes for crossbreeding purposes. However, these initiatives have also facilitated the loss of indigenous genetic diversity. A typical three-way breed crossing programme has been initiated by the National Animal Genetic Resource Centre and Data Bank (NAGRC&DB) in Uganda. The programme is producing a hybrid from Large White sows mated to Landrace sires, with the resultant crossbred sows mated to a Duroc terminal sire to produce the NAGR-Pig that holds quite a significant promise for the Ugandan pig industry (NAGRC&DB 2022).

19.6.1.3 Community-Based Breeding Programmes

Community-based breeding programmes (CBBP) are promoted mainly as a strategy for smallholder farmers to improve their livestock breeds. These programmes are defined as being typically related to low-input systems with farmers within geographical boundaries having a common interest in working together for the improvement of their genetic resources

(Wurzinger et al. 2021). Community-based breeding programmes can also offer the opportunity for in situ conservation of indigenous pig genetics. However, constraints such as a lack of marketing strategies have greatly hindered its development as a breeding strategy when compared to community-based breeding schemes for other livestock species. The use of communal boars is widespread among the smallholder pig farmers of Africa. In several countries, for instance, Uganda, a household may own a boar that is used by home studs for natural servicing, being that over 52% of all smallholder pig farmers do not keep their own boar. However, the main challenge with these typical communal boars is that they lack the improved genetic qualities and they do aid the spread of African Swine Fever (ASF). Furthermore, farmers tend to select replacement stock from within their herd; thus resulting in the maintenance of a specific breed. This may lead to a very high risk of inbreeding that might negate the efforts to conserve and utilise the breed (Halimani et al. 2012). However, there is limited literature on the aspect of community-based pig breeding programmes in Africa.

19.6.1.4 Efforts to Breed for Swine Fever Tolerance

There is wide genetic variation in the extent of susceptibility to diseases and parasites among different pig breeds, particularly on the African continent. The indigenous pig breeds have shown better chances of survival to various disease outbreaks and have a higher capacity to utilise fibrous and poor-quality feed resources compared to the exotic breeds (FAO/ILRI/AU-IBAR 2017). Furthermore, indigenous pig breeds have been reported to survive outbreaks of African swine fever in Mchinje District of Malawi and Angonia District in Mozambique (Halimani et al. 2010). These present opportunities for selection within the tolerant breeds for resistant animals, introgression of the resistance genes into their commercial counterparts and/or identification of the genes for inclusion in other strains (Wurzinger et al. 2021). However, these qualities and breeds that exhibit these qualities have been understudied while the genetic progress in resistance to disease is low. A study conducted in Northern Mozambique to evaluate the heritability of ASF resistance genes by expositing offspring of outbreak survivors to African swine fever virus indicated that ASF resistance was not inherited and hence not genetic but rather a result of enzootic stability between the indigenous pigs and the virus (Penrith et al. 2004). Efforts elsewhere particularly in mainland Europe and Asia indicate the possibility of disease control through selective breeding for African swine fever tolerance, however, the veracity of results so far obtained is still suspect (Guinat et al. 2017).

19.6.1.5 Breeding Programmes for Breeder Companies

Breeding programmes of private pig breeding companies are considered trade secrets and hence these are not publicly provided. Nevertheless, information on the breeds and commercial pig lines of focus and the locality of the breeder companies is provided in Table 19.4.

The Pig Improvement Company (PIC), at its establishment towards the end of the 1950s, aimed at exploring the benefits of a high health status breeding environment and genetic improvement. Large White (LW) females and Landrace (LR) males were used to start the initial herd. To ensure that the progeny was free of pathogens, for example, the hysterectomy technique was used. The womb was surgically removed just prior to giving birth naturally avoiding the contamination of the offspring. With this technology, 80 disease-free piglets were produced to start the breeding programme. The mating of LW females with LR males resulted in a 10% increase in the pigs' size, feed conversion, and live weight gain as a result of 'hybrid vigour'. It was necessary to include animals with good fertility characteristics because litter size is only inheritable by 10%, whereas feed conversion and live weight gain can be up to 30% inherited (Zylbersztajn et al. 2000).

The internationalisation strategy for PIC was developed in the 1970s. It necessitated the development of a range of selection standards directed at specific countries with their own particular

Table 19.4 Pig breeding companies operating in Africa

Nr	Company name	Head office (origin)	African office location	Breeds/lines	Website
1	Pig Improvement Company (PIC)	Europe: PIC UK	South Africa:	Gilts; Camborough. Boars; PIC337, PIC 410, PIC800	https://www.picrsa.co.za/
2	DanBred	Europe, Denmark	South Africa: DANBRED AFRICA (PTY) LTD.	DanBred landrace (LL), DanBred Yorkshire (YY), and DanBred Duroc (DD), DanBred hybrid	https://danbred.com/
3	Topigs Norsvin	Norway and Netherlands	South Africa	Terminal boars: TN select, TNTraxx, TN talent, TN tempo, Norsvin Duroc, TN Duroc. Parent sows TN70, TN60	https://topigsnorsvin.co.za/
4	Choice Genetics	USA:	No office	Parent gilt: CG36, grand parent females: M3 Largewhite, M6 landrace terminal boar: P26, P81, P90	https://choice-genetics.com/en/
5	Alliance Genetics South Africa	South Africa	South Africa Pretoria	Landrace, Largewhite, Duroc, F1 crossbred gilts	https://www.alliancegenetics.co.za/index.htm

production system and distinct market requirements. As a result of this, races of pigs such as the Pietrain were introduced that had desirable production traits despite being susceptible to the Pale Soft Exudative (PSE) muscle. The Duroc race proved to be particularly promising when introduced in systems that require robustness in a harsher environment and improved meat quality. International PIC believed that the main role of the associated companies was to guarantee that the clients adopted the standards considered necessary for business success (Zylbersztajn et al. 2000).

Improvements in pigs at the international level have been constant over the past years, but new technology provided a powerful tool for accelerating the process. PIC patented an identification method for isolating the ESR gene whose occurrence is associated with an increase in reproductive capacity. PIC-sponsored researchers had identified an association of the RYR gene to high-quantity non-fat meat and also high susceptibility to stress; the RN gene with acid meat, the K88 gene with resistance to *Escherichia coli* and the MHC gene with offspring size, bacon thickness and piglet mortality. Improvement programmes could now be accelerated and targeted more accurately by 'gene tagging'.

PIC also collaborates with its international partners, stakeholders and clients to ensure that the environment and human resources needed to achieve the best out of its products are in place. This is because all the investment in pork improvement could be wasted without suitable management of the herd with appropriate facilities run by skilled personnel using good-quality inputs (Zylbersztajn et al. 2000). This is a lesson Africa should be mindful of before importing any exotic animal genetic resource.

The pig sector has a pyramidal structure and some cooperative companies of pig breeders such as Topigs are involved in breeding. There are more breeding companies in the pig sector than in poultry although a few of them have large market shares such as PIC. As in poultry, the organisations involved in genetic improvement have worldwide distribution networks. Compared to poultry breeding, the number of breeders, that is, people owning male and or female animals, is much larger in pig breeding (Nimbkar and van Arendonk 2010). Vertical integration from genetics to pork products is high in North America, and fast growing in many European countries (Gura 2007). Commercial producers buy both sows and boars of specialised lines or crosses from breeding companies and crossbreed them to produce pigs for slaughter. Artificial insemination (AI) is used in the pig industry. In contrast to poultry, there are still breeding associations for pigs in many countries (Nimbkar and van Arendonk 2010).

Leading pig breeding companies have implemented single-step evaluation for genomic selection. Overall, this increases EBV accuracies by half. Further improvement requires focus on trait- and line-specific QTLs, exploitation of crossbred performance for non-additive genetic effects, and training for hard-to-measure traits. The multi-breeding-company multi-line crossbred pig production structure limits very high accuracies. Increased genotyping and phenotyping will lead to improved training data and may increase accuracies by two-thirds rather than half. Novel technologies will allow for genotyping of all selection candidates, reducing the generation interval and emphasising the need for inbreeding control, more efficient breeding structures, and higher selection intensities (Knol et al. 2016).

PIC markets approximately 2 million breeding animals with a volume of sales approaching US $400 million a year. PIC has 30 to 40% of the market in North America and 11% of the market in Europe, and is represented in around 30 countries with more than 1500 employees. 1,6 million breeding sows are sold each year, raised on some 40 farms. Gross margin is at 35%. PIC belonged to Sygen (turnover 129 million USD) until in 2005 the UK-based Genus plc, owner of the world's largest cattle breeding company, ABS, bought Sygen, a specialist in quantitative genetics of pig and shrimps, with its daughter, PIC, the world's largest pig breeding company (Gura 2007).

Hypor, the world's second-largest pig breeding company, still belongs to Nutreco, based in

NL, which is Europe's largest animal compound feed and fish feed producer. Its breeding division, Euribrid, also comprises the world's second largest turkey breeding company, Hybrid, and the fourth largest broiler breeder, Hybro. The total turnover of Hypor is approximately 35 million €. Hypor has around 250 employees and is represented in Canada, Spain and Belgium, with a market share between 20 and 24%. It also holds substantial market shares in the Netherlands, Italy, Germany, Poland, Japan, Mexico and the Philippines (Gura 2007).

The Dutch cooperative *Topigs* is globally the third largest pig breeding organisation, producing almost 850,000 gilts per year. Topigs is a subsidiary of the Pigture Group Pig Breeders Co-operative which is owned by 3000-member pig farmers in the Netherlands. The Pigture Group Pig Breeders Co-operative owns 77.5% of Topigs; 22.5% are owned by Europe's largest fresh-meat processor Vion Food Group. The Pigture Group has around 400 employees and a turnover of 103 million €. In the Netherlands, Topigs has a market share of over 80%, and with a line well suited for Parma ham, it leads the Italian market. In 2006, it opened nucleus farms in Russia and Croatia. Production and distribution of the breeding material are based on a franchise system. Topigs highly values its independence and, therefore, makes its genetics freely available. Topigs is the first European pig breeding organisation that has been certified for the Code of Good Practice for Farm Animal Breeding and Reproduction Organisations, Code-EFABAR (Gura 2007).

Monsanto's share in the US pig genetics market currently is about 10%. In 1998, Monsanto acquired DeKalb with, among others, their pig breeding sector, and in 2001, Monsanto purchased the Canadian pig breeding enterprise Unipork. Monsanto also is the exclusive distributor of the 'Genepacker' boar of JSR Genetics, UK. Monsanto has license contracts with Metamorphix, which in turn has near to exclusive access to the pig genome (Gura 2007).

About 42% of global pig production is industrial, with five dominating breeds (Large White, Duroc, Landrace, Hampshire and Pietrain). According to FAO, 66% of the mothers of European fattening pigs are hybrid crosses of the 'Large White' and 'Landrace' breeds. Effective population size, a parameter used in breed conservation to calculate genetic diversity, in pigs was found to be 71, 74 and 61 animals for the Yorkshire, Hampshire and Duroc, respectively. While these effective population sizes are somewhat larger than those reported for Holstein, Brown Swiss and Jersey cattle, they are still under the 100 head which is considered a critical level for maintaining genetic diversity (Gura 2007).

19.6.2 Molecular and Assisted Reproductive Innovations for Pig Improvement

19.6.2.1 Genomic Selection

The molecular and assisted reproduction technologies relevant to livestock improvement have been described in more detail in Chap. 21. Although the capacity for implementation of genomic selection (Lillehammer et al. 2011) is still in development in Africa, it has been shown to increase rates of genetic gain in pig nucleus breeding schemes (Halimani et al. 2012). For instance, GS has the potential to improve feed efficiency traits, minimise the cost of recording and account for environmental sensitivity that occurs due to differences in feeding systems between environments (Lillehammer et al. 2011). To utilise the potential of GS, it is essential to include animals in the reference population from both the nucleus and production environments. For example, when implementing genomic selection for feed efficiency traits, the reference population should be based on the feeding and management structure of the population and the reference population should involve animals from the environment where the breeding goal is targeted (Swart et al. 2010). In future years, there is a need to broaden pig breeding goals to include welfare-relevant traits in order to counter the effects of selection on pro-

ductivity and to more directly improve welfare traits in their own right, environmental adaptation traits, disease-relevant traits and other lowly heritable traits.

19.6.2.2 Nanotechnology

Evidence exists that shows that nanoparticles increase the life of spermatozoa and improve the general fertility of sires. An extensive review of the applications of nanotechnology to animal reproduction specifically on the management of mammalian spermatozoa has been provided by Feugang and colleagues (Feugang et al. 2019). They did show that treatment of boar sperm with nanoparticles enhances fertility and provides a practical biomedical application to improve economic productivity for farmers. More stakeholder collaborative efforts and research in this direction within the African context are therefore recommended.

19.6.2.3 Clustered Regularly Interspaced Short Palindromic Repeats/Cas9 (CRISPR-Cas9) System

This technique is being used for livestock to enable the production of resilience against diseases, enhance reproductive traits, and act as a model for biomedical research (Penrith et al. 2004). One application of Cas-9-based gene modification has been in the production of pigs with the activity of porcine endogenous retroviruses made non-functional, hence a pathway for transplantation of organs from pigs to humans. Alterations that have been done include knocking out and in of short palindromic repeats associated proteins into pig genetic material to insert preconfirmed alterations (Jabbar et al. 2021) to enhance production parameters such as the formation of standard heat, improve food digestion and increase resistance against pig ailments.

The Cas-9 technique has enabled knocking out the sexually determined region of the Y gene of pigs by micro inoculating Cas plasmid cytoplasm. Sex change is so valuable as it influences economic gain due to varied economic benefits harvested from wither female or male pigs.

19.6.2.4 Transgenesis

Genetic engineering has been used for the introduction of foreign genes such as genes controlling growth to increase growth and improve carcass quality (Madan 2005). Transgenesis refers to the process of transferring an exogenous DNA segment or gene (transgene) to an animal so that it is able to pass the transgene on to all of its offspring. In this way, a transgenic pig is one that has stably incorporated engineered DNA into its germline and is thus a genetically modified organism. Where the appropriate institutional and human capacities exist, transgenesis could be used to introduce useful genes such as those for improved growth, production, disease resistance and thermotolerance into livestock species to enable them to adapt and produce in various environments.

19.6.2.5 Assisted Reproductive Technologies

Reproductive biotechnologies are of critical value to African pig genetic improvement and have had varying levels of success in different African countries. The primary goals of the assortment of technologies/innovations are increasing production, reproductive efficiency and enhancing the rates of genetic improvement (Madan 2005). Additional techniques that further enhance reproductive efficiency and pregnancy rates of pigs are the evaluation of sperm fertilisation capacity, sperm sexing, oestrus synchronisation, fixed-time insemination, embryo splitting and in vitro embryo production.

The uptake of pig artificial insemination (AI) in Africa is still very low compared to progress with bovids, but successful conception rates of field AI programmes in a few countries are quite impressive (Niyiragira et al. 2018). Whereas bovine AI is mainly challenged by high technical expertise of the practice and the low spread of cryo-storage facilities, pig AI is limited by the limited availability of inseminators, insemination kits and a poor fresh semen distribution mechanism in most countries. The biggest boost of AI in swine is the lack of boars in most smallholder pig farms (Bamundaga et al. 2018). To reduce

costs associated with multiple inseminations that are conventionally required, research has recently focussed on improving oestrus detection followed by carefully timed single-dose insemination. Results of farrowing rates and litter sex ratios have been quite comparable for single and double AI and adoption of this biotechnology in Eastern Africa is on the rise (Bamundaga et al. 2018).

Oestrus synchronisation adds value and success rate to swine artificial insemination. The major impetus of this technology is the limited skill to detect oestrus by most smallholder farmers in Africa. The oestrus cycle in domestic pigs runs for 18–24 days consisting of a follicular phase lasting 5–7 days and a luteal phase of 13–15 days (Soede et al. 2011). The follicular phase enables small antral follicles to develop into large, pre-ovulatory follicles. Pigs are able to produce between 15 and 30 follicles, the number is influenced by several factors including age and nutritional status among others (Blödow et al. 1990). Gilts are usually inseminated at their second or third oestrus cycle after the onset of puberty while sows should be served at the first oestrus following the weaning of its litter. Oestrus and ovulation occur 4–7 days after weaning, with the cessation of lactational anoestrus (Brüssow and Wähner 2011). This means if the pig in the luteal phase receives a dose of prostaglandin, it will come to oestrus within 72 hours and this is the window of action for insemination.

19.7 Prospects for Sustainable Utilisation and Conservation of Indigenous Pigs of Africa

African pig genetic resources constitute an important component of animal agriculture contributing to food security, wealth creation and sustaining livelihoods. African indigenous pig breeds remain vital functional components of animal agriculture and it is important to recognise this fact and put in place appropriate breeding strategies for their sustainable utilisation and conservation. National governments should ensure the implementation of the pig component of their strategic plans on animal genetic resources improvement and conservation. Programmes favouring in situ conservation of indigenous pig genetic resources within their production systems should be promoted. Additionally, depending on the location, production system and the availability of resources, ex situ conservation options should also be explored to maintain the pigs for future generations.

Ex situ in vitro conservation may be expensive for some African countries, especially those that do not have national gene banks in operation. It is, therefore, imperative that the five African subregional gene banks, now rebranded as African Union Animal Resources Seed Centres of Excellence (AU-ARSCoE), prioritise pig genetic resources from such countries. These centres are located in Entebbe, Uganda for Eastern Africa Region, Bambui, Cameroun for Central Africa, Gabarone, Botswana for Southern Africa, Bobo-Dioulasso, Burkina Faso for Western Africa and Tunis, Tunisia for Northern Africa. Pig genetic material that could be conserved cryogenically at these regional centres includes embryo, ova, germinal cells, tissues, DNA and semen.

19.8 Capacity Building for Pig Genetics and Breeding in Africa

In order to have vibrant pig breeding programmes, there is a need for higher degree training (certificate, diploma and bachelor and post-graduate degree level) in human capacity. Institutions of higher learning in Africa, particularly those focusing on Animal Science, should train more animal breeders and geneticists to lead the crusade for sustainable use and conservation of Africa's pig genetic resources. Africa's human and institutional capacity needs to be upscaled to enable the continent to make good use of innovative technologies in pig breeding and genetics for increased production. In consultation with the government, industry and the relevant stakeholders, universities should put up relevant and practical graduate programmes across Africa in modern technologies as applied to pig breeding in partic-

ular and animal breeding in general. Additionally, AU-IBAR (Wurzinger et al. 2021) indicates the need for strengthening the various stakeholder institutions including teaching, research, extension, trade and marketing as well as those dealing with policy and legal aspects. Furthermore, all stakeholders should play their unique roles in the management of farm animal genetic resources while exploring public–private partnerships in capacity building. There is also a need for people trained in modern technologies and operationalisation of established regional gene banks (the African Union Animal Resources Seed Centres of Excellence) and national AI centres across the continent. Existing partnerships between African scientific organisations with companies that specialise in pig reproduction technologies such as Pig Improvement Company (PIC), KUBUS Spain, Minitube GMBH and Hendrix Genetics should be strengthened and new partnerships explored.

In many African countries, there is a general lack of practical livestock-specific education, and many private education initiatives that provide post-primary and post-secondary school vocational education in Agriculture find difficulty in gaining accreditation. Very few institutions offer a livestock and animal science-specific programme and where they exist there is no specialisation in the field of piggery biotech and business. Where they exist, the programmes are highly theoretical and, hence, students find difficult to utilise the knowledge acquired. For example, Makerere University in Uganda, the University of Ghana and many other African universities are located in the capital cities and their teaching farms are located far from the campus and students' residences which makes it difficult to acquire practical skills in pig management and production on a sustainable basis. There is therefore a need to rethink the location and programming of agricultural training institutions. Integration of field attachments and internships into curricula could go a long way to ameliorate the situation. These could be offered at private agricultural establishments, research institutes, and within and across African states.

19.9 Conclusion and Future Perspectives

Africa boasts of a wide diversity of pig genetic resources including indigenous breeds, locally adapted exotic genotypes, and crosses between indigenous and introduced exotic breeds. Pigs contribute greatly to wealth creation, meat production, employment and various industrial products such as gelatin, wax, soap, biofuels and manure, but in many parts of Africa, the full benefits from the pig are not yet realised. Breeding programmes are often based on specific production objectives and the prevailing production systems. Pig production systems and farmers are unique and vary from one region of Africa to another, and also from country to country in a given sub-region. These systems have market-oriented breeding objectives that unfortunately often fail to match the available improved genotypes to favourable production environments. There are many examples of locally adapted exotic pig breeds not producing to their maximum because of the poor environment and management. Over the years, pig breeding in Africa has shifted from breeding for just high production to breeding for production efficiency, health, functional, resilient and adaptive traits. The African pig production value chain is bridled with various challenges from lack of planned breeding programmes, poor conservation of indigenous pig genetic resources, poor pig housing, high feed and veterinary costs as well as diseases, particularly the dreaded African Swine Fever. At the same time, emerging innovative technologies provided with the right human and institutional resources can help turn most of the challenges into opportunities and in the process help improve pig breeding in Africa.

Sustainable pig breeding in Africa will require the conservation of indigenous pig genetic resources through their sustainable use and ensuring that they remain vital components of the production system. In this regard, future pig breeding goals should focus not only on large litter sizes, feed conversion efficiency and growth rates but also on welfare traits like heat tolerance,

adaptation as well as carcass quality and traits that will require indigenous pig breed contributions. Sustainable pig breeding programmes will also require infrastructure for data collection and their evaluation to guide future initiatives. We need to learn from best pig breeding practices and take advantage of available innovative reproductive technologies including artificial insemination and embryo transfer to speed up pork production for food security and wealth creation. National governments should conserve a wide variety of pig genetic resources to better respond to future environmental uncertainties and changing market demands. Individual farmers may invest in conservation efforts but government departments must be in the vanguard of this deliberate action. Pig farmer organisations should be capacitated and encouraged to be part of a national pig production platform to ensure that agreed-upon farmer-trait preferences are considered in future pig breeding programmes. At the same time, multinational pig breeding companies doing business in Africa should be mandated to contribute towards sustainable pig breeding programmes by contributing towards in situ and ex situ conservation of pigs in Africa. Finally, Africa needs to invest in its human and institutional resources to take advantage of emerging technologies such as genomic selection, transgenesis and assisted reproductive technologies including artificial insemination and embryo transfer. This will require comprehensive training programmes from the secondary to tertiary levels to ensure sustainable pig breeding as well as sustainable use and conservation of pig resources in Africa.

Part III

Leveraging Modern Technologies for Improved Utilization of African Livestock Genetic Resources

20 Role of Modern Technologies for Sustainable Genetic Improvement of African Livestock

Eveline M. Ibeagha-Awemu, Sunday O. Peters, Martha N. Bemji, Jean M. Feugang, Richard Osei-Amponsah, Daniel Trocmé, and Raphael Mrode

Abstract

Evidence of the impact of advanced technologies in genetics, nutrition and health management in the last seven decades has led to a twofold increase in the milk produced by a Holstein cow and a fourfold increase in the size of a broiler chicken in Western countries. Therefore, harnessing breakthrough technologies of genomic breeding, reproduction, management practices (health and environment), etc., with supporting infrastructure, funding and technical know-how is key to solving current problems and achieving rapid developments in the African livestock sector. This chapter presents an overview of some modern technologies that have played and continue to play significant roles in advancing sustainable genetic improvement in the livestock sector. Firstly, Section 20.2 presents the key issues impeding sustainable livestock improvement within Africa's complex livestock production systems. Then the phenomics technologies used for data capture to support genetic selection are presented in Section 20.3 followed by the breakthrough genomics technologies responsible for sustained genetic improvements in livestock traits (Section 20.4). The emerging technologies of genome editing (Section 20.4.3) and cellular agriculture (Section 20.4.4) are also presented. Breakthrough reproductive technologies that have been responsible for the spread of high-

20.1 Introduction

The rapid growth of Africa's population, currently 1.4 billion and estimated to reach 2.5 billion by 2050, is not matched by growth in agricultural productivity, including livestock production. Despite the high genetic diversity (species and numbers) of African livestock populations (see Chapters 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, and 13), productivity is low, plagued by a myriad of problems, and unable to sustain lives and economic development. Sustainable improvement of African livestock species is urgently needed to meet the food needs of the people as well as for sustained economic development of the various countries.

To advance the needed solutions to Africa's food and health needs, it is generally accepted that modern technologies will play a big role. In particular, developments in genomics, reproduction, growth, phenomics, health and management technologies, etc., will support rapid growth in

the livestock sector. Effective research and development activities in solving even basic problems require multidisciplinary, problem-solving and technological approaches. For instance, major breakthroughs and scientific progress in deciphering whole-genome sequences to developing vaccines for the control of diseases resulted from harnessing new technologies, supporting infrastructure and the joint efforts of large multidisciplinary teams of professionals of varied backgrounds, such as biologist, clinicians, bioinformaticians, mathematicians, computer scientists and project administrators among others.

In particular, the implementation of genetic improvement has been the most efficient strategy used to increase the biological performance, efficiency and sustainability of animal production systems in recent decades. The genetic improvement science evolved through the application of statistical approaches, quantitative genetic theories, artificial insemination and organized breeding practices, which resulted in rapid gains in livestock traits in the past decades, and in recent times more genetic progress in livestock traits is achieved with the implementation of genomic selection and advanced reproductive technologies.

Technological developments of genomic tools such as next-generation and third-generation sequencing approaches, and dense single nucleotide polymorphism (SNP) genotyping panels have been crucial to both advance basic knowledge on the genomic bases of complex traits and increase the rate of genetic progress in livestock production and health. Aided by these and other technologies, genomic information is now routinely used in selective breeding to support livestock production, in species like cattle, chicken and pig (Georges et al. 2019). Genomic technologies have consequently transformed the livestock industry in terms of increased productivity, environmental adaptation and health management. Therefore, efforts to advance livestock improvement in Africa will require multiple technologies and approaches, including genomics, reproduction, nutrition management, phenomics, statistical/bioinformatics management of data, etc., and the involvement of multidisciplinary teams with the required supporting infrastructure, government policies and financial investments. This chapter will focus on phenomics, genomics, reproduction and other emerging (gene editing, cellular agriculture) technologies that can support sustainable genetic improvement in African livestock production systems, while technological developments supporting other aspects of livestock production that are necessary for optimal genotype x environment interaction for optimal phenotypic expression, like nutrition and health, have been presented in Chapter 21.

The adoption of technology in various aspects of livestock farming has been extensively studied (Feder et al. 1985; El-Osta and Morehart 2000). It is stipulated that larger farms tend to be at the forefront of adopting technologies which have helped to increase profitability and feed quality, and reduced production costs and incidence of disease outbreaks. In dairy production, the late adopters of technology are small-scale milk producers because most of the technologies are capital-intensive and not easily affordable (El-Osta and Morehart 2000), which is one of the issues facing livestock farming in Africa. However, with the current low levels of productivity of most African livestock, the adoption and use of modern technologies are necessary to drive and sustain improved management and productivity. This chapter will focus on different technologies for sustainable genetic improvement adopted by low-, medium- and large-scale livestock production systems.

20.2 Key Issues Related to Sustainable Livestock Improvement in African Livestock Production Systems

In Africa, 70 percent of the resource-poor farmers own animals which represent about half of their assets and account for 20% agricultural output (The World Bank 2018). Resource-poor small-holder farmers constitute the largest

labour force that produces most of the milk and meat in Africa. Given that farming is subsistence in nature, sustainable livestock production and improvement are marred by several factors. These limitations (e.g. low productivity, genetic erosion through indiscriminate crossbreeding, lack of performance recordings, limited feed resources, among others) are examined below to provide recommendations for affordable technologies that could promote the improvement and sustainability of the livestock enterprise.

20.2.1 Low Productivity of Indigenous Animal Genetic Resources

Livestock productivity is generally low across the African's production systems. Current indicators show that agricultural output in terms of meat, milk, hide and skin, and draft power is generally low, irrespective of the type of production system (pastoral, agro-pastoral, mixed small holder farming, urban or peri-urban) (Ibeagha-Awemu et al. 2019). Considering the predominant meat and milk-producing livestock species (cattle, goat, pig, poultry and sheep), Africa has the highest number of cattle breeds (44.6%) in the world followed by Europe (25.1%) and Asia (16.2%), while North America has the least numbers (0.9%) (Table 20.1). However, Africa has only 19.9% of live cattle and ranks least in terms of milk and butter production and only better than Oceania by 3.7% in meat production in 2019 (Table 20.1). The productivity of chickens and pigs is considerably lower compared with other continents. Although Africa ranked second in the number of live sheep and goats, meat production from these species is proportionately lower than in the Asian continent (Table 20.1). The low productivity of the African indigenous livestock resources is generally due to poor nutrition (low quality and quantity of feed materials, limited grazing land, low-quality pasture), poor management (e.g. disease) and lack of sustained genetic selection of high-producing individuals. Production is characterized by extensive systems of management that are not designed to optimize animal growth and productivity, lack of data recording schemes as means to judge animal performance, unimproved breeding animals, indiscriminate mating and crossbreeding within and between breeds, high disease burden, limited water resources, desertification and increasingly less rainfall in many parts of Africa, limited support from national governments and lack of appropriate legislation promoting livestock improvement by most governments.

Implementation of innovative technologies, including genomic and management technologies to increase milk and meat production, technologies to improve nutrition and health, and phenomics technologies for data recording and reproduction technologies (discussed in this chapter and Chapter 21) will go a long way in advancing the livestock sector in Africa.

20.2.2 Erosion of Diversity Through Indiscriminate Crossbreeding

In most African livestock production systems, directional or intentional breeding of animals is not practised. Rather, animals breed indiscrimi-

Table 20.1 Production share of live animals and some products by continent in 2019

Continent	Live animals (%)					Meat production (%)					Milk/Butter (%)
	Cattle	Goat	Sheep	Pig	Chicken	Cattle	Goat	Sheep	Pig	Chicken	Cattle
Europe	9.9	2.1	12.7	21	10.6	19.5	2.7	15.9	26.4	16.8	53.3
Americas	35.6	4.2	8.0	17.1	26.6	48.1	2.9	5	17.4	44	20.3
Asia	31.9	56.9	40.6	58.4	54.5	19.4	70.5	47.2	54.7	33	12.5
Oceania	2.7	0.4	11.6	0.6	0.6	4.6	0.4	13.9	0.5	1.3	10.9
Africa	19.9	36.4	27.1	3.0	8.1	8.3	23.4	18.1	1.0	5.0	3.0

Source: Data used to generate this table was from FAOSTATS (2019)

nately within and between populations. As a result, frequencies of genes that favour increased genetic gains in many traits are constantly diluted, resulting in no genetic gain in traits over the years. Crossbreeding activities varied widely across species and countries (Leroy et al. 2016) due to indiscriminate use of breeding animals, thereby causing high gene flow between populations and erosion of animal genetic diversity in cattle (Traoré et al. 2017; Ibeagha-Awemu et al. 2004; Mwai et al. 2015), sheep (Brahi et al. 2015), chicken (Eltanany et al. 2011; Kejela 2020) and pig (Ramirez et al. 2009). Given the poor performance of indigenous livestock, some African countries adopted crossbreeding of locally adapted breeds with improved exotic breeds as the quickest approach to enhance productivity. According to the history of animal genetic improvement, mostly crossbreeding with exotic breeds started in West Africa and extended to other regions of sub-Saharan Africa by colonial settlers (Madalena et al. 2002). In Cameroon, Nigeria and Ghana, crossbreeding with exotic and indigenous breeds for improvement in meat and milk production took place in the early decades of the twentieth century. However, crossbreeding programmes were not sustainable due to the poor adaptation of the exotic and crossbreds to low-quality feed and the environmental conditions (Leroy et al. 2016; Madalena et al. 2002). Although attention shifted from crossbreeding to straight breeding in the 1980s following the recognition of adaptive features of indigenous breeds (Madalena et al. 2002), their genetic uniqueness and adaptation to local conditions have been compromised, giving way to genetically mixed populations with weak differentiation between sub-populations in chicken (Eltanany et al. 2011), pig (Ramirez et al. 2009) and sheep (Brahi et al. 2015; Agaviezor et al. 2012). Carefully designed breeding programmes (see Chapters 15, 16, 17, 18, and 19) and implementation will limit the effects of indiscriminate crossbreeding and promote sustainable genetic gain increases in desired traits and improvement in overall livestock productivity.

20.2.3 Scattered, Small Herd Sizes and Lack of Performance Recordings

Information on the phenotype is fundamental for understanding the genetic basis of performance and for making informed decisions for effective herd and flock management. Unfortunately, African subsistence agricultural systems are characterized by scattered, small herd sizes, and most smallholder farmers make use of indigenous and nondescript crossbreds with no animal recording (Ibeagha-Awemu et al. 2019; Zonabend et al. 2013a; Marshall et al. 2019). This is further compounded by a lack of coordination among the institutions that are set up to support animal breeding programmes and a lack of skilled manpower (Zonabend et al. 2013a).

While adequate and sustained animal performance recording is the backbone of livestock improvement schemes in industrialized nations, livestock data recording is not commonly practised in most African countries. This lack of sustained data recording schemes in Africa is caused by many factors, including poor animal identification systems and inadequate infrastructure for collecting and processing data (Ojango et al. 2017). Only a few countries in Africa (e.g. South Africa, Kenya, Ethiopia, Botswana and Zimbabwe) have organized and sustained or on-and-off or collapsed data recording schemes for performance monitoring. The adoption of phenomics technologies suitable for smallholder farmers and for all production systems will facilitate data collection, which is the basic requirement for performance evaluation and monitoring.

20.2.4 Limited Quantity and Quality of Feed Resources, and Low Efficiency of Feed Utilization

Many forage-based animal production systems in the tropics grow slowly and produce small amounts of milk and meat because their diets are

inadequate in protein, energy and micronutrients (National Research Council 2009; Muyekho et al. 2014). Many ruminant animals usually receive or graze only plant residues (e.g. wheat straw and corn straw) in the dry season. About 72% to 93% of the feed consumed by ruminants in Africa is made up of low-quality natural pastures and crop residues (FAO 2014). Supplemental feeding with concentrates is common in semi-intensive and intensive systems of production, which caters to only ~10% of the ruminant livestock produced in Africa. Improving the nutritional quality of forage and crop residues is necessary for sustainable livestock production in Africa. Common methods for increasing digestibility and protein content of crop residues include physical (grinding, chaffing and chopping of roughage or fibrous feeds and pelleting), biological or chemical treatment (e.g. ammonization, alkali and urea) (Valli 2020). Forage can be improved by breeding and the creation of improved pastures for grazing. In particular, the implementation of genomic breeding technologies for improving the nutritional and yield qualities of forage crops holds great potential for improving livestock productivity in Africa.

20.2.5 Animal Health and Welfare

Livestock productivity is hindered by several constraints, including a high prevalence of diseases and parasites irrespective of production systems (Santoze and Gicheha 2019). Certain types of livestock systems are associated with zoonotic and emerging infectious diseases or food-borne illnesses (Kristjanson et al. 2010). This has implications for the high cost of disease control, as witnessed by improved dairy production in Kenya (Muyekho et al. 2014). According to the Food and Agricultural Organization (FAO) (FAO 2018), poor awareness of animal health in subsistence-oriented production systems, combined with poor communication and transport infrastructure, often translates into ill-functioning private and public animal health services, thereby calling for the strengthening of existing health services and the establishment of alternative forms of animal health services.

20.2.6 Environmental Pollution/ Degradation

Livestock and livestock systems can have negative effects locally which include land conversion and land degradation. Twenty percent of the world's pastures and rangelands have been degraded to some extent through overgrazing, compaction, and erosion caused by livestock activities. Poultry, pig, sheep, goat, cattle and other domesticated animals generate around 85 percent of the world's animal faecal waste (The World Bank 2018) which can contribute to environmental pollution if not properly disposed of or managed**.** Most cities in Africa are characterized by the constant presence of livestock which is a source of pollution and may be reservoirs of diseases including zoonotic diseases (Wilson 2018). It has been estimated that the livestock sector in Africa contributes to more than 70% of the continent's agricultural greenhouse gas (GHG) emissions, mainly attributed to methane and nitrous oxide from cattle and their manure (ILRI 2021). However, due to huge research gaps**,** understanding of Africa's contribution to global GHG emissions remains incomplete and highly uncertain (Kim et al. 2016).

20.2.7 Farmers' and Herders' Clashes

Insecurity has discouraged both farming and herding in many areas, with serious effects on livelihoods and food supply (Blench 2004). The presence of animals in many African cities is a major source of conflict (Wilson 2018). In Nigeria and Ghana, violent herdsmen and smallholder farmer conflicts are mainly due to the migration of herdsmen from the northern regions, which is aggravated by climate change and diminishing agricultural lands, to the southern regions in search of pasture for their animals and low adherence to the ECOWAS (Economic

Community of West African States) Protocol on Transhumance (Asueni and Godknows 2019; Majekodunmi et al. 2014). It has been noted that other important aspects of violence beyond 'farmer-herder clashes' include revenge for past attacks, economies of conflict (cattle rustling and armed robbery for gain), resource scarcity, decreasing interdependence of pastoral and agricultural economies, cultural/religious differences between herders and farmers and institutional failures to resolve conflicts as well as the broader political and historical contexts (Asueni and Godknows 2019; Higazi 2013). Addressing this issue is paramount to supporting livestock and crop production, as well as saving lives. The local, national and regional governments in affected areas must take concrete steps to addressing farmer-herder conflicts by setting supporting livestock policies, creating designated grazing lands and grazing corridors away from crop farm lands and taking adequate measures to protect the lives of crop farmers.

20.2.8 Marketing Access

Livestock marketing faces many challenges in Africa, including the lack of marketing facilities, inadequate marketing channels and infrastructures, organization and methods, inadequate government policies and limited access to across country and international markets (Ibeagha-Awemu et al. 2019). These challenges must be addressed by all African countries and livestock production must be recognized as a viable business to spur increased implementation of modern technologies for increased productivity.

20.2.9 Funding

The implementation of modern technologies described in the sections below is dependent on available/adequate and sustainable funding of livestock research, farming and associated aspects, including capacity building, health management, feeding management and market access among others. Livestock production is an important source of food for the population and merits government funding as does services like education, health and the military, among others.

20.2.10 Government Policies

Policies aimed at sustainable livestock production and mitigation of the impact of animal production are largely aspirational goals. While many countries in Africa recognize the need for livestock breeding and management policies for setting priorities and directing activities in livestock breeding (Zonabend et al. 2013b), the implementation of policies is lacking. Recently, the Africa Union InterAfrican Bureau for Animal Genetic Resources (AU-IBAR) undertook a study with the aim to facilitate or fast-track implementation of the Global Plan of Action for the sustainable use of animal genetic resources in Africa (AU-IBAR 2018). Despite such initiatives, livestock production in most of Africa is unregulated and saddled with low human and institutional capacity to take advantage of appropriate innovative technologies. Therefore, putting in place enabling national, regional and continent-wide policies aimed at supporting growth of the livestock sector are necessary for the growth and expansion of livestock production and marketing in Africa.

20.3 Information and Phenomic Technologies in Animal Production

Phenomics may be broadly defined as the application of technologies to enable the collection of phenotypes cheaply, easily, more efficiently and in large volumes. It is therefore very important as phenotypic data play a key role in the design of effective herd and flock management systems and in understanding the genetic basis of livestock performance. In addition, at the national level, capturing phenotypes is fundamental in national aggregates of produce that underlines government agricultural policies and projections (Mrode et al. 2020). Therefore, at the farm level,

phenomics is important for profitability and in the design of breeding programmes, and at the national level for effective government agricultural policies. Labour accounts for about 70% of the production cost of most livestock products, therefore in an attempt to reduce cost, there have been significant developments in the last two decades in sensors, digital communications and other technologies that enable cheaper and more accurate recording of existing phenotypes and access to new ones. Also, the more accurately we can capture phenotypic records, the higher the rate of genetic progress that can be achieved. The elaborate efforts on technologies to capture data or performance are proving valuable for data collection, especially for difficult and expensive to measure traits such as reproductive and health events, feed intake and carcass traits.

In the following sections, we examine existing and emerging technologies for information and phenomics, and in particularly their suitability and usage in African production systems, given that systematic data capture has been a missing foundational stone that has hindered sustainable livestock genetic improvement programmes in Africa. In general, the degree to which these technologies are used is influenced by cost, practicality and portability.

20.3.1 Information Systems in Livestock Management

What has information technologies to do with the development of livestock breeding and farming activities? Economically, the production and income of farmers can grow only with their ability to sell quality meat and dairy products on the national and international markets at competitive prices. But nowadays, having access to these markets requires providing quality proof. It thus requires animal registration and traceability as well as performance management. The interest of farmers in high-performance breeds will be strictly proportional to their awareness of this economic opportunity.

This is where integrated information systems come into play. Their ability to integrate traceability, health, reproduction, performance recording, genetics and marketing of products in a unique system, and to provide each type of user their rights, is the main key to success. Indeed, the development of the livestock sector needs all these aspects to be synchronized.

France was the first country to identify its cattle in the 1970s, creating a strong link between identification, health and genetic systems. The European Union has progressively adopted restrictive regulations due to the bovine spongiform encephalopathy crisis and the growing demand for traceability. The whole world has taken inspiration from these principles of regulation to increase their ability to export their products.

In 2015, Kyrgyzstan was assisted by FAO in implementing an integrated system of animal identification and traceability. The integrated identification and traceability system was developed by Adventiel (https://www.adventiel.com/) in collaboration with public organizations. The multi-partner system created the ability to collect continuously accurate information on livestock on the field (which gave a modular structure to the system): with a mobile application, a web portal and a common database. Specifically, it records:

- Identity of all farmers, farms, premises, marketplaces and slaughterhouses.
- Identity of animals, unique from birth to death (in line with the International Committee on Animal Recording guidelines).
- Traceability of the movement of live animals.
- Record of animal health events and status (prevention, diseases, treatments, etc.)

These modules are the core of the system. Additional components are as follows:

- Marketing modules such as traceability of animal products' batches.
- Reproduction and insemination modules.
- Performance recording field applications.
- Genetic, genotyping and pedigree management module. Genetic improvement is impossible at a large scale without extensive identification of the animals.

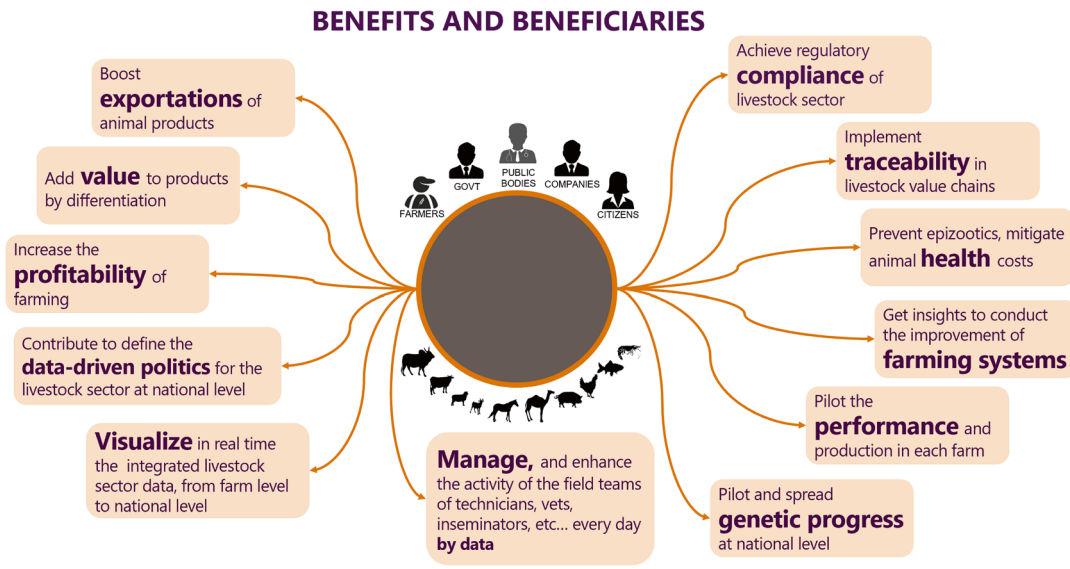

Fig. 20.1 Benefits and beneficiaries of a livestock identification and management system

Next is the ability to exchange data with other systems in a secure manner at the national and regional scales and to offer reliable guarantees regularly to users (buyers and/or foreign authorities). This possibility to provide guaranties from the suppliers to the users accords numerous benefits (Fig. 20.1):

- Foster long-term commercial relationships and alliances in the region and beyond.
- Dramatically reduce the restrictions and prohibitions on animals and products.
- Allow economic players to pay equitable prices to farmers for highly valuable products.

20.3.2 Sensors for Fertility, Health and Body Weight Traits

Sensors are defined as devices that measure a physiological or behavioural parameter of an individual animal that might be related to fertility or health or any other trait, and that enable automated, on-farm detection of changes that warrant a management intervention (Rutten et al. 2013). Sensors can be classified into two categories: attached and non-attached. The attached sensors are either on-animal sensors that are fitted on the outside of the animal's body, or in-animal sensors that are inside the body such as rumen implants or bolus. On-animal sensors such as wearable sensors can monitor the overall well-being of the animal, such as milk quality, pregnancy hormones, rumination, illness, and lameness efficiently and more accurately (Fig. 20.2) (Siberski-Cooper and Koltes 2021). For non-attached sensors, animals may pass by, over, or through these for the measurements to be taken. This class of sensors includes on-line sensors that automatically take a sample such as milk that is analysed by the sensor or in-line sensors that take measurements in a continuous flow of a product (e.g. milk from cows during milking) (Simm et al. 2021). In general, sensors monitor the daily activity and health-related issues of animals and at the same time generate data for the entire herd, which is analysed and used for herd/farm management decisions. The performance of wearable sensors commonly used to collect behavioural and physiological data for precision livestock farming was recently reviewed (Lee and Seo 2021).

Most sensors have been developed for livestock management with the aim of reducing labour

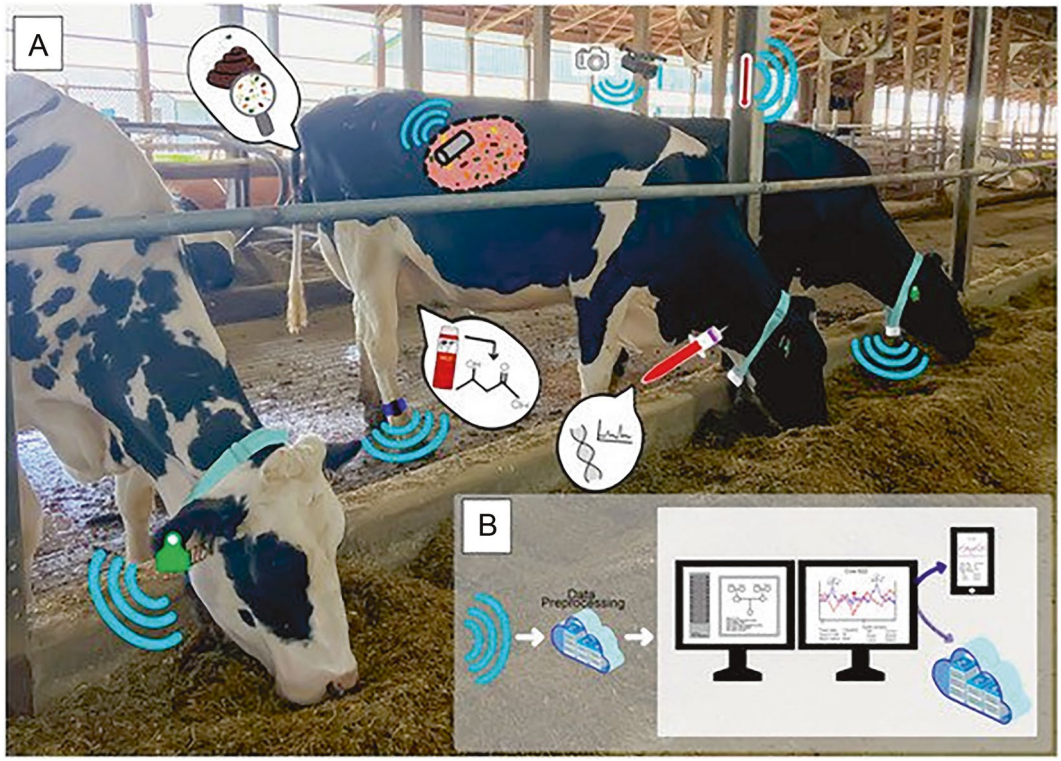

Fig. 20.2 Wearable sensors such as milking collar, leg band and ear tags, temperature and proximity sensors; image-based monitoring systems and internal sensors collect data (**a**) which is analysed (**b**) for informed management decisions. (From Siberski-Cooper and Koltes (Siberski-Cooper and Koltes 2021), licensed under CC-BY 4.0)

requirements and costs. There are several sensors for the automated detection of oestrus, based on either the activity of the cow or on progesterone level of milk. Also, electronic Alpha-Detectors (e.g. Alpha-D) detect the animal's electronic identification and transmit the data on the frequency of mating, true and false coverings and the number of animals mated to a centralized computer. This type of sensor therefore interacts with individual animal electronic identification and collects data to feedback systems. The sensors that monitor the activity of cows are pedometers, activity meters (sometimes referred to as activometers) and three-dimensional (3D)-accelerometers (Rutten et al. 2013). These are usually on-cow sensors with pedometers and 3D accelerometers usually attached to one of the cow's legs and the activity meters to a neck collar.

The automatic monitoring of progesterone levels in collected milk samples is achieved using on-line sensors such as biosensors and immunostrips. An oestrus alert is provided for the farmer with these sensor systems and in some cases with a probability measure of the alert. Some sensors monitor and report on the reproductive state of the cow such as postpartum anoestrus, oestrus cycling or potentially pregnant.

Several activity meters have also been used for the automatic detection of health traits such as locomotion problems in dairy cows. The walking behaviour/gait has been measured in cattle and poultry using sensors such as 3D accelerometers and/or video cameras. For example, accelerometers (tied around the foot, neck or head) measure the movement, speed and direction of animals (Roland et al. 2018). Three axial accelerometers

for instance record movement patterns and behaviour, such as resting, grazing, moving and running/playing or lameness in animals in a three-dimensional pattern (Fogarty et al. 2018). A recent study demonstrated the use of axial accelerometers for reproduction control/management in dairy sheep (Mozo et al. 2019). In addition, the detection of locomotion problems has been automated by means of several off-animal sensors such as four balance-weighing floors, weighing platforms, parallel force plates and force distribution plates by studying the weight distribution among the cow's legs (Rutten et al. 2013). In these systems, animals are required to stand on or walk over these sensors and an alert for abnormal locomotive behaviour is provided to the farmer, with some measure of the degree of reliability or analyses of processed sensor data such as walking activity or weight over time.

Rumination activity collars and sensors assist in detecting behavioural and activity changes in cows, and early indication of sickness or infection. Devices like pedometers effectively track specific cow actions like its readiness for breeding or going into labour, facilitating the farmers' help for opportune assistance. The rumination collar uses a microphone to measure a dairy cow's rumination to ensure a smooth transition. Changes in rumination can be an early sign of calving diseases, negative impacts of ration changes, cow discomfort, etc. Knowing normal rumination patterns for a specific dairy cow helps mitigate the effects of manageable stressors (Groher et al. 2020; Silvi et al. 2021).

A rumen bolus measures rumen temperature and pH levels to help identify systemic infections that need to be treated. If a rumen bolus tells a dairy producer that a cow's pH is dropping, it is a sign that a total mix ration (TMR) is not thoroughly mixed, and a ration change has negative impacts. This can help producers make appropriate changes to their dairy cattle nutrition programme (Krpalkova et al. 2021; Simitzis et al. 2021).

Increasingly, automated weighing techniques are being used to monitor growth or to monitor changes in weight in several species that may provide an early indicator of health issues. Typically, animals walk over platforms mounted on weigh cells, with both weights and animal identities being captured using non-attached sensors (Simm et al. 2021).

The electrical conductivity (EC) of milk has been used for routine in-line tests for the diagnosis of sub-clinical mastitis in dairy cattle for some years (Milner et al. 1996). Typically, milk EC is determined by measuring the concentration of cations and anions. During infection, milk concentrations of Na^+ and Cl^- ions increase while concentrations of lactose and K^+ are decreased. The sensor system uses the statistical relationship between the EC measurements and a gold standard measure for mastitis, such as the California Mastitis Test, to provide the farmer with a mastitis alert and an associated degree of reliability.

20.3.3 Animal Position Monitoring

Monitoring animal position, foraging and other behaviours can benefit animal health and welfare by continuously monitoring each animal in the flock. Any small deviation from 'normal' behaviour (for that individual animal) can be quickly identified and flagged to the farmers. Some farmers use Radio Frequency Identification tags to track animals' origins, movements and whereabouts. Some farmers use pedometers (like Fitbits for cows) to track the daily activities of each cow and to identify cows that may need a little extra care or help (Silvi et al. 2021; Krpalkova et al. 2021). Other times, farmers track, monitor, and control nutrition, behaviour, pregnancy, milking frequency, milk output anomaly and activity level in real-time owing to wearable animal gadgets similar to human fitness trackers. These intelligent animal trackers may be placed on the ears, tails, legs, neck, or any other portion of the body (Silvi et al. 2021; Shalloo et al. 2018). Cattle monitoring drones track the cattle and herd them back from the fields to the barns. Some drones are outfitted with thermal sensing equipment, which allows them to track cattle based on their body heat. Drones may

also scan pasture lands and communicate information about whether they are suitable for cattle grazing (Joshi et al. 2019).

A computer-controlled gate system opens and closes electronically in automated cow traffic management system. These gates can categorize livestock based on their readiness to milk. The animals ready to be milked are transferred to the milking area, while the others are placed in the waiting area or back to their barns. Global navigation satellite system technology also allows for characterizing grazing behaviour, including grazing patterns, paths and favoured areas. Grazing activities can also be differentiated based on the speed of movements. Tracking location on pasture, through global positioning system sensors, has been successfully used to detect static or dynamic unitary behaviours differentiated through changes in path speeds, such as foraging or grazing, resting and walking. Likewise, the use of global positioning system 'collars' for livestock has opened the possibility of recording detailed position data for extended periods, thus allowing for a complete understanding of the habits and causes of the spatial distribution of ruminants (Shalloo et al. 2018; Monteiro et al. 2021).

20.3.4 Automated Systems for Measuring Feed Intake

Feed intake constitutes about 70% of the production costs in most livestock systems, therefore improvement in feed efficiency will enhance farm profitability and reduce the environmental impact of livestock production. However, capturing individual animal feed intake is very expensive and difficult. The earlier systems for capturing feed intake involved the use of specialized equipment that consisted of an individual bin for an animal. Then the access of each animal is restricted to only one bin through the use of an electronic identification device mounted in a collar. Initially, a certain amount of weighed feed is added to the bin and after a specified time interval (12 hours, for instance) the feed remaining in the bin is weighed and discarded. Therefore, the feed consumed by the animal with access to the bin was calculated as the difference between the two feed weights. However, this system, although cheap, is labour intensive as feed has to be manually weighed in and out of the bin, and it might also influence the cows' feeding behaviour.

Advances in technology have resulted in the emergence of several automatic systems to measure individual animal intake, but most of these systems are rather expensive and tend to be used mostly in nucleus breeding populations or research farms. In general, these systems have feed bins mounted on weigh cells that are constantly monitored. The identity of animals accessing a bin is captured from an electronic identity device either on the neck collar or ear tag by an aerial device mounted on the entry to the bin. The weight of the feed bin is constantly monitored, therefore, the feed intake for a particular animal is recorded as simply the change in weight of the bin during the period the animal is registered as present at the feed bin. The system offers flexibility as animals can feed at any bin and individual animal feeding behaviour can be studied from additional records on animals such as the daily profiles of feed intake per animal, meal size, meal duration and the frequency of feeding.

Some examples of modern technologies for measuring individual feed intake and in some cases water intake, include GrowSafe (GrowSafe Systems 2021), Calan Broadbent Feeding System (American Calan Inc 2019) and Insentec Roughage Intake Control system (Hokofarm Group 2021).

20.3.5 In Vivo Techniques for the Prediction of Carcass Traits

Carcass and meat quality traits are very important traits in a society that is becoming more health conscious by considering which animal products to consume. However, these traits are expensive and difficult to measure and direct measurement can only take place after slaughter, which usually precludes such measurements on selection candidates in the breeding programmes. In the last

decade, much research has been tailored in finding non-invasive techniques to predict various carcass traits, such as carcass fat and lean weight or proportion or distribution, on live animals (in vivo). A detailed review of non-invasive techniques for carcass and meat quality trait measurements was presented by Scholz and colleagues (Scholz et al. 2015). In general, these techniques involve the use of electromagnetic or mechanical energy, which is able to pass completely or partially through body or carcass tissues, like muscle, fat and bone. As indicated by Scholz and colleagues (Scholz et al. 2015), the electromagnetic signal produced by the instrument may originate from mechanical energy such as 'photon' radiation (X-ray-computed tomography (CT), dual-energy X-ray absorptiometry) or sound waves (ultrasound) or radio frequency waves (magnetic resonance imaging). The signal interacts with tissues in the body or carcass at the atomic or molecular level, resulting in secondary signals that are detected by the instruments and processed to measure tissue depth, area, volume or distribution of fat, muscle and bone or bone mineral. The measurements from these devices are usually validated through a regression equation; with these measures used to predict the measurements obtained directly from the carcass or with proportions or weights of tissues from carcass dissection. The measure of accuracy of prediction by the device is measured by the R^2 of the regression analysis, with high R^2 values indicating high precision of prediction.

Ultrasonic measures have been the most widely used, especially in pig, for in vivo prediction of meat quality, as a result of being relatively cheap, mobile and moderately accurate. More recently, especially for sheep meat, CT has been used more widely in breeding programmes for livestock and it is considered to be the most accurate of the methods discussed above. The details of the application of CT scanning for various carcass traits and utilization in sheep breeding programmes were presented recently (Simm et al. 2021). In summary, CT scanning has been used to estimate carcass composition and muscularity in UK terminal sire breeding programmes since 2000 (Bunger et al. 2014). More recently, intramuscular fat in live lambs and carcass cuts has been measured by CT scanning as a measure of meat quality (Lambe et al. 2017). The results of Lambe and colleagues showed that utilizing CT measurements in a selection index can maintain levels of intra-muscular fat, hence improving eating quality, while also improving carcass quality through increased lean per cent and decrease in total fat in commercial slaughter lambs (Lambe et al. 2017).

20.3.6 Video Image Analysis/ Computer Vision Technologies for Weight, Conformation and Carcass Traits

The prediction of carcass weight as well as the weight of individual primal cuts and conformation and fat class through automated video image analysis (VIA) carcass grading technologies has been implemented in a number of countries. For instance, the VBS2000 VIA machines (E + V Technology 2021) are used in several abattoirs in the UK for this purpose. The automated VIA carcass grading technology involves the use of video cameras on the slaughter line and specialist software to classify the carcasses. In practice, one side of the carcass is suspended on a holding frame while a digital camera on the VIA machine takes a 2D (under normal lighting) and 3D (under striped lighting) image, using a previously calibrated lighting arrangement. These images are analysed to predict the weight of the carcass, the individual primal cuts, conformation and fat class. The prediction of the weights for the carcass cuts is based on a multiple-regression method using both the carcass weight and the VIA information. The precision of prediction (R^2 values) reported by Pabiou and colleagues (Pabiou et al. 2011) ranged from 0.65 for the predictions of low-value cuts (lean trimmings, ribs, flank, and brisket) in heifers to 0.93 for predictions of high-value cuts (silverside, topside, knuckle, salmon cut) in steers. The automation of this process means that carcass weights and primal cuts can be measured in a large number of animals thus enabling genetic evaluations for

these traits. Medium estimates of heritability (0.40 to 0.46) were reported (Moore et al. 2017) for a range of cuts in crossbred beef cattle in the UK. Breeding values are being routinely calculated for various prime cuts in the UK and this implies that breeding animals can be selected for a higher proportion of high-priced cuts. Moreover, the use of these traits in genomic selection means selection for carcass weight and primal cuts was carried out early in life, thereby reducing the generation interval.

More recent application of VIA involves the use of 3D imaging technology and machine learning algorithms (artificial neural networks) to predict live weight and carcass characteristics of live beef animals. The benefits of these approaches include the ability to obtain multiple measurements of traits of interest with minimal animal stress and use the repeated measurements to monitor changes in weight and conformation and predict the optimal time of slaughter. Using three-dimensional images, liveweight on finishing steer and heifer beef cattle of various breeds and machine learning algorithms, Miller and colleagues (Miller et al. 2019) predicted liveweight and several carcass characteristics for the animals. The accuracy of the prediction models they developed based on R^2 was 0.7 for liveweight, 0.88 for cold carcass weights and 0.73 for saleable meat yield. The use of 3D imaging technology has also been used to predict liveweight and various body measurements such as body volume, area, and length in pigs (Wang et al. 2008) and broilers (Mortensen et al. 2016).

20.3.7 Milk Mid-Infrared Spectral Data

There has been an increasing use of milk spectral data as an innovative and low-cost phenotyping strategy in dairy cattle for health and resilience traits. Milk contains molecular signatures or chemical properties reflecting the physiological status of the cow, their performance, their behaviour and environmental impact which can and is being increasingly explored by mid-infrared (MIR). The MIR spectrum represents the absorptions of infrared radiation at frequencies correlated to the vibration of specific chemical bonds within a molecule. Therefore, the MIR milk spectrum represents the chemical composition of milk. The ability of mid-infrared to explore these properties in the milk has resulted in the usefulness of spectra data for various purposes. Major milk components such as fat, protein, urea and lactose contents have been routinely predicted by MIR spectrometry globally (Luinge et al. 1993). The use of MIR has been extended to obtain other phenotypes and has been used in equations to predict several traits of economic importance in dairy cattle. Studies have indicated the ability of MIR to predict individual and groups of milk fatty acids with moderate to high accuracy (Soyeurt et al. 2011; Maurice-Van Eijndhoven et al. 2013), milk technological traits such as milk coagulation properties (Visentin et al. 2015), milk titratable acidity (Visentin et al. 2015; Toffanin et al. 2015) and milk minerals (Toffanin et al. 2015).

Secondly, traits of importance in terms of the resilience of cows and environmental impact can also be predicted based on the longitudinal nature of the relationship between the trait of interest and the MIR spectra. Two studies have documented the ability of the MIR spectrum to predict methane emissions in dairy cows (Dehareng et al. 2012). This link materializes from ruminal fermentation resulting in the production of de novo milk fatty acids as well as the eructation of methane emissions (Chilliard et al. 2001). Nitrogen in the urine of grazing animals can be an important source of groundwater pollution. Based on MIR analyses, Beatson and colleagues (Beatson et al. 2019) reported a heritability of 0.22 for measures of milk urea nitrogen (MUN) concentration, indicating the possibility of selection for lower MUN.

Of much interest also is the use of MIR to predict health traits. Clinical and sub-clinical ketosis results in elevated concentrations of ketone bodies such as acetone and β-hydroxybutyrate in blood and milk. The usefulness of MIR-predicted contents of acetone and β-hydroxybutyrate in milk as a tool for screening for cows less susceptible to ketosis was demonstrated by de Roos and colleagues (de Roos et al. 2007).

In general, MIR has been applied in the measurement of individual milk fatty acids, milk coagulation properties and milk mineral content (Soyeurt et al. 2011; Toffanin et al. 2015); cow feed intake and feed efficiency (McParland et al. 2014); susceptibility to ketosis (de Roos et al. 2007) and methane emissions (Vanlierde et al. 2018). The estimates of correlation coefficient squared (R^2) between various milk fatty acids predicted from MIR and actual measurements in the validation data sets reported by Soyeurt et al. (Soyeurt et al. 2011) varied from 0.38 to 0.98. Using MIR to predict methane emissions, Vanlierde and colleagues (Vanlierde et al. 2018) reported a validation accuracy of 0.57 compared to methane measurements in a respiration chamber. These authors concluded that MIR spectra could be used as a potential proxy to estimate daily methane emissions from dairy cows, cheaply, reliably, rapidly and on a large scale.

20.3.8 Measuring Greenhouse Gas Emissions

In ruminants, methane is produced as a natural part of the digestion process, where microbes in the rumen break down feed and release methane as a by-product, primarily through eructation or belching. Climate change mitigation efforts have focused attention on the greenhouse gas produced by the livestock sector. Globally, agriculture is directly responsible for 14% of annual GHG emissions (Vermeulen et al. 2012), with methane emissions from ruminants accounting for around 80% of all livestock emissions and cattle is responsible for the majority of the emission (Gerber et al. 2013). These observations have resulted in attempts to develop techniques for direct and indirect measures of CH4 emitted at the individual animal level to enable the development of various mitigation approaches including genetic improvement. The gold-standard method for measuring the amount of CH4 is the use of respiration chambers and there are two types: the closed-circuit chamber, where the increasing concentration of methane is measured (Boadi et al. 2002) and an open-circuit chamber which involves analysing the composition of the in-flowing and out-flowing air, which are then compared. However, respiratory chambers are expensive and not very suitable for measuring a large number of animals; therefore, various proxy methods are being investigated. Some of these include the SF6 (sulphur hexafluoride) tracer technique, which involves inserting a calibrated source of SF6 into the rumen of the animal being measured. The ratio of CH4 to SF6 in the breath of an animal is measured over a 24-hour period, at regular intervals, and corrected with reference to the background methane concentration. Since the concentration of the tracer is known, the rate of production of CH4 can be inferred. In general, repeated 24-h samples collected over 5 successive days show good day-to-day consistency in daily emission for each animal. The disadvantage of the technique is that the marker SF6 is itself a potent greenhouse gas.

Another instrument that has been used is the hand-held laser methane detector, or laser gun, to measure methane outputs from an animal over short periods of time. The laser methane detector is positioned about one metre distance from the mouth and nostril area of the animal and methane concentrations are recorded at regular short intervals (Chagunda and Yan 2011). Various indirect predictions for the amount of methane an animal produces have also been studied by examining feed intake, milk production and body weight. The methods used to monitor greenhouse gas emissions and indirect predictors were recently reviewed (Hill et al. 2016).

20.3.9 Phenotyping of Livestock Welfare

Recent greater public awareness of animal welfare issues and demand for better raising conditions for food-producing animals have pushed livestock producers to place increasing emphasis on welfare traits. Consequently, management and breeding technologies and practices developed in recent years have been tailored to enhance animal welfare. Thus, an aggregation of multiple welfare indicators for facilitating the overall assessment

of animal welfare is of great significance (Botreau et al. 2007). Such indicators will help to identify or develop the most resilient animals (e.g. disease resilient and heat resilient) and to develop mitigation strategies. Some indicators of animal welfare can be assessed prior to clinical signs (e.g. milk somatic cell count and mastitis). Animal welfare assessment depends on some key indicators developed in a Welfare Quality Project by Rushen et al. (Rushen et al. 2011) including good feeding, good health condition, adequate housing and appropriate behaviour. These conditions can be assessed using various parameters such as blood parameters (König and May 2019); body condition score (Roche et al. 2009); cannibalism (Lambton et al. 2015); feeding behaviour such as active chewing time, standing and lying time and rumination time (Ding et al. 2018); proportion of time active and posture (Vasseur et al. 2012); immune response (Kovács et al. 2014) and response to infection (Nyman et al. 2014). Various technologies used to measure these variables were recently reviewed (Brito et al. 2020) including technological devices such as sensors (cameras, microphones) to capture vocalizations, thermometers, automatic scales to measure body weight and lean-fat ratios, automated feeding and milking systems, milk spectral data, electrodes to detect heart rate and skin conductivity and accelerometers.

20.3.10 Digital Capture of Phenotypic Data

There has been an increasing trend in the application of digital tools and mobile apps to capture livestock performance data for farmers in order to increase accuracy, avoid translation errors and reduce costs. The approach circumvents the settling up of elaborate infrastructure to capture performance data and has therefore become very important in low- and middle-income countries where herd sizes are small and very dispersed.

The African Dairy Genetics Gains (ADGG) project has implemented the use of digital tools to collect milk yield and other performance data in small dairy cattle systems in East Africa since 2016. The system is based on the Open Data Kit which is formatted to collect performance data and other farm characteristics. The data are automatically relayed to a database for processing and analysis (Ojango et al. 2018) and this implies the availability of a reliable internet service. Usually, this is a challenge in most developing countries as the connection could be intermittent. The Community-Based Breeding Program in Ethiopia has adopted another approach using tools (Anicloud and AniCapoture) developed by AbiocusBio Limited (https://abacusbio.com/) that permit offline performance data capture for small ruminants.

In addition, ADGG collaborating with Green Dreams Tech Ltd. and operating under the name iCow in Kenya, Ethiopia and Tanzania (Green Dreams Tech 2019) has used the mobile phone for a range of farmer training and advisory applications by sending specific training materials and alerts to improve management (Fig. 20.3).

Some of the hand-held tools are also employed for data capture and data viewing in developed countries including the Pocket Companion used to capture milk performance data by National Milk Records, one of the milk recording agents in the UK (National Milk Records 2021). Similarly, The Cattle Information Service, another milk recording company in the UK, has developed a mobile app for iPhone or Android called Mobile Herd (Cattle Information Service 2021) which enables data to be collected and analysed while out and about on the farm.

20.4 Genomic and Emerging Technologies

The genome holds the blueprint information for characters and traits in all living organisms and genomics encompasses the study of the complete genetic information of living organisms embedded in their DNA and related molecules that result from reading the genome like RNA and proteins. Starting with the launch of the human genome sequencing project in 1990, then an ambitious project to sequence the entire human genome, rapid developments in genome sequenc-

Fig. 20.3 iCOW system on mobile phones used for farmer training and advisory applications

ing applications have made it possible to unravel the mystery of the genomes of living organisms. The sequencing of the human genome (1990 to 2003) provided unprecedented insight into the genetic blueprint of a human and the unravelling of the genetic bases of diseases, as well as understanding the impact of living conditions (or lifestyle) and the environment on the genome and health (Gates et al. 2021). Thus, insights garnered from genomics hold the keys to attending to rapid innovations across many sectors, including animals and plants, and present huge opportunities to advance human health, animal health, agricultural productivity and, in particular, animal production.

20.4.1 Genomic Technologies

To enable effective application of genomic information in human, plant, and animal health management, and livestock and crop improvement, sequencing and genotyping technologies have been developed to support genome analysis including sequencing of portions of the genome and whole organism sequencing, and genotyping of sequence variations in a few samples to large number of samples.

20.4.1.1 Genome Sequencing for Detection of Sequence Variations

Following the unravelling of the three-dimensional structure of the DNA molecule by Watson and Crick in 1953 (Watson and Crick 1953), methodology developments for the study of the nature of DNA and proteins started. However, strategies to sequence the DNA and RNA molecules started in the 1970s, culminating with the development of Sanger's chain-termination breakthrough technology in 1977 (Maxam and Gilbert 1977) and the birth of first-generation sequencing. Further developments of the Sanger technique led to the emergence of commercial and automated DNA sequencing systems (Hunkapiller et al. 1991) which facilitated genome sequencing of complex species at an increased speed. First-generation sequencers generated short reads necessitating techniques like 'shotgun sequencing' (Anderson 1981) to support the sequencing of long fragments (long fragments are fragmented into short sequences,

cloned, sequenced and overlapping sequences assembled into contigs) of the genome. The study of the genome sequence was further aided by the development of the polymerase chain reaction, recombinant DNA technology (Saiki et al. 1988) and other techniques in the 1970s and 1980s, which made possible the generation of high concentrations of desired DNA fragments for sequencing. Further developments, especially the development of the pyrosequencing method which uses the same technique of sequencing by synthesis (SBS) as Sanger sequencing, heralded Next-Generation-Sequencing (NGS) technology. The first successful NGS system, the 454 Life Sciences/Roche system used the pyrosequencing technology (Margulies et al. 2005). These developments were fuelled by the need for large-scale collaborative science and genome projects of the 1980s and 1990s, in particular, the human genome project which brought together a large group of researchers from many institutions across the globe who contributed to the development of tools, methods and technologies for genome interrogation and sequencing. The high-throughput capability of NGS through performing high numbers of sequencing reactions in parallel on a micrometre scale made possible by improvements in microfabrication and high-resolution imaging heralded second-generation DNA sequencing (Shendure and Ji 2008) and the emerging of NGS systems using various sequencing technologies, and mostly dominated by Illumina (www.illumina.com). Further developments including the ability to sequence single molecules without the need for DNA amplification shared by previous technologies are considered the birth of third-generation sequencing (Heather and Chain 2016). The widely used third-generation technologies include the single molecule real-time (SMRT) technology developed by Pacific Biosciences (https://www.pacb.com/) and nanopore sequencing technology developed by Oxford Nanopore (https://nanoporetech.com/). While second-generation sequencers produce short reads of up to 1000 bp, the third-generation range of sequencers can sequence full-length transcripts or generate reads up to >4 MB. The evolution of available NGS systems, their characteristics and capabilities are shown in Table 20.2. Concurrent with the development of NGS technology and systems were progressive developments in sequencing chemistry and procedures. Notable applications of NGS systems include amplicon DNA and RNA sequencing, custom sequencing, targeted DNA sequencing and whole-genome DNA and RNA transcriptome sequencing. With these tools, the genomes of animals, plants and humans have been studied in greater detail and the information generated is being used to manage the health of humans, animals and plants, and in animal and plant improvement. Aided by these tools, the whole-genome and pangenome sequences of several livestock species have been published (Table 20.3). Moreover, these tools also facilitate the unravelling of the transcriptome, epigenome, metabolome, metagenome, proteome, etc., structures and variations under various conditions and influencing factors, and use in designing production and disease management strategies.

With these technologies, the genomes (DNA and expressed RNA molecules) and epigenomes of several African livestock species have been studied and all types of sequence variations detected (Paguem et al. 2020; Ayalew et al. 2024a, b; Gheyas et al. 2022; Mauki et al. 2022; Tijjani et al. 2024).

20.4.1.2 Genotyping Technologies

The developments of sequencing technologies enabled the sequencing of animal and plant genomes and the detection of all kinds of sequence variations including single nucleotide polymorphisms (SNPs), indels (insertion or deletion of bases in a sequence), copy number variations (CNVs) (where portions of the genome are repeated), translocations and transversions. Genome sequencing to detect sequence variations, irrespective of the method and scale is expensive and is mostly feasible on a limited number of samples. To apply knowledge of sequence variations for population use or on a large number of samples, genotyping methods were developed. Genotyping techniques enable the detection of an individual's (animal/plant) genotype at a locus or loci of interest, thus facili-

Table 20.2 Technologies and sequencing systems for next-generation sequencing

Provider	Instrument/label	Reads per run	Read length	Chemistry
Illumina	iSeq 100	4 M	2×150 bp	Sequencing by synthesis
	MiniSeq	25 M	2×150 bp	Sequencing by synthesis
	MiSeq Series	25 M	2×300 bp	Sequencing by synthesis
	HiSeq 2000/2500	4 B	100–125 bp	Sequencing by synthesis
	HiSeq 2500 RR	600 M	150–250 bp	Sequencing by synthesis
	HiSeq 4000	5 B	150 bp	Sequencing by synthesis
	HiSeq X	6 B	150 bp	Sequencing by synthesis
	NextSeq 550 series+	400 M	2×150 bp	Sequencing by synthesis
	NextSeq 1000 & 2000	100 M to 1.8 B	1×50 to 2×300 bp	Sequencing by synthesis
	NextSeq P1	100 M	2×300	Sequencing by synthesis
	NextSeq P2	200 M	2×300	Sequencing by synthesis
	NovaSeq 6000	20 B	2×150 bp	Sequencing by synthesis
	Genome Analyzer IIx	138–168 M	1×35 to 2×75 bp	Sequencing by synthesis
Applied Biosystems/ ThemoFisher Scientific	SOLiD 1	40 M	25 bp	Sequencing by ligation
	SOLiD 2	115 M	35 bp	Sequencing by ligation
	SOLiD 3	320 M	50 bp	Sequencing by ligation
	SOLiD 4	2 B	50 bp	Sequencing by ligation

Provider	Instrument/label	Reads per run	Read length	Chemistry
	ONSO System	400–1000 M	2×100 to 1×200 bp	Sequencing by binding (SBB)
OxFord Nanopore	GriDION MK1	250 Gb	>4 Mb	Protein nanopores (PN) sequencing technology
	PromethION 2	580 Gb	>4 Mb	PN sequencing technology
	PromethION 48	7 Tb	>4 Mb	PN sequencing technology
	PromethION 48	14 Tb	>4 Mb	PN sequencing technology

NB: Information in this table only serves as a guide and it does not represent a complete list of sequencers nor providers. Consult providers of the technologies and instruments for more detailed, precise and specific information on the platforms: ThermoFisher Scientific (https://www.thermofisher.com/); Roche (https://www.roche.com/); Illumina (https://www.illumina.com/); Singular Genomics (https://singulargenomics.com/); Element Biosciences (https://www.elementbiosciences.com/); Pacific Biosciences (https://www.pacb.com/) and Oxford Nanopore Technologies (https://nanoporetech.com/)

tating its application in a large number of samples and at cheaper cost.

Methodological developments in the last 50 years saw progression from methods capable of genotyping single loci to whole genome sequence (WGS) variants. The methods include those that (1) detect single loci: random amplification of polymorphic DNA, amplified fragment length polymorphism, restriction fragment length polymorphism, single-strand conformation polymorphism; (2) detect simple sequence repeats like microsatellites: short tandem repeats, simple sequence repeats, variable number of tandem repeats, etc.; (3) detect multiple loci: low- and high-density DNA genotyping chips or DNA microarrays (see Table 20.4) and genotyping-by-sequencing, and (4) detect whole genome sequence variants: whole-genome deep sequencing by NGS. Notable examples of available whole-genome-wide genotyping arrays or microarrays for livestock species are listed in Table 20.4.

These genotyping tools are efficient for assessing the relationship of sequence variations with traits of interest, biodiversity, detection of signatures of selection and quantitative trait loci mapping, and for making decisions regarding breeding, breed conservation and development of new breeds or genetic lines. Consequently, information obtained from sequence variant genotyping provides data for breeding decisions, breed conservation and development of new breeds or genetic lines. A major pitfall of currently available high-throughput genotyping arrays (Table 20.4) is the bias towards Western breeds or populations used to establish such arrays. Therefore, most of the genotyping applications currently available in the market (Table 20.4) do not adequately represent the sequence variations in the genomes of African livestock species as few African livestock breeds were included in the development of the assays. Consequently, limited African livestock-specific variations are included in the majority of the available genotyping assays. Therefore, a combination of technologies like whole-genome sequencing, genotyping assays, genotyping-by-sequencing and genotype imputation could be a reliable approach to identifying population (e.g. *Bos indicus*) specific variations that are associated with traits of economic importance in African livestock. Alternatively, genotyping assays containing genetic variation information specific to African indigenous livestock populations should be developed

20.4.1.3 Quantitative Trait Loci Mapping

Since the genetic variation that underlies many livestock traits (e.g. milk yield, growth, wool production or quality and meat quality), disease susceptibility and morphology is complex and directed by loci that have effects on the phenotype, quantitative trait loci (QTL) mapping or analysis is undertaken for use in breeding programmes. Thus, all kinds of genomic variations (SNPs, CNVs, microsatellites, WGS variants,

Goat	2019	Li et al. (2019)
Pig	2023	Jiang et al. (2023)

etc.) are used in QTL analysis to determine a link/association between a trait or phenotype and genotype (genomic variation) in order to explain or elucidate the genetic variation underlying different traits (Leal, 2001). Therefore, QTL mapping attempts to identify regions of the genome or DNA closely linked to genes and underlying a specific trait through statistical analysis of genomic variations and traits in populations. QTL mapping dissects complex traits into its component alleles and also quantifies the relative effects of alleles on the traits as well as locates the genomic regions of marker–trait association. QTL mapping provided the basis for marker-assisted selection (MAS) to expedite the breeding process of specific traits following proper estimation of QTL position and effects.

QTL mapping in livestock started in the 1980s and today, thousands of QTLs have been mapped for various traits in livestock (Table 20.5) (Hu et al. 2022). It was predicted that the application of genomic markers linked to QTLs in dairy and other livestock in breeding programmes could increase the response to selection by up to 30% (Kashi et al. 1990). The potential benefits of MAS depend on the QTL effect and the strength of the marker–QTL linkage.

20.4.2 Breeding Technologies

The dairy cattle population has been undergoing selection for milk production and other traits for many decades. Prior to 2009, the methodologies used cantered on phenotypic measurements of traits on animals as the only way of measuring genetic differences between animals, but genomic technologies are helping to address new breeding objectives faster. Thus, knowledge of the association of sequence variations with livestock traits of economic importance opened up the possibility of including them in breeding programmes and disease management. Genetic markers associated with traits of interest are used to guide management or future selection decisions because inheritance of the marker automatically confers the desired positive effect. Genetic markers have over the years been used in different programmes aimed at genetic improvement of desired traits such as marker-assisted selection and genomic breeding. Recent advancements are making it possible to study

Table 20.4 Genome-wide genotyping chips for various livestock species

Species	Genotyping chip or array	Number of markers[a]	Manufacturer[b]

epigenomic variations and to edit the genomes of animals and this information may soon find application in breeding.

20.4.2.1 Marker-Assisted Selection Technology

Marker-assisted selection is a concept that utilizes the information of polymorphic loci (biomarkers: DNA, RNA, proteins, etc.,) as an aid to selection. Thus, MAS also known as marker-aided selection is a process whereby a trait of interest is selected based on its association with a polymorphic biomarker. MAS is an indirect selection process because a trait of interest is selected based on a marker linked to it and not based on the trait itself. The usefulness of MAS is that the effect of genes or markers on health and production is directly measured based on the genome information or genetic makeup of the individual and not on the phenotype. MAS in addition to its use in breeding for specific traits is also used for ancestry determination and in conservation programmes by ensuring that particular traits or useful genes in a population are maintained for future exploitation.

The application of genetic markers in MAS for livestock genetic improvement was made possible by developments of molecular genetic techniques from the 1970s and relied on the genotypes of individuals at specific or limited loci (Hill 2014). MAS that relies on markers with major effects prompted linkage mapping studies, the development of microsatellite markers and the detection of QTL in livestock species from the 1980s onwards.

The use of MAS to increase the rate of genetic progress in breeding populations is reliant on the target trait as well as the information on the marker–QTL relationship (Wakchaure et al. 2015). Sexing embryos is a unique example of marker-assisted selection in the cattle industry. In selection programmes, MAS is extremely useful since it overcomes the constraints of traditional breeding methods. It increases the genetic gain through reducing generation interval but requires information on alleles or markers associated with the target traits jointly with quantitative estimates of these associations prior to application to a specific animal population and it increases the rate of introgression of favourable alleles into desired

populations. Genetic markers that indicate desirable alleles of economically important attributes might be used in conjunction with estimated breeding values (EBV) to guide mating decisions, resulting in larger genetic gains over a wider range of traits (Calus 2010). Economic trait loci must be found, verified and described for efficacy in enhancing genetic gain before MAS may be employed in commercial production (e.g. dairying) (Sonstegard et al. 2001). The development of MAS programmes is divided into three stages: (1) Detection phase: Polymorphisms in DNA sequences are employed as linked or direct markers in the detection phase to find QTL segregating in certain populations with specified allele frequencies. One or more markers related to QTL are used to quantify the magnitude of QTL allele effects and the position of the QTL in the genome (Alvarez-Castro and Carlborg 2007) (2). Evaluation phase: The associated markers are tested in target populations or families during the assessment phase to see if the discovered QTLs are segregating in those groups (Lynch and Walsh 1998) (3). Implementation phase: To establish a genotyping database, linked markers that have been shown to be predictive in a population are utilized within families, and direct markers are used across families. These data are combined with phenotypic and pedigree information in genetic assessment to anticipate the genetic merit of individuals within a group (Davis and DeNise 1998).

Linked and direct markers are used in MAS. Linked markers are genetic markers that are close enough to the trait gene on the chromosome to be transmitted or inherited simultaneously. Linked markers are limited in that they cannot be used to predict phenotype until the inheritance of markers associated with genes of interest is researched within families, which can alter due to recombination events. Direct markers on the other hand are functional polymorphisms in the gene that determine phenotypic variation. Once the functional polymorphism is understood, it is easy to predict the effect of certain alleles in animal populations. As a result, 'direct' markers outperform 'linked' markers when it comes to forecasting phenotypic variance of target attributes within a population (Dekkers 2004).

Molecular markers can be used to track down and identify genetic diseases and morphological deformities in livestock animals. The cause and origin of these problems may be traced back to genetic changes and DNA mutations that affect protein structure and function. This knowledge can help breeders avoid such faults to keep their animals healthy.

20.4.2.2 Genomic Breeding

From the 1980s to the early 2000s, QTL data were incorporated into linear models for genetic evaluations. Estimation of the breeding value of a trait under selection was determined by summing the estimated effects of several markers and QTLs (Weigel et al. 2017) for use in MAS of young sires, in inter-breed introgression programmes for loci that alter performance attributes or disease resistance/susceptibility, etc. During this time, genetic markers used for QTL detection were mostly restriction length fragment polymorphisms and microsatellites. With the development of next-generation sequencing technologies and genotyping capabilities of all kinds of sequence variations in a large number of samples, it was possible to predict breeding values from dense markers and use them in breeding programmes in a process called genomic selection (GS) (Meuwissen et al. 2016). Therefore, genomically best linear unbiased prediction (GBLUP) was developed based on the understanding that quantitative traits are controlled by many loci that contribute equally to a trait meaning homogeneous variance among markers (Goddard 2009). In the same light, genomic estimated breeding value (GEBV), regarded as the sum of the effects of dense or thousands of genetic markers as well as their haplotypes across the whole genome, were calculated or predicted and applied in selection programmes (Meuwissen et al. 2013). Therefore, selection decision based on GEBV is known as genomic selection. Application of GS starting from 2009 has revolutionized dairy cattle (Wiggans et al. 2017a), pig (Zhang et al. 2018a) and poultry (Avendaño et al. 2010) breeding in several Western countries.

Implementation of genomic breeding, which relies on the use of genomic information in the form of SNPs resulted in rapid genetic improve-

ment in lowly heritable traits (e.g. fertility, lifespan and health traits), shortened generation interval, selection of animals at an early age, higher rate of genetic gain, reduced cost of progeny testing as GEBVs are available early in life, increased reliability of predicting breeding value and higher intensity of selection (Wiggans et al. 2017b).

Genome variation currently exploited for genomic breeding explains only a portion of the phenotypic variance or heritability in traits (Ibeagha-Awemu and Khatib 2017). The missing portion of variation may be due to yet to be identified large number of variants with smaller effects; low frequency or rare variants with potentially large effects that are not represented in currently available genotyping arrays that focus on common variants with a population frequency of five percent or more; gene × gene interactions, copy number variants; inadequate documentation of shared environment among relatives; epigenetic variation, epigenetic effects and noncoding RNA regulation of phenotypic expression (Eichler et al. 2010). Moreover, it is generally accepted that epigenetic mechanisms form part of the uncovered players in the expression of complex animal health and production traits, and are likely responsible for a portion of the missing variation in livestock traits and also for the non-accounted portion of trait heritability in current genetic improvement schemes (Ibeagha-Awemu and Zhao 2015). Therefore, the detailed characterization of all kinds of livestock functional genomic variations, epigenomic variations/modifications, non-coding RNA expression and variation, and their interaction with the environment will ultimately provide a holistic view of information for improvement decisions and application in African livestock populations.

20.4.3 Genome and Epigenome Editing Technologies

Advances in DNA and RNA manipulation starting in the 1970s opened up new frontiers in genome editing enabling a better understanding of the contribution of individual gene products to disease development and other traits. The technologies for editing the genome (Table 20.6) developed rapidly in the last 30 years and have wide applications in basic to applied biotechnology, agriculture and biomedicine. Major milestones starting with the development of DNA strand break and repair to the development of the

highly efficient CRISPR/Cas system and the production of transgenic livestock are summarized in Table 20.6.

Major advances in genetically engineered farm animals by DNA microinjection into the pronucleus of zygotes lead to the production of transgenic animals including livestock animals (cattle, goat, pig, rabbit and sheep) (Hammer et al. 1985). Several methods are used for transgenic animal production, including recombinant retroviruses, sperm-mediated DNA transfer, germ cell transplantation, nuclear transfer cloning, pronuclear injection and embryonic stem cells (Wheeler and Walters 2001; Wall 2002).

Gene editing or genome editing, or genome engineering is a procedure by which DNA is inserted, deleted, replaced or modified in an individual's genome. Genome editing can be performed in vivo or in vitro by delivering an editing apparatus in situ, which deletes, adds or modify genes as well as performs more targeted genomic modifications. Generally, systems like zinc finger nucleases (ZFN), transcription activator-like effector nucleases (TALEN) and Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR)/Cas9 are commonly used to achieve efficient genome editing by introducing genes or alleles of interest into a recipient genome, by editing a section of the genome, deleting a portion of the genome or by switching genes on or off (Randhawa and Sengar 2021; Nakamura et al. 2021; Perisse et al. 1713).

In general, targeted DNA or genome editing or alteration starts with the generation of a nuclease-induced double-stranded break (DSB), which causes the stimulation of highly efficient recombination mechanisms of cellular DNA in mammalian cells, followed by repairs using either of the two mechanisms, nonhomologous end-joining (NHEJ) or homology-directed repair (HDR), which occur in most cell types and organisms (Fig. 20.4) (Randhawa and Sengar 2021; Li et al. 2020). Following the successful generation of a targeted DSB, the repair mechanisms can be used to restructure the cleaved DNA by introducing a desired change (delete or introduce) in the genetic code using an exogenous nucleic acid template. Therefore, genome editing can enable the alteration of an animal's genome by altering a section (a single base pair or a stretch of nucleic acids) of the genome or by introducing a stretch of nucleic acids from another source.

In livestock animals, the main method used to produce livestock harbouring nuclease-mediated, genetic changes in their genomes is cell nuclear transfer of edited somatic cells, particularly homology-directed repair donor-template alterations (Tan et al. 2016). Genome editing therefore offers the livestock industry efficient opportunities to introduce desired genetic variation into livestock breeding programmes through targeted inactivation of gene function and/or through allele introgression while avoiding the undesired linkage drag (Van Eenennaam et al. 2021).

Genome editing and its application in livestock have been discussed in several recent reviews (Perisse et al. 1713; Van Eenennaam et al. 2021; Karavolias et al. 2021). In summary, various gene editing techniques have been used to target certain genes in livestock species and to generate transgenic animals, like the MSTN or double muscling gene in cattle, sheep and pigs; the polled allele in cattle; the LDLR gene in a pig model of atherosclerosis; lysostaphin (LSS) gene for mastitis resistance in cattle, etc., to address disease resistance, productivity, product quality and environmental adaptation. Some genes that have been edited in livestock are summarized in Table 20.7.

Similar to genome editing, epigenome editing at epigenetic loci of interest represents an innovative method that might selectively and heritably alter gene expression. In contrast to genome editing, epigenome editing technology changes the chromatin state without changing the DNA sequence (Lau and Suh 2018). The feasibility of adding or removing epigenetic marks by different compounds has made it possible to introduce a wide range of epigenetic drugs for human disease treatment, among other applications (Montalvo-Casimiro et al. 2020). An example is the FDA-approved DNMTi 5-aza-2′-deoxycytidine, a DNA methylation inhibitor, known as a cancer drug since 1968 because of its cytotoxic effects on cancer cells (Heerboth et al. 2014). However, a proof-of-concept of this technology was dem-

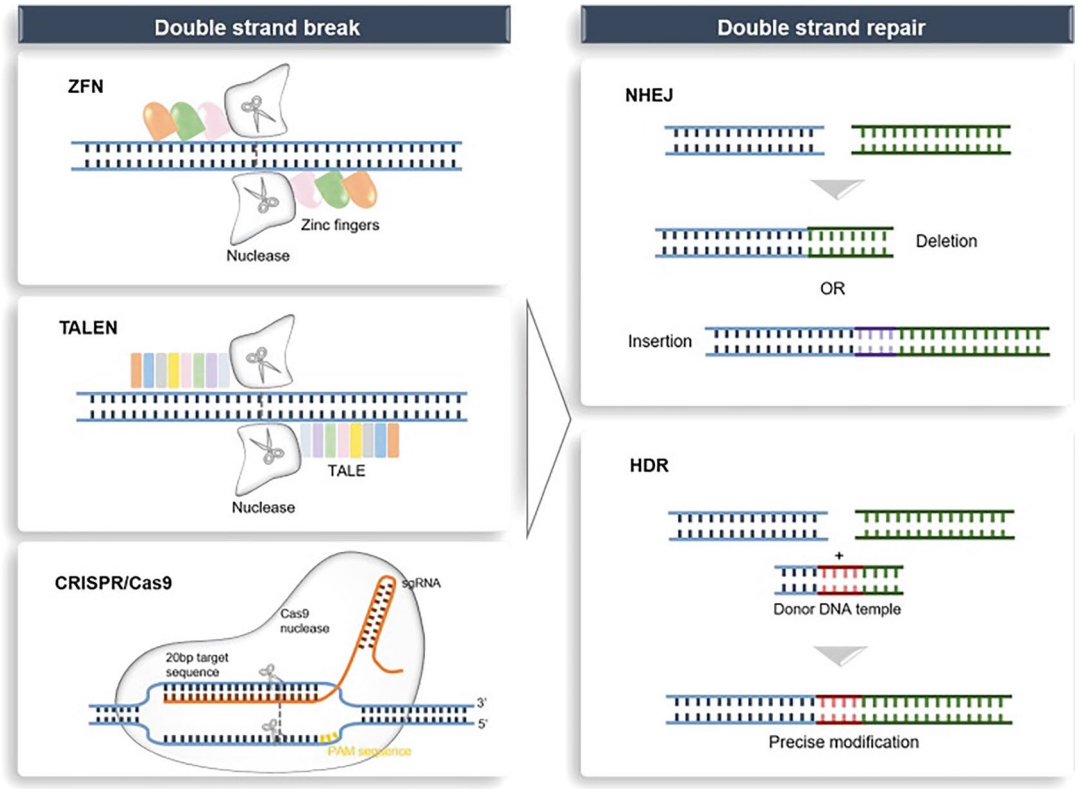

Fig. 20.4 Genome editing platforms and mechanisms for DSB repair with endogenous DNA. Genome editing nucleases (ZFNs, TALENs and CRISPR/Cas9) induce DSBs at targeted sites. DSBs can be repaired by NHEJ or, in the presence of donor template, by HDR. Gene disruption by targeting the locus with NHEJ leads to the formation of indels. When two DSBs target both sides of the amplification or insertion, a therapeutic deletion of the intervening sequences can be created, leading to NHEJ gene correction. In the presence of a donor-corrected HDR template, HDR gene correction or gene addition induces a DSB at the desired locus. DSB double-stranded break, ZFN zinc-finger nuclease, TALEN transcription activator-like effector nuclease, CRISPR/Cas9 clustered regularly interspaced short palindromic repeat associated 9 nuclease, NHEJ nonhomologous end-joining and HDR homology-directed repair. (From Li et al. (2020), licensed under CC-BY 4.0)

onstrated in human cell lines, where targeted acetylation of gene promoters and enhancers resulted in the successful transcriptional activation of several genes (Hilton et al. 2015). For livestock breeding purposes, these technologies can be used to introduce or fix favourable alleles and epigenetic marks for addressing disease resistance, increased productivity and environmental adaptation. Although epigenome editing is yet to be performed in livestock, a simulation study by Jenko et al. (Jenko et al. 2015) demonstrated that genome editing to promote alleles of polygenic traits could double genetic gains when compared to conventional genomic selection.

The technologies of genome and epigenome editing could be applied in livestock management to (1) move genetic elements between breeds and species; (2) alter existing genetic elements to create new ones, effectively expanding the available genetic diversity (σA); (3) modify genes to address traits ranging from production efficiency to animal welfare, environmental sustainability and disease resistance; and (4) introduce useful alleles in the absence of linkage drag or other unwanted traits. The various techniques that have been applied to generate gene-edited livestock are summarized in Figure 20.5 (Perisse et al. 1713). Therefore, the adoption of epigenome and

genome editing technologies could significantly impact animal health, production, reproduction and environmental adaptation using targeted manipulation of candidate genes affecting corresponding traits.

20.4.4 Cellular Agriculture

To satisfy the increasing demand for animal food products by an ever-increasing human population, more efficient ways of making available animal-based foods are being developed to sustain growing demand while tackling challenges associated with traditional livestock farming such as animal welfare and environmental issues (pollution/degradation). Among the solutions, the production of livestock products from animal cells or engineered microbes is presented as a viable alternative to increasing the production of animal products without the negative effects associated with traditional livestock farming and for consumers who advocate for responsible livestock farming but do not wish to change their dietary habits. Cellular agriculture (CA), a term coined by Isha Datar, a Canadian molecular biologist (Groen 2022) is generally defined as the production of animal products (e.g. eggs, meat, milk, and seafood) and ingredients from cell cultures in vitro, artificially or lab-grown rather than from farmed animals (Ong et al. 2021). According to the production method, CA is either cellular (cell cultivation or tissue engineering) or acellular (precision fermentation) based (Stephens et al. 2018). CA therefore comprises numerous innovative technologies and approaches that use cells, cell culture, tissue engineering or precision fermentation to make food products (e.g., meat and milk, etc.) and other materials (Fig. 20.6). Although CA is an emerging technology that is still in the development phase, it has attracted the attention of many industrialists, investors and governments who are scrambling to support the growth of the industry and to put in place necessary regulations. Although animal production is still developing in Africa, CA may offer opportunities to diversify and create products with high nutritional content without the many problems currently facing livestock production. The economic opportunity presented by CA was recently analysed and estimated as a $12.5 billion opportunity in food innovation in Canada creating about 30,000 to 142,000 jobs (OG 2021).

20.4.4.1 Cellular or Cultivation-Based Cellular Agriculture

Cultivation-based CA (e.g. cultured meat and milk, etc.) uses cells or cell lines taken from living animals, cultured on engineered tissue (such as scaffolds) in bioreactors (in vitro) to produce products with lesser amounts of life animal tissue input and other inputs compared to conventional

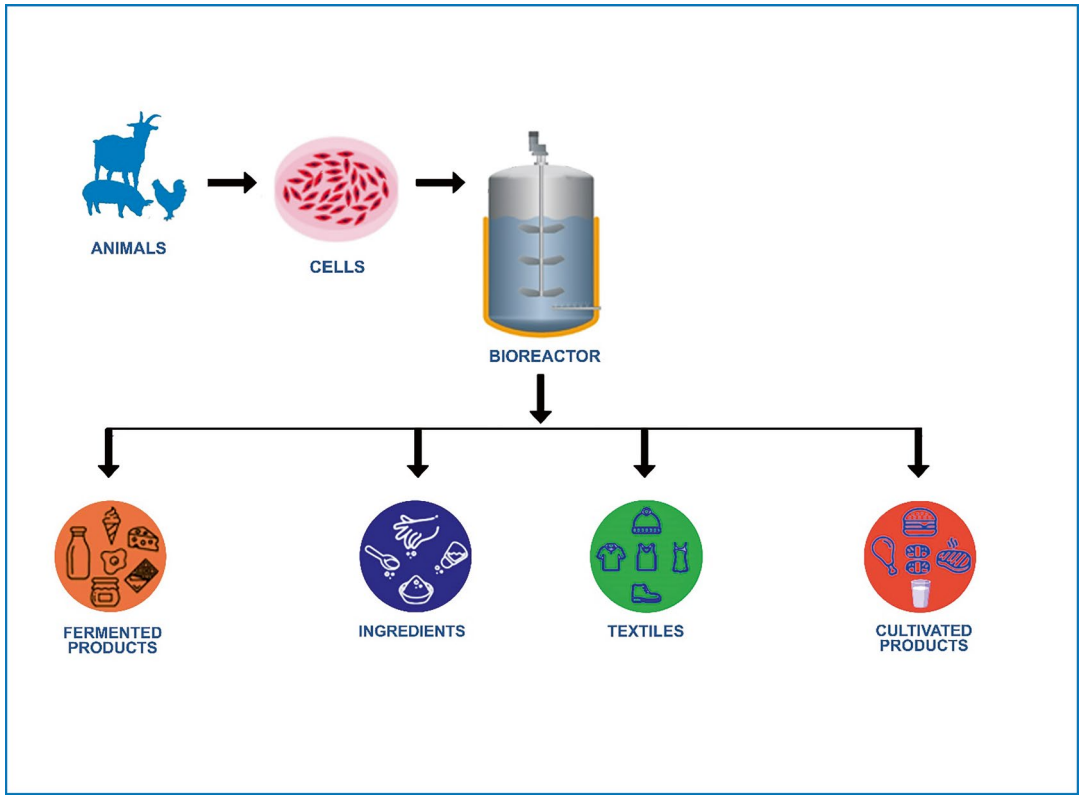

Fig. 20.6 Cellular agriculture uses cells from animals or precision fermentation technologies to produce products of animal origin (meat, eggs, milk) and fermentation products for use as ingredients for the creation of varied products including textiles

production methods. The cells used as starting material could be taken from the animal through the biopsy approach and grown in vitro or genetically modified (immortalized cell line) for perpetual growth in culture. The steps involved in cell-cultured meat and seafood technologies were described recently (Ong et al. 2021; Kwon et al, 2024; Reiss et al, 2021; Soleymani et al, 2024; Munteanu et al. 2021); and it involves (1) obtaining the cell from a live or slaughtered animal (e.g. embryonic stem cells, mesenchymal stem cells, induced pluripotent stem cells, myosatellite cells (adult stem cells) or primary cells lines); (2) cells are isolated and (3) culture conditions optimized. Moreover, genetic modifications of desired characters can be performed (4). Biomass production (includes proliferation, differentiation and/or maturation of cells in bioreactors); (5) on attaining the desired biomass, the product is harvested and processed by the addition of other ingredients for the manufacture of various products (Fig. 20.7).

Several companies are today using cultivation-based CA to manufacture a variety of products such as cell-cultured meat, egg white and milk (Table 20.8). Singapore was the first country to grant approval for a cell-cultured chicken used as an ingredient in a hybrid product made with plant protein (SFA 2020). Today, several countries including Isreal, the USA and Australia have granted regulatory approval for cell cultivated products such as cultivated chicken, quail and beef, and cultivated pork fat.

20.4.4.2 Acellular or Precision Fermentation-Based Cellular Agriculture

Precision Fermentation-based CA manufactures by precision fermentation using genetic engineering approaches or industrial biotechnology

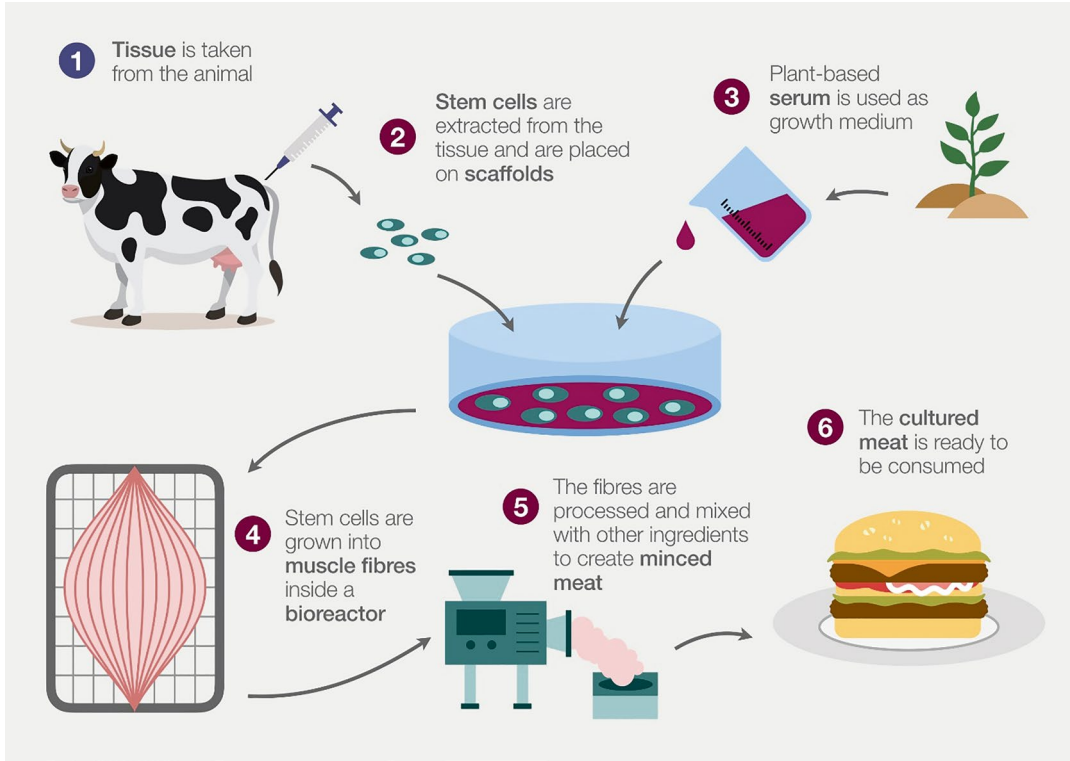

Fig. 20.7 Main steps involved in the production of cell-cultured meat

and microorganisms such as bacteria, yeast or algae. These microorganisms are typically genetically modified by adding recombinant DNA bearing a desired gene and mass produced in bioreactors to produce specific proteins (caseins, ovalbumin, etc.), fats, collagen and other molecules that can be used to biofabricate animal products such as gelatine, enhanced milk products, chocolate, honey and leather, among others. The process of precision fermentation-based cellular agriculture has been discussed in recent reviews (Eastham and Leman 2024; Dupuis et al., 2023; Oliveira et al., 2024; Knychala et al., 2024) Some companies today use precision fermentation-based systems to produce a variety of products. For example, Meadow company uses a precision fermentation system harbouring genetically modified cells with instructions to produce a specific type of collagen for the manufacture of leather. Other examples include The EVERY Company (egg white), Perfect Day (milk), Pembient (Rhinoceros horn), etc. (Table 20.7).

20.4.4.3 Potential Benefits of Cellular Agriculture

The potential benefits of CA products have been summarized in many review articles (Stephens et al. 2018; El Wali et al. 2024; Munteanu et al. 2021; Kadim et al. 2015; Treich 2021) and include (1) potential to increase the availability of animal-based products and to meet the needs of consumers concerned about the environmental impact of conventional livestock production; (2) potential to support the production of specific livestock products in larger quantities (e.g. lactose free milk, casein proteins); (3) it offers wide possibilities to edit or modify genes to support the production of desired livestock phenotypes; (4) potential to reduce greenhouse gas emissions as well as solve other environmental issues like soil and water pollution compared with conven-

tional livestock production; (5) potential to reduce the risks of emerging infectious diseases associated with the storage, production and consumption of animal food resulting from conventional farming; (6) potential to support the production of products of desired nutritional quality; (7) potential to ensure food safety as lab-grown products are kept in controlled environments with close monitoring to easily detect microbial contamination and to remove such, compared with conventional farming which can introduce disease pathogens or antimicrobial resistant genes into the food chain; (8) less space requirement is needed for lab grown-food thus sparring the environment; (9) potential to lower global food insecurity since indoor production of CA products can still occur even during unfavourable conditions like natural disasters and pandemics; (10) CA products have strong moral implications as their production is largely not based on the slaughter of animals. It should be noted that many of these benefits are not yet supported by scientific or substantial evidence.

20.4.4.4 Challenges of Cellular Agriculture

Cellular agriculture is a developing technology and it is plagued by a myriad of challenges which have been discussed extensively by several recent review articles (Munteanu et al. 2021; Treich 2021; Chriki et al. 2022). The major concern relates to food safety considerations, contamination during the manufacturing processes, consumer acceptance/perception, ethical issues and

many unknowns like the economic benefits and environmental issues associated with CA. Many governments such as Singapore, Canada, United States, Isreal and the European Union have or are working to put in place safety regulations to guide CA processes and ensure the safety of CA products.

20.5 Reproductive Technologies to Enhance Meat and Milk Production

Compared to developed and emerging countries, limited impacts have been observed in the application of reproductive biotechnologies in African livestock. However, various biotechnological techniques are increasingly used in African cattle breeds, being the most used livestock species for all assisted reproduction technologies (ART). These include oestrus synchronization, superovulation and ovum pick-up (OPU), semen collection and artificial insemination (AI), in vitro fertilization (IVF) and embryo culture, and in vivo embryo flushing and transfer. The sections below describe the use of these technologies in livestock under various production systems in Africa.

20.5.1 Artificial Insemination

Among the ART adopted to improve the livestock industry's viability, AI is one of the most powerful technologies; the first ART generation tool applied in livestock production systems to advance genetic improvement and selection of desired animals. Cattle, pig and sheep/goat account for most mammalian inseminations, the successes of which rely on the efficiency of semen collection, handling and preservation (Ugur et al. 2019). AI is the most widely used ART in African livestock systems.

20.5.1.1 Semen Collection

There are three methods of semen collection used in artificial insemination (Patel et al. 2017). First, using an artificial vagina is the most common method for semen collection from most domestic livestock. This method requires the male to mount a teaser female or dummy, and the penis is diverted into the artificial vagina, giving a thrust to semen release or ejaculation. Second, electroejaculation is a reliable method to stimulate the male by using a low-voltage current to nerves that control ejaculation and emission. It is commonly applied to rams and bulls; however, this technique is unaffordable to most smallholder farmers, and its use may be prohibited in several countries. Third, the transrectal massage method involves stroking the ampullae, seminal vesicles and prostate gland through the rectum wall in bulls (Rouge and Bowen 2002).

20.5.1.2 Oestrous Synchronization

Oestrous synchronization involves manipulating the reproductive processes using a combination of hormones that bring several females into oestrus (heat) at a similar time. Various oestrous synchronization protocols that utilize different hormones are used in small ruminants, beef heifers and replacement dairy heifers (Rodning et al. 2012). Prostaglandin (PGF2α), progestins and gonadotropin-releasing hormone are used in oestrus synchronization protocols. Prostaglandin is injected intramuscularly and subcutaneously to cause luteolysis of the corpus luteum and induce oestrus behaviour. The PGF2α is commercially available as Lutalyse® (Zoetis). Synthetic analogues of prostaglandins such as Fenprostenol®, Estrumate® and estroPlan® have been found to have a more rapid and dramatic effect in synthesizing progesterone (Omontese 2018). For better response, two injections of prostaglandins are administered 9–11 days apart.

Progestins include melengestrol acetate, ingested in feed and progesterone, administered vaginally through a controlled intravaginal drug release device. It inhibits heat; a cow or heifer usually comes into heat 1 to 3 days after removal. Moreover, a gonadotropin-releasing hormone injection administered 48 hours after a prostaglandin injection has provided a more concise synchrony of ovulation (Rodning et al. 2012).

20.5.1.3 Insemination Versus Natural Breeding

Compared to natural breeding, AI has revolutionized the livestock industry by promoting the utilization of genetically superior males (Paxton 2021). Using AI in farms eliminates the need for a breeding male whose semen is commercially available in various specialized AI centres and reduces the risks of transmission of genital diseases. Hence, removing the costs associated with the maintenance of breeding bulls leads to increased profitability (TNAU 2009). Furthermore, the possibility of using frozen and extended semen has made it possible to extend the shelf-life and maintain the fertilizing potential of harvested spermatozoa, therefore preserving the fertility of selected males used to sire many females (Ugur et al. 2019).

In many African countries, AI is limited due to several constraints (see Chapter 24). Consequently, AI is less affordable for most African smallholder farmers who rely upon natural mating as a standard and cheaper alternative breeding practice, requiring only the maintenance of genetically superior males on the farms during the breeding season. Most importantly, it eliminates the use of well-trained technicians and the knowledge of the structure and function of reproduction on the operator's part (TNAU 2009). Today, the AI technique in Africa is used especially in crossbreeding between exotic sires and indigenous African cattle to increase milk production and beef potential of local cattle breeds. AI has the potential to increase genetic gains using internationally proven exotic sires. Thus, the ADGG project has used AI to produce crossbred dairy cattle that combine the productivity of Western breeds and the tropically adapted East-African zebus in Tanzania and Ethiopia. In Tanzania, 236,335 doses of semen from Boran, Sahiwal, Mpwapwa, Ayrshire, Friesian, Jersey and Simmental were distributed to different organizations or farmers operating medium- and large-scale dairy and beef production farms to upgrade the indigenous cattle breeds (Msalya 2017). The combination of AI with oestrus synchronization allows the insemination of a larger number of cows on a predetermined date. The use of oestrus synchronization in breeding programmes has shown conception rates comparable to natural mating on the African continent (Van Marle-Köster and Webb 2014).

20.5.2 Embryo Transfer

20.5.2.1 Superovulation

Superovulation is a reproductive technology used in the dairy industry to increase the reproductive rate of superior females. It is an essential process of embryo transfer that increases the number of oocytes available at ovulation and for fertilization (Lonergan and Boland 2011).

The use of hormones such as equine chorionic gonadotrophin, follicle-stimulating hormone, pregnant mare's serum gonadotropin (PMSG) and horse anterior pituitary extracts permits the growth of subordinate follicles alongside their dominant counterpart. Nevertheless, the quality of gonadotropin preparations influences the effectiveness of superovulation. For example, the combination of follicle-stimulating hormone and luteinizing hormone plays an important role as they control the growth of ovarian follicles. Superovulation using human menopausal gonadotrophin has revealed effectiveness in cattle, sheep and goat (González et al. 2001). Its application in cattle has achieved an average of six transferable embryos per session. In goat, superovulation by PMSG resulted in lower fertilization and embryo recovery rates than the horse anterior pituitary (González et al. 2001).

20.5.2.2 Insemination and Embryo Flushing

Heat or oestrus detection is critical for efficient reproduction management. The difficulty in determining oestrus (onset and end) requires careful observation of the animal's behaviour using visual and/or sensing aids. Insemination should be done sometime between the onset of heat activity (oestrus) and ovulation, with the morning (AM)/evening (PM) rule being the easiest practical method of timing insemination. Insemination is performed by natural mating or AI using frozen, chilled or fresh semen.

Insemination is done approximately 4, 12, 24 or 36 hours after the onset of standing oestrus (Hasler 2004). In sows, inseminations occur 36 and 42 hours after human chorionic gonadotropin injection. In the ewe, however, the risk of fertilization failures in ewes due to higher ovarian stimulation and response to gonadotrophin oblige for surgical insemination directly into the uterus using laparotomy or laparoscopy (Ishwar and Memon 1996). For further improvement of reproductive success, many commercial farms are adopting fixed-timed insemination requiring a cocktail of hormonal treatment of females prior to insemination (Lamb et al. 2010; De Rensis and Kirkwood 2016).

In vivo-produced embryos may be collected through flushing (cows) or laparoscopic surgery in ewe, doe and sow (Besenfelder et al. 1997). In cows and heifers, a Foley rubber catheter is mainly used for insertion through the cervix of the donor cow (Callesen et al. 1996), and through which a buffer medium (e.g. Dulbecco's phosphate-buffered saline supplemented with 1% faecal calf serum) is flushed into and out of the uterus to collect the embryos seven days after oestrus. Each uterine horn is filled and emptied five to ten times with 30–200 mL of the buffer medium each time, according to the size of the uterus. Embryos are then flushed out, collected with the liquid and separated from the flush media for examination under a stereomicroscope to determine their quality and stage of development (Hasler 2004). In the ewe and doe, embryos are surgically collected 3 to 7 days after oestrus under general anaesthesia through a midventral laparotomy (Moore 1982).

20.5.2.3 Transfer to Surrogates

In cattle, each embryo is loaded into a 0.25 mL insemination straw. This procedure is done under microscopic viewing with the aid of a 1 mL syringe and requires considerable practice, patience and skill. Before embryo transfer, the recipient's ovaries are palpated rectally to determine which ovary has ovulated. Next, a transfer gun, also called an insemination rod, is passed through the cervix, with the tip of the rod allowed to slide into the horn of the ovary possessing the active corpus luteum. Finally, the embryo is gently expelled into the forward end of that uterine horn.

In small ruminants and sows/gilts, each embryo is loaded into a 0.25 mL sterile insemination straw. The straw is placed in an ordinary insemination pipette or a specially designed embryo transfer catheter, a thinner and more extended version. Laparoscopy has been reported effective in these species but requires more experience to obtain reasonable pregnancy rates (Besenfelder et al. 1997). In addition, the oestrous cycle of the recipients must be synchronized with that of the donor. Before transfer, it must be ascertained that oestrus has occurred within ±24 hours of the donor and that a functional corpus luteum is present (Hasler 1998).

Multiple ovulation and embryo transfer (MOET) in combination with cloning and embryo sexing can potentially increase reproduction efficiency and genetic gains. The MOET has been used in various livestock species and wildlife on the African continent and has increased the conception rates to above 50% when combined with better embryo sorting and transfer of more than one embryo per recipient female (Van Marle-Köster and Webb 2014).

20.5.3 In Vitro Fertilization and Embryo Culture

20.5.3.1 Oocyte Collections: Post-mortem Versus Alive Animals

Oocyte collection is either from the post-mortem (slaughterhouse)-derived ovaries or living animals after ovum-pick-up (OPU). In cows, follicular aspiration of collected ovaries may vary from eight to nine oocytes per ovary and around 15 developmentally competent cumulus–oocytes complexes per animal (Fair et al. 1995).

In contrast, the OPU technique, which consists of the transvaginal removal of the oocytes by aspiration of the ovarian follicles under ultrasonography guidance, is a harmless procedure performed on donor cows constrained in a chute. This procedure is a modified technique of human reproduction that has become the tool of choice

for ovarian oocyte retrieval in veterinary-assisted reproduction (Pieterse et al. 1988). The OPU is performed on stimulated and non-stimulated cows with a variable frequency that depends on the utilized protocols (e.g. one or two sessions/week). Higher numbers of puncturable antral follicles of 5–10 mm (6 to 16), oocytes (6 to 12) and blastocysts (>2) are generated per OPU session (Stubbings and Walton 1995). Although OPU has a great advantage in producing many oocytes per donor, there is a need for special care such as animal welfare, repetitive epidural anaesthesia, ovary stroma integrity and adhesions must be considered (McEvoy et al. 2006).

On the other hand, laparoscopy-guided follicular puncture is also used in large and small ruminants (Baldassarre et al. 2001). This technique has the advantage of doubling the efficiency of oocyte collection, but adhesions may limit their use on donors. In vitro-produced embryos based on laparoscopic-aided ovum pick-up obtained oocytes may become an alternative to conventional embryo production in small ruminants, as it may significantly improve the problems in vivo technology carried over the years (Cognie 1999).

Regardless of their origins, oocytes enclosed with more than three layers of cumulus cells, forming the cumulus–oocyte complexes, are selected under a stereomicroscope for in vitro maturation (IVM).

20.5.3.2 In Vitro Maturation

At birth, oocytes are blocked at prophase I of meiosis. Their developmental competence is progressively acquired during intrafollicular growth, with the oocyte accumulating various compounds during its development (Fair et al. 1995; Lonergan et al. 1994). In most ruminants, the oocyte will undergo final maturation during the last 24 h following the luteinizing hormone surge and ovulation. In contrast, this maturation will resume spontaneously in vitro after removing the cumulus–oocytes complexes from its surrounding follicular fluid, known to contain a maturating inhibiting factor. The maturing oocyte undergoes both cytoplasmic and nuclear maturation.

Cytoplasmic maturation is characterized by changes in organelles, proteins and transcripts (Hyttel et al. 1997). Meanwhile, the progression of meiosis from prophase I to the metaphase of the second meiotic division corresponds to the nuclear maturation that makes a second arrest while waiting for fertilization. In livestock, around 85% to 90% of the cultured immature oocytes will reach the second meiotic division at the end of IVM under proper conditions (Lonergan and Fair 2016).

20.5.3.3 In Vitro Fertilization

Upon completion of IVM, oocytes are co-incubated with spermatozoa for up to 18 to 24 h while undergoing IVF. The IVF usually occurs in a culture dish where both male and female gametes are placed into a microenvironment of 50 to 100 µl, for low numbers of OPU donor oocytes or > 400 µl, for abattoir mass-collected oocytes (Gordon 2003). Spermatozoa are washed and selected (e.g. swim-up or density gradient centrifugation procedures) to remove freezing media, seminal plasma, debris and dead spermatozoa. The purified motile spermatozoa must be treated with capacitating agents (e.g. heparin) to gain the ability to penetrate the zona pellucida of the oocyte (Parrish et al. 1986). Large numbers of oocytes can be fertilized in groups using conventional frozen semen. Below are further adjustments to ensure high fertilization rates:

- Selecting high-fertile bulls.
- Adjusting capacitation agent concentration.
- Optimizing the composition and volume of the fertilization medium.
- Adjusting oocyte density (number per volume of medium and per spermatozoa).

A major advantage of IVF is that it requires a small number of spermatozoa to fertilize the collected oocytes (Van Soom et al. 1991).

Following interaction with the spermatozoon, meiosis of the oocyte will resume for completion, and the second polar body will be extruded within the perivitelline space. Thus, the oocyte is a proper haploid cell in which the remaining set of chromosomes will pair with their sperm-derived homologs. This process is known as amphimixis,

which establishes fertilization and returns to the new zygote's diploid status (Sirard 2001).

Thereafter, the presumptive zygotes are denuded from their surrounding cumulus cells and transferred into the culture medium for additional culture in defined, semi-defined or complex media until the blastocyst stage, which is the last stage for in vitro embryo culture for most livestock animals (Feugang et al. 2009). Despite the efforts, the proportion of fertilized oocytes or zygotes that develop to the blastocyst stage seems to plateau around 30–40% (Rizos et al. 2002). Currently, the quality of oocytes remains the main limiting factor to the efficiency of in vitro embryo production. Indeed, studies show that in vivo matured oocytes yield more blastocysts than their IVM counterparts (Sirard and Blondin 1996). It is essential to adjust the duration of the IVM phase according to follicular maturity to the in vivo-maturation period for that species and to culture conditions (Hyttel et al. 1997).

The in vitro embryo production technique has several challenges. For instance, the complexity of culture conditions requiring a fully controlled environment (gas and culture compositions), the need for highly qualified personnel, and related reagents and equipment costs are significant limitations for implementing the technique in numerous African countries.

20.5.4 Pregnancy Detection and Monitoring

Pregnancy diagnosis in domestic livestock is a vital fertility management tool, and there is a need to check animals for pregnancy early (Bekele et al. 2016). Methods of pregnancy detection include transrectal palpation, ultrasonography and visual techniques such as non-return to oestrus and exposure to a bull. Oestrus detection after insemination is beneficial as it allows for detecting non-pregnant cows and re-synchronization. Non-return to oestrus assumes that the animal is pregnant. Transrectal palpation involves palpating the reproductive tract through the rectal wall 35 days post-breeding (Youngquist 2006).

On the other hand, pregnancy detection relies on A-mode, Doppler ultrasound, and B-mode or real-time ultrasonography. In addition, the most reliable indicator of pregnancy is blood progesterone, which can be quantified in a laboratory using an RIA or ELISA test (Fricke 2010). However, sheep and goats' plasma or milk progesterone assay is not accurate for pregnancy diagnosis (Goel et al. 2009).

Furthermore, digital infrared thermal imaging (DITI) has been introduced into livestock for the improved management of environmental changes, (re)production and health conditions (Hellebrand et al. 2003). The DITI method relies on detecting infrared energy emitted from an object and converting it into temperature displayed as a temperature gradient or thermogram. Despite the challenges of interpreting data due to factors such as coat colour and environmental variables, the DITI is a non-invasive, non-destructive and effortless method capable of detecting scrotal temperatures, health, oestrus and pregnancy statuses of various livestock (Stelletta et al. 2012). However, the DITI utilization in livestock farms is still limited and inexistent in African countries.

20.6 Future Perspectives and Conclusion

The factors impeding the implementation of modern technologies for livestock genetic improvement have been discussed in Section 20.2 and Chapter 2. Addressing these challenges will be an important step towards advancing African livestock genetic improvement. For example, the implementation of genomic selection in African livestock will require breed-specific tools; like genotyping arrays specific for African livestock. Characterizing the genomic variation in African livestock and association with traits of interest is an important step in prioritizing genetic markers for breeding and health management. Recent initiatives like the African BioGenome project (Ebenezer et al. 2022), which has as its goal to sequence the genomes of plants and animals in Africa, will facilitate the catalogu-

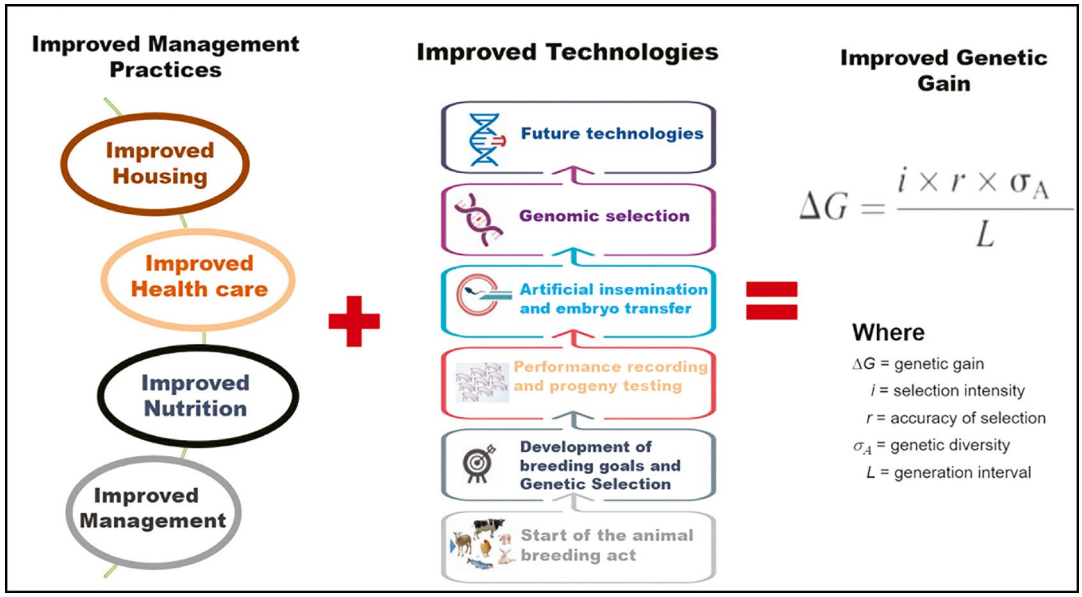

Fig. 20.8 Schematic representation of improved farm management practices and technologies that have led to enhanced genetic gain in dairy cattle breeding and improvement in milk production. (From Ibeagha-Awemu and Yu (2021), licensed under CC-BY 4.0)

ing of the genomic variations necessary for the implementation of genomic breeding in the continent.

The implementation of modern technologies has been the bedrock of improved productivity in the dairy, swine and poultry sectors in Western nations. The improvements were through advances in all aspects of livestock management such as improved management practices, improved nutrition, improved health care, improved genetic/genomic selection, reproduction technologies, etc. (Fig. 20.8) (Ibeagha-Awemu and Yu 2021).

The introduction of modern technologies in dairy production in some African countries has resulted in increased milk production and farm incomes. A typical example is the African Dairy Genetic Gains (ADGG) (https://www.ilri.org/research/projects/african-dairy-genetic-gains) project by the International Livestock Research Institute (ILRI) (Kenya). The ADGG project is operating in seven countries (Ethiopia, Tanzania Uganda, Kenya, Nigeria, Zambia and Nepal) and its main goal is to address some of the challenges faced by smallholder livestock producers through the application of ICT and genomic technologies, among others. The ADGG project has developed a robust, agile and scalable data platform and capture tools. It has also developed and promoted several digital tools (e.g. ADGG dairy tool: Helping your cow to calve- (Ojango et al. 2020a); ADGG dairy tool: Ensuring dairy herd hygiene (Ojango et al. 2020b)). The ADGG project is therefore providing dairy cattle genetic gains with the potential to transform the lives of millions of smallholder dairy families in the participating countries with the potential to extend to other African countries.

The ADGG is a practical example of how modern technologies and technical know-how with the participation of relevant expert institutions harnessed in a farmer-oriented manner delivered and achieved increased livestock productivity and farm incomes. The significant improvement in productivity is attributable to the practical application of the know-how of participating researchers and expert institutions/bodies instituted systems that applied modern tools of milk production technologies (genetics, ICT, data processing, AI, etc.) spanning individual farm

levels to group levels to country/regional levels by collecting performance data and sharing information for the benefit of participants at all levels within the ADGG project. The ADGG instituted system acts at a national/regional scale to provide official standardized identification, data collection structure covering all participating farms, exchange of data with extension personnel, veterinarians and farmers, interpretation of performance recording data, provide information/advice on nutrition and insemination frequency, enhance follow up of health, production, insemination as well as connect farmers with key service providers among others.

The application of in vitro embryo production (IVEP) for cheaper production of a predictable supply of embryos from the ovaries of live or slaughtered cows in the Boran cattle was demonstrated (Mutembei et al. 2015). Using IVEP and OPU techniques, the authors reported that in vitro embryo production obtained an oocyte maturation rate of over 90%, over 70% cleavage rate and an embryo output of 30–50% blastocyst rate. The conception rate from embryo transfer they reported was 45–50%, with 17 calves born reaching puberty without any abnormalities.

The use of microsatellites for parentage verification was demonstrated in the Boran breed by Kios and colleagues (Kios et al. 2012). A microsatellite marker panel consisting of 14 markers has been developed and utilized for parentage verification in the Angora Breed (Visser 2011).

The use of high-density markers (SNPs) allowed accurate estimation of breed composition and parentage assignment in smallholder dairy farms in Africa which do not perform pedigree recording (Strucken et al. 2017). Genotyping 2940 crossbred dairy cattle in Kenya, Uganda, Ethiopia and Tanzania with 777 K Illumina BovineHD SNP chip, it was demonstrated that a panel of 200 SNPs gave the best prediction of breed composition while another set of 200 SNPs was the most accurate at parentage assignation (Strucken et al. 2017).

Further practical examples of the prospects of modern technologies in African livestock genetic improvement are presented in Chapters 22, 23 and 24.

In conclusion, modern technologies have been the main tools behind livestock genetic advances achieved in the last seven decades. Although these technologies have been applied to a lesser extent in African livestock, their adoption is feasible and will facilitate rapid progress as demonstrated with the ADGG project.

21 The Role of Modern Technologies for Improving the Production Environment of Livestock in Africa

Eveline M. Ibeagha-Awemu, Faith A. Omonijo, Martha N. Bemji, Obioha Duranna, Iliya D. Kwoji, Michael O. Ozoje, and Richard Osei-Amponsah

Abstract

Technology was instrumental in advancing human civilization, and present-day modern technologies are enabling breakthrough innovations in medicine, agriculture, and other science sectors in Western countries. Current levels of livestock productivity in Africa are suboptimal and marred by a myriad of problems requiring urgent intervention. Modern technologies, known to be instrumental in advancing the livestock sector in western countries, will play a big role in supporting rapid growth in the African livestock sector. This chapter presents modern technologies that have advanced many aspects of livestock management in recent decades. First, Section 21.2 presents the technologies used for assessment and improvement of production efficiencies followed by examination of the technologies in animal welfare management (Section 21.3), while some of the technologies enhancing meat production, processing, and preservation are presented in Section 21.4. This is followed by an overview of the technologies for livestock nutrition and feeding (Section 21.5), livestock health management (Section 21.6), housing and milking management (Section 21.7), and technologies in pastoral livestock production systems (Section 21.8). To fully benefit from these technologies, current challenges (Section 21.9) must be addressed to pave the way for accelerated improvements in the African livestock sector following their adoption and implementation.

21.1 Introduction

As pointed out in Chapter 20, genetic improvement is only one part of overall livestock improvement. While productivity and production require appropriate genetics, the expression of the genetics of the animal (to its fullest potential) is dependent on provision of a suitable production environment, including quality feeds and feeding regimen, health, housing, and overall management, including such operations as milking, and specific considerations for management under pastoral conditions. Over the years, demand for food and products of animal origin are increasing drastically worldwide owing to an increasing human population. For instance, the global meat consumption was reported to increase from 23.1 kg to 42.2 kg per person per year from 1961 to 2011 (Sans and Combris 2015). This growth in demand for livestock-derived foods will likely remain strong in low- and middle-income countries, increasing from 29% to 35% by 2030 and to 37% by 2050 in sub-Saharan Africa (Enahoro et al. 2019). Current meat production in Africa remains insufficient to satisfy demand. At the same time, the direct and indirect negative impacts of climate change on livestock production, including desertification and dwindling water resources, will remain perennial challenges in most production systems. Under these conditions, intensification of livestock production via the use of available technologies and innovations will be a viable strategy to facilitate the rapid production of livestock products (meat, milk, etc.) to meet the ever-increasing demand in Africa. Therefore, to address the animal protein needs of Africans in response to UN sustainable development goals and objectives of making food available to all by 2063, it is generally acknowledged that modern technologies will play a major role.

The adoption of technology in various aspects of livestock farming has been extensively studied (El-Osta and Morehart 2000; Khanal et al. 2010; Groher et al. 2020). It is stipulated that larger farms tend to be at the forefront of adopting technologies which have helped to increase profitability and feed quality, and reduce production costs and incidence of disease outbreaks. In dairy production, the late adopters of technology are small-scale milk producers, because most of the technologies are capital-intensive and not easily affordable (El-Osta and Morehart 2000), which is one of the issues faced by livestock farming in Africa. However, with the current low levels of productivity of most African livestock, the adoption and use of modern technologies are necessary to drive and sustain improved management and productivity. The implementation of modern technologies has been the driving force behind rapid improvements in the health and productivity in the beef, dairy, swine, and poultry industries in many western nations. These

improvements were achieved through advances in all aspects of livestock management such as advances in management practices, improved nutrition, improved health care, improved housing, improved genetic/genomic selection strategies, and improvements in reproduction management (Ibeagha-Awemu and Yu 2021). While Chapter 20 addressed the key issues related to sustainable livestock improvement and the role of modern technologies in driving sustained genetic improvement in livestock, this chapter will focus on the different technologies facilitating progress in livestock nutrition, health, housing, and overall management, including such operations as milking and specific considerations for management under pastoral conditions.

21.2 Technologies for Assessment and Improvement of Production Efficiency

The current low productivity levels of most African livestock can be oriented toward more sustainable systems and increased efficiency outcomes by adopting technologies that improve livestock farming practices, feed efficiency, precision feeding, welfare management, breeding and improvement management, disease management, and health and environment management. These provide opportunities to move the African livestock sector toward more sustainable development and improved contribution to livelihoods.

21.2.1 Feed and Growth Efficiency in Livestock Systems

Efficiency in broad terms refers to the ratio of output to input, intending to minimize the inputs while maximizing outputs. Production efficiency involves better feed utilization, accompanied by optimum growth potentials and high reproductive abilities. Therefore, production efficiency describes the measures that showcase the reproductive, feed, and growth outcomes in livestock operations. These production efficiency measures have important implications for individual livestock operations and the general public, such as providing food security for a growing world population (David et al. 2021), projected to reach 9.8 billion in 2050 by the United Nations, and would require about 70% more food.

Feed constitutes a significant expense in any livestock operation and is a primary driver of growth and production of products such as meat, eggs, and wool. Other items that constitute the total variable costs in livestock operations include labor, fuel, yardage, bedding, and so on. Feed accounts for a majority of these variable costs in livestock operations; at least 50% in cattle operations (Kennedy et al. 1993), up to 85% in pig operations (McGlone and Pond 2003), and about 65% of egg production costs (Aggrey et al. 2010). For cattle operations, about 75–85% of the total energy intake is channeled toward the maintenance requirements of beef cattle females (Durunna et al. 2011b). The significance of the cowherd expenses on the entire enterprise is due to their longevity, size, and varying feed requirements to meet nutrient needs for different stages of production (such as pregnant, lactating, or open cows). From Western Canadian data (WCCCS 2014), the cow needs to produce about five calves to recover all her costs or to break even on the heifer-development costs, which may translate to staying on the herd for at least 6 years. In addition, reproductive soundness is a significant determinant of the culling decisions in most herds while some productive cows (calving annually) have been retained for over 12 years in some operations (WCCCS 2014).

Feed intake is usually estimated as a percentage of the body size, implying that as cows approach their mature body sizes, their expected feed intake will be maximum. Further, as the cows move through different production phases (from open cow to calving to lactating cow), the feed quality and quantity also determine their abilities to rebreed in subsequent years, hence their longevity in the operations may be affected. The availability of sufficient quantity and quality of feed will support better growth. However, the ability of the animal to convert the feed materials

into products or "farm currencies" (meat, egg, milk, etc.) can also depend on the genetic potential of the animals to utilize feed effectively. Significant variations exist in individual animals' ability to use feed (Durunna et al. 2011a; Nkrumah et al. 2007), which means that individual differences in feed intake can be exploited to increase farm profitability by selecting animals that are more efficient at feed utilization. The efficiency of converting consumed feed into products, especially when feed resources are limited, enhances the profitability and sustainability of livestock enterprises. The issues may be exacerbated if stored forages are insufficient to meet the animal's growth requirements due to quality or quantity issues. The producers may reprioritize their objectives toward low-cost feeds that support maintenance requirements rather than growth. Unplanned disposal or sale of livestock (at below-market prices) may occur if feed becomes unaffordable or unavailable. Using efficient replacement candidates in breeding plans will reduce the long-term production and product costs of the livestock enterprises, thus animals with better production efficiency potentials may offset the potential excesses from high feed costs.

21.2.2 Strategies to Improve the Efficiency of Livestock Operations

Strategies that will facilitate improved livestock production (feed, growth, and reproductive) efficiencies in developing countries include adoption of improved production management, improved plant and animal breeding management, improved feed processing and forage utilization, effective utilization of human food waste or by-products, and improved health and immunity of animals (Terry et al. 2020).

Some production management strategies that maximize carcass weight within the shortest time enhance the production efficiency of livestock. These practices generally have positive impacts on the operation's profitability and the environment. Such management strategies include the incorporation of growth implants, ionophores, and beta-agonists to improve growth rate and feed efficiency or deploying precision feeding technologies in intensive production systems to ensure that nutrient/feed demands are met without overfeeding. Even though small-holder operations would benefit from the impact of these strategies, the costs associated with implementing them may exceed the benefits, thereby limiting the adoption of these technologies by the small operations.

Growth implants promote protein deposition rather than fat, thereby improving weight gain, total meat yield, and ribeye area. The growth implants could contain natural or synthetic hormones that influence the hormone content of the animal. Two major classes of growth implants available in Canada include estrogenic (e.g., estradiol, estradiol benzoate, or zeranol) and androgenic (e.g., trenbolone acetate) compounds. Results from a feedlot phase study on steers that received growth promotants (implants with trenbolone acetate + estradiol, and monensin in the feed) showed that body gain increased by about 21% while feed efficiency improved by about 23% compared to steers that received grass silage alone (Berthiaume et al. 2006).

Ionophores (such as monensin, lasalocid, or laidlomycin propionate) belong to a class of antimicrobials that inhibit the ability of bacteria to reproduce. They affect the ion gradient in microorganisms, making them expend more energy by preventing them from maintaining normal metabolism. The ionophores' inhibition of acetogenic bacteria in the rumen increases the amount of propionate generated. Beta-agonists are compounds added into feed, but they do not influence the hormone levels in the animal but rather redirect nutrients at the cellular level such that more growth occurs at the muscle tissues, improving feed efficiency and carcass leanness. While implants have been available since 1975, beta-agonists have only been available since 2004 (Radunz 2011).

In-feed antibiotics in poultry increase growth and improve feed efficiency; however, concerns over the development of antimicrobial resistance have led to the search for alternatives in the poultry industry. Alternatives to in-feed antibiotics

use in the poultry industry include prebiotics, probiotics, enzymes, phytogenics, and organic acids. Prebiotics are non-digestible feed ingredients that enhance the growth or activities of some gut bacteria. Probiotics are live microbial feed supplements that create intestinal microbial balance. Enzymes such as phytase, carbohydrases, and proteases are biologically active proteins derived from microbes that facilitate digestion and absorption of nutrients. Phytogenics are bioactive compounds of plant descent added into livestock feed (especially pigs and poultry) to facilitate productivity. Organic acids such as simple monocarboxylic (e.g., acetic, propionic, or butyric acid) or carboxylic (e.g., lactic, malic, or citric acids) acids improves growth performance and efficiency in broilers. Animal breeding programs that select animals with genetic potential for faster growth while receiving the most abundant or economic feed options have positive impacts on production efficiency and farm profitability. The genetic approach exploits the genetic variations within the replacement candidates and can pass on those beneficial traits to their offspring. The efficiency traits, such as residual feed intake and residual body gain (RBG) are moderately heritable (Durunna et al. 2012) and can be included in breeding programs. The strategy has been applied in ruminants and non-ruminants (including pig and poultry) and it is more sustainable (especially for developing countries in Africa) because the improvements are additive, cumulative, and permanent since the traits are passed on from one generation to another. On the other hand, plant breeding programs that develop plant varieties with higher yield and greater digestibility potential increase the production efficiency of livestock (Terry et al. 2020).

21.2.2.1 Technologies to Assess and Improve Production Efficiency

Traditional Tools to Assess Production Efficiency

There are several measures to assess feed and growth efficiency. As mentioned earlier, the more common assessment expresses the outcomes as ratio traits where inputs such as feeds are expressed relative to the outputs such as meat, milk, wool, or other livestock products. Animals that produce greater output per input (e.g., feed consumed) are more desirable. Common traits used to evaluate performance metrics in developing and developed countries include body weight, milk yield, and body condition score. The most common method to assess feed efficiency is feed conversion ratio (FCR) or its inverse, gain to feed ratio (GFR). The FCR refers to the quantity of feed consumed per body gain, while the gain to feed ratio is the quantity of body weight gain per feed intake. These two interpretations are well understood and adopted by producers in developing and developed countries. They are easy to measure even with limited technologies. For example, a cattle or small-ruminant producer may measure the quantity of feed consumed by an animal by summing the number of bags of commercial feed (with known weight), while the body weight(s) could be estimated using a weigh tape by measuring the heart girth. Alternatively, the actual weight could be captured with a weigh scale.

However, incorporating ratio traits such as FCR in breeding or selection programs may present some issues (Gunsett 1986) that may have long-term implications on the livestock enterprise from a feed efficiency standpoint. One of the major concerns is that two animals with identical FCR might differ in their average feed intake or daily gain. In such scenarios, unanticipated outcomes could arise when different selection pressures are applied to the numerator or denominator (i.e., the feed or gain) components (Durunna et al. 2011a; Nkrumah et al. 2007). Applying more selection pressure on the trait with higher variance may result in the indirect selection of animals with higher values. For example, broader variance in body gain may result in the indirect selection of animals with larger frame sizes (because they put on more weight than the others), and not necessarily that they have better feed efficiency potentials. The long-term implication of animals with larger body sizes may result in higher feed intake requirements by such animals.

Some traditional measures of growth efficiency include the Kleiber ratio and relative growth rate. The Kleiber ratio measures growth efficiency independent of feed intake (Hoque et al. 2009). It is calculated as the ratio of the average daily gain to the animal's metabolic weight. On the other hand, the relative growth rate measures the rate of growth of each animal relative to its final weight in the measuring period and may be expressed as the percentage gain (Winder et al. 1990).

Modern Tools and Technologies to Assess Production Efficiency

The recent and more popular feed and growth efficiency measures are residual feed intake (RFI) and residual body gain (RBG). RFI is the difference between the actual feed intake and expected intake based on estimated maintenance requirements and production potentials (Durunna et al. 2011a). It provides the best opportunity to select animals with efficiency measures independent of other traits considered. RFI models can accommodate additional adjustments for body composition measures such as backfat thickness (Durunna et al. 2012; Basarab et al. 2011) and activity levels (Durunna et al. 2012; Basarab et al. 2011). These adjustments ensure that the efficiency measures are phenotypically independent of the traits included in the models. For example, positive relationships exist between RFI and backfat, indicating that inefficient animals, i.e., animals with positive RFI will tend to have higher backfat thickness than their efficient contemporaries. Adjusting the models for the backfat level also ensures that the selection efforts do not discriminate against backfat thickness.

The RBG is the difference between the actual gain and the expected gain based on feed intake and other energy sinks adjusted in the model. Residual feed intake and gain (RFIG) is another recent measure that combines the desirable features of residual feed intake (RFI) and RBG in one trait.

Using these recent efficiency measures in Africa requires individual animal data, which is cumbersome in a large cohort if manually done. For example, manual measurement of delivered feed and the refusals for 50 heads housed in individual pens will require significant hours of labor for an individual. Technician bias may also be introduced if several people collect the data from different animals. Another implication of using a trait like RFI or RBG is the additional need to measure body composition, such as ultrasound backfat thickness. Measuring the backfat thickness, especially in cattle, will require handling facilities to restrain the animals and trained technicians to scan and interpret the results.

Deploying automatic feeding systems that can measure individual animal feed intake in a group setting will significantly reduce the errors that may arise. Some examples of such systems for sheep, goat, and cattle include Vytelle Sense ® (previously GrowSafe® Systems) (Vytelle, Calgary, Alberta, Canada), Insentec® (Hokofarm Group, Emmeloord, The Netherlands), SmartFeed® (C-Lock Inc. Rapid City, South Dakota, USA), Calan Broadbent (American Calan, Northwood, New Hampshire, USA), or BioControl CRFI systems (BioControl, Rakkestad, Norway). Few automatic feeding systems exist for poultry but the Bird Individual Ration Dispenser-electronic (Pampouille et al. 2021) may have commercial utility. The disadvantage is that these automatic units are expensive to purchase and maintain.

Furthermore, Mrode and colleagues (2020) identified insufficient funding as a critical bottleneck hindering livestock improvement programs in some African countries. Sustaining data collection efforts toward a livestock improvement program requires a good understanding of the values of the phenotypes collected toward future infrastructure or phenotyping activities. The high cost of measuring individual animal performance has often left producers in these countries to use subjective means, such as guess-estimates of bodyweight or milk yield. Other products such as eggs from laying hens are easier to count and record; however, tracking the individual feed consumption of livestock in small-holder farms in Africa is not common.

Poultry remains the most popular source of proteins and revenue in developing countries but

the rising cost of poultry feed echoes the need for systems or tools that will identify and develop more efficient (feed and growth) birds. The birds are usually selected for traits such as faster growth, increased yield and feed efficiency. Selecting efficient poultry has moved from labor-intensive traditional phenotyping of large number of birds raised in cages to the use of individual identification through radio frequency identification (RFID) tags.

21.2.2.2 Precision Livestock Farming, Machine Learning, and Artificial Intelligence

Precision livestock farming, which uses state-of-the art technologies for monitoring and data capture, provide the farmer with more objective data on animal and its environment for informed decisions and choices about the sustainability of farming activities and production system (Fig. 21.1). Precision livestock farming is developing rapidly and appears to be the main driving force behind the industrialization of animal farming (Werkheiser 2018). Precision livestock farming means using automated remote detection and monitoring of individual animals for health and welfare factors through capture and analysis of real-time images, sounds, tracking data, body weight, and body condition, as well as biological metrics, etc., which helps in the early detection of diseases, physiological status, welfare issues, etc., at the farm level (Berckmans 2014; Benjamin and Yik 2019). Generally, precision livestock feeding (PLF) technology is regarded as a means of narrowing the gap between animals and producers in the face of expanding systems (Norton et al. 2019). Thus, the main goal of PLF is to develop livestock monitoring and management systems with technologies to support the farmer (Berckmans 2014). Examples are sensor technologies for observing animals, the use of modern control theory to improve automation of the production process in welfare, health and production monitoring, and meat processing, and the application of artificial intelligence or advanced data processing methods to synthesize and combine different types of production and processing data (Barbar et al. 2022; Park et al. 2022; Fuentes

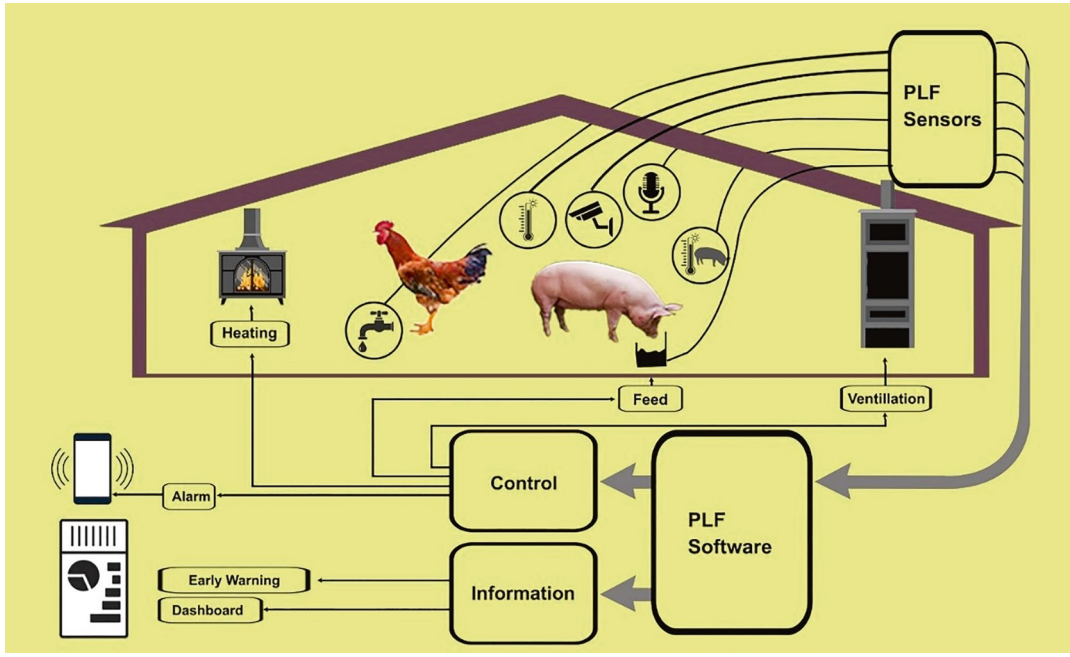

Fig. 21.1 A precision livestock farm uses state-of-the-art technologies to continuously collect data on animal (microphones, cameras, sensors) followed by continuous data analysis to provide real time information or data to support management and production decisions as well as resolve health and welfare issues

et al. 2022). Precision livestock farming is therefore an interface between different scientific disciplines and stakeholders in the livestock industry and requires the fulfilment of certain conditions to achieve sufficient levels of monitoring and management (Berckmans 2009), which include (1) animal variables, such as parameters related to behavior, physiological state, and welfare of animals, which requires continuous measurement with accurate and cost-effective sensor technologies; (2) reliable prediction models on how animal variables vary and how animals will respond at every moment, and (3) integration of predictions and on-line measurements for automatic monitoring and/or management. A recent review discussed livestock farming digital transformation under three themes with several examples: (i) biometric techniques for assessing health and welfare, (ii) animal identification and traceability, and (iii) application of machine and deep learning application to address complex problems (Fuentes et al. 2022). Therefore, machine learning and artificial intelligence are crucial aspects of PLF. Several examples of the incorporation of artificial intelligence-driven automation for achieving efficiency in meat/poultry processing, poultry breeder and broiler management, etc., have been described (Barbar et al. 2022; Park et al. 2022). Furthermore, case studies of the use of digital livestock tools in Kenya and India were recently presented (Daum et al. 2022).

Machine learning is an aspect of artificial intelligence that makes use of algorithms for predicting statistics and inference (Morota et al. 2018). Machine learning is gaining interest in the area of PLF because it enables computer algorithms to progressively learn from big data sets generated from sensor and improve themselves accordingly, thereby eliminating the use of human data analysts. Machine learning helps animal geneticists to predict phenotype based on prior genetic information, identification of outliers in a population and imputation of genotype. Machine learning can help in detecting disease (e.g., mastitis) from automated milking machines in dairy herds by estimating animal body weight and monitoring of gut health microbiome. Furthermore, machine learning has been recognized as a tool for monitoring animal welfare by predicting the early chance of dairy cattle lameness and mastitis, which can have an adverse effect on milk quantity and quality (Warner et al. 2020).

21.2.2.3 Blockchain Technology

Blockchain technology is an advanced tool that can be used to promote transparency on the history of an animal (Picchi et al. 2019). This is because consumers are keen on knowing the prior health condition of an animal before it is slaughtered for human consumption. The increase in foodborne illnesses has increased consumers' distrust of food labels. With the use of blockchain, there is an increased likelihood of regaining consumer's trust by offering product traceability from producer to retailer (Connolly 2018). Blockchain technology is an electronic ledger comprising unique QR codes attached to livestock products' labels. These codes when scanned with mobile devices can provide details regarding the cattle feed, any plausible administration of a treatment, rearing process, an incident of slaughter, time and location of milk production, processing techniques, added ingredients, the product's market release date, the origin of the milk, how old it is, what type of transportation and cold milk chain facilities were used, etc. The consumers can scan the codes using their smartphones, tracking the entire milk production process thread leading to the final product. Customers nowadays want to know where their dairy products come from. This necessitates end-to-end supply chain transparency to increase client confidence (Simitzis et al. 2021). Many dairy producers, suppliers, and stakeholders utilize blockchain technology to provide customers with real-time data about their products. Blockchain technology offers numerous benefits to livestock agriculture, such as automated transactions, decentralized systems that could contribute to more efficient systems of auditing for certification and regulatory organizations, system integration and proper record keeping of chain transactions throughout the lifecycle of an animal from farm to fork. This will, in turn yield greater traceability and transparency within

livestock agriculture. Blockchain technology could as well proffer solutions to sustainability and ethical concerns raised by consumers on how food animals are raised. Furthermore, blockchain technology could be used in tracking livestock disease breakouts, including salmonella outbreak, H1N1 swine flu, foot-and-mouth and mad cow diseases, and Avian influenza (Lin et al. 2018). In the event of a livestock disease outbreak, farmers all over the world can access data on the disease (the cause of the disease outbreak, how animals were treated, and precautionary measures to be considered). All these will help livestock farmers make informed decisions on what to do during a disease outbreak or an outbreak that is likely to reach their farms.

21.3 Technologies in Animal Welfare and Management

The safety and health of animals and farm workers are paramount to addressing animal welfare issues and public acceptance. In recent years, great strides have been achieved in developing technologies to address improved productivity, efficiency, safety, and animal welfare, including remote monitoring technologies, automated dairy installations, feeding technologies, pasture-based technologies, automated cleaning systems and herd management systems. Good animal welfare practices support livestock operations to improve productivity, efficiency, profitability, sustainability, and public perception or social license (Grandin 1995). Animal welfare measures can be classified into animal-based, management-based, and resource-based measures (Forkman and Lund 2017). These measures address the overall status-assessment of the animals, management routines (such as appropriate use of antibiotics or analgesics) that maintain animal health, and provide enhanced habitation resources that do not expose animals to risk factors such as injury or disease (Madzingira 2018). Understanding the impact of sound welfare practices on production efficiency will reduce associated morbidity or mortality of the animals and minimize safety concerns for the handlers. Enhanced welfare practices also positively impact reproduction, growth, productivity, and meat quality, which influence farm profitability (Rushen 2001). Addressing welfare concerns related to environmental conditions will improve feed and growth efficiencies.

Heat stress issues resulting from elevated ambient temperatures, relative humidity, or stocking rates will reduce the performance of animals. Livestock operations with poor air quality, ventilation systems, and inadequate provision of shades will exacerbate the negative impacts of inclement environmental conditions. Providing suitable bedding materials promotes health and improves production efficiency through comfortable rests for the animals. Hard, slippery, uneven, or muddy surfaces may expose the animals to injuries and diseases such as sores, lameness, foot rot, or mastitis. It is also essential to ensure that facilities and equipment used in managing animals do not predispose the animals to stress, injuries, or death; instead, such tools should reduce excitement and agitation in animals. Technologies and methods that reduce stress in livestock will support improved productivity and efficiency. These include incorporating excellent stockmanship procedures that improve human-livestock interactions during herding and handling (Petherick 2005). Low-stress techniques will minimize unnecessary anxiety tendencies that may disrupt the normal state of the animals. In the absence of less-painful husbandry practices, pain mitigation methods should be adopted to reduce the pain duration and facilitate the animals' recovery.

21.3.1 Technologies to Reduce the Impact of Animal Production on Animal, Human, and Environment Health (the One Health Concept)

In recent times, the One Health Approach (OHA) has been adopted to support global health security through collaborative and multi-disciplinary approaches cutting across boundaries of the

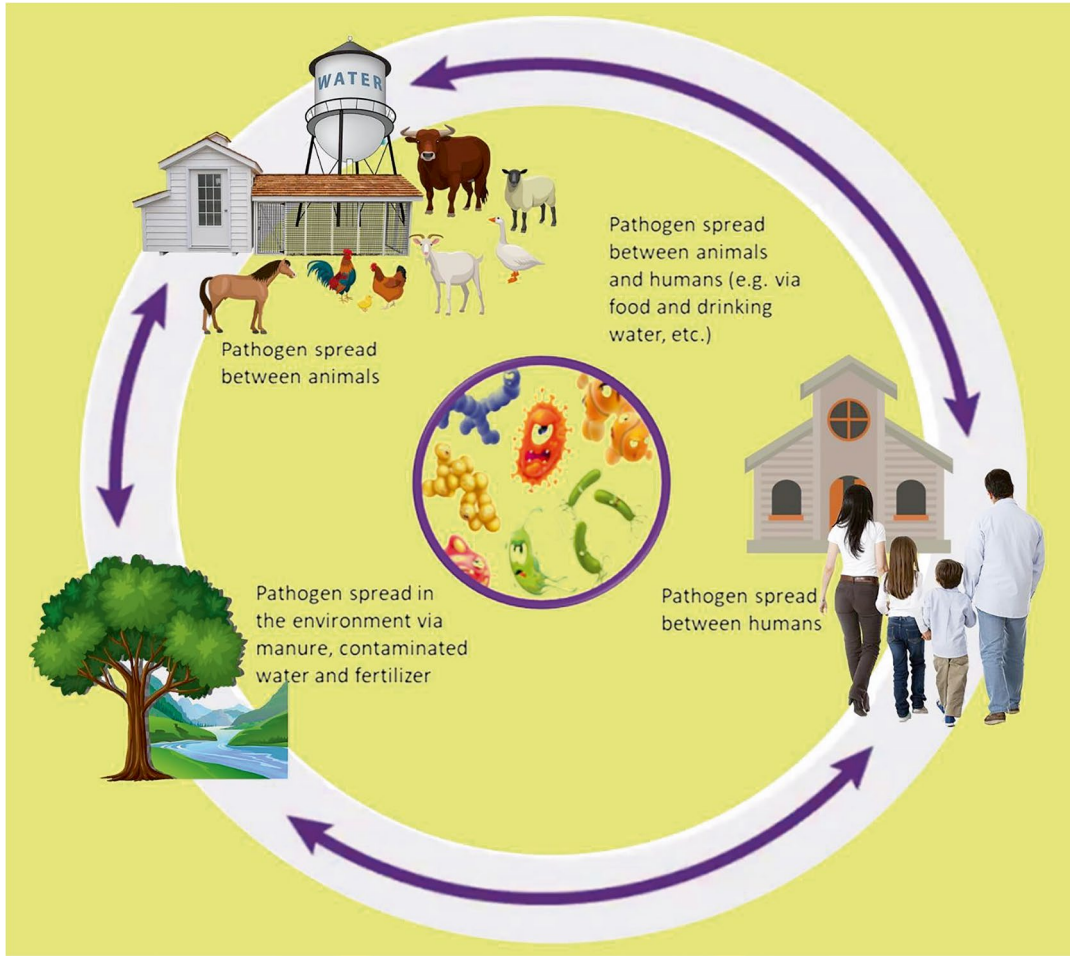

Fig. 21.2 The one health concept

human-animal-environment interface to tackle shared health threats such as zoonotic diseases, antimicrobial resistance, food safety, and so on (Sinclair 2019). The OHA is depicted in Fig. 21.2. Since the first use of the term "One-Health" following the outbreak of the SARs (severe acute respiratory disease) in early 2003, many countries over the last decade have implemented the OHA with demonstrated benefits (Sinclair 2019). The principles of the OHA will benefit efforts to develop plans for response and control of zoonotic diseases for the health benefit of animals, the environment, and the society. The impact of animal production on the health of animals, the environment, and humans is through the production of varied products, manure (which contains pathogens and excess nutrients), greenhouse gases, etc., and their proper management is necessary to safeguard animal, environment, and human health. Various technologies that ensure the safety of by-products of animal farming, such as pathogens, manure, and greenhouse gases (GHG), will be examined in this section.

21.3.1.1 Technologies to Handle Farm Animal Manure and Storage

Animal manure is a mix of animal feces and/or urine and bedding materials, and it is an integral part of sustainable crop production. Animal manure is mostly applied to soils as a form of fertilizer to enhance crop yield, build organic soil matter content, buffer soil pH, increase biological

activities, and improve soil physical properties (Zhang and Schroder 2014). However, the increasing use of concentrated animal feeds in operations has resulted in the production of animal manure in large quantities that is more than the soil and crop requirement (Table 21.1), thereby raising environmental concerns. This has led to the disposition of surplus animal manure, which is posing a threat to the environment. It was reported that the amount of nitrogen (N) and phosphorus (P) in animal manure produced in livestock and poultry farms is 50% more than what is economically and environmentally sustainable (Jackson et al. 2000). Long et al. (Long et al. 2018) used ten farms as a case study and discovered that between 2013 and 2015, animal manure was applied to soils, which already had excessive amounts of P (soil test $P > 50$ ppm). It was further stated that the excess P nutrient applied to the soil would have been enough for an additional 10,000 acres of land where soybean crops, for example, can be cultivated. Therefore, the author suggested that ten times of the land (from 2440 acres to 23,109 acres) used by the farms would have been appropriate to safely apply the same quantity of manure. In the USA, it was estimated that approximately 1.4 billion tons of manure was produced from more than 9.8 billion heads of livestock (beef cattle, dairy cows, swine, poultry, goat, sheep, horse, etc.) in the year 2017 (Pagliari et al. 2020). Likewise, 8.1 million tons of manure N and 2.6 million tons of manure P were excreted by poultry and livestock in the same year, out of which over 75% of the total manure N and P produced were from beef cattle, followed by dairy, horse, and broilers (Table 21.1).

Excessive manure application to the soil can affect water (surface and groundwater) and air quality. Heavy rainfall can cause surface runoff from manured land that contains excess nutrients and organic materials, which when it comes in contact with surface water, can lead to algal blooms, which increases turbidity and biochemical oxygen demand. The polluted surface water can cause offensive odor that is detrimental to aquatic animals (e.g., fish) if the dissolved oxygen goes below the thresholds; and may result to the accumulation of nitrate–nitrogen (NO_3–N) and P (Pagliari et al. 2020). The surplus NO3–N can also get to ground water through drainage pathways or leaching into ground water. Likewise, soluble P losses are more in areas with high rainfall and sandy or loamy sandy soils, as these soils have more water infiltration and reduced cation exchange capacity. Soluble P has a tremendous effect on water quality since it is directly bioavailable to algae and macrophytes; however, particulate P is only available once it has been converted to inorganic P (Pagliari et al. 2020). The sustainable management of manure is a global issue, particularly in most developing countries, where conventional management practices are mainly limited to land application and stockpiling (Fernandez-Lopez et al. 2015; Adghim et al. 2020). Improper manure manage-

Table 21.1 Number of poultry and livestock species and the estimated amount of manure produced, and nitrogen and phosphorus excreted in the USA in year 2017

Livestock[a]	Number of animals (1000 head)	Manure produced (tons/y)	Nitrogen produced (tons/y)	Phosphorus produced (tons/y)
Beef cattle	108,405	1,200,000,000	6,294,416	2,233,503
Dairy	14,181	145,000,000	1,663,735	258,803
Swine	129,388	596,000	3967	1511
Chicken (layer)	375,845	49,000	672	251
Chicken (broiler)	8,913,000	1,050,000	14,438	4463
Turkey	242,500	35,000	594	225
Horse	3914	36,000,000	197,647	141,176
Total	9,822,460	1,382,730,000	8,175,469	2,639,932

[a]Adapted from Pagliari et al. (2020)

ment causes issues related to environmental degradation, climate change, resource depletion, acidification, eutrophication potential, and water scarcity (Adghim et al. 2020). The importance of effective manure management and utilization has gained the attention of most national governments, with many having national policies related to manure management. To reduce the impact of animal manure application to land on the quality of air and water, several management practices have been instituted including application of the exact amount of nutrients needed by the soil. This can be achieved by performing soil testing and animal manure nutrient testing to know the exact nutrient content of the soil and manure before animal manure application. In the absence of manure testing facilities, book values of manure nutrient contents can be used (Christensen and Sommer 2013). However, it is important to keep in mind that manure nutrients might change due to several factors like efficient use of nutrients by animals due to breeding efforts, manure management systems, and animal feeding practices. It is expedient to follow best management practices to maximize the use of manure for food production without jeopardizing the environment. Therefore, this section focuses on several technologies for the best management practices that can be adopted to reduce the impact of animal manure produced in the environment.

Manure storage (includes collection, handling, and storage) has been very helpful in managing manure nutrients. Manure storage helps farmers to apply manure when the soil and plants can best make use of it, which could help prevent excessive application of manure to soils and in turn enhance crop production. The manure storage facilities must be well designed and structured in a way that will prevent environmental pollution (e.g., odor, flies, and pollution of ground and surface waters). Manure can be solid (greater than 15% dry matter), slurry (5–10% dry matter), or liquid (less than 5% dry matter) depending on the content of manure solids and this will impact the options to consider during manure handling and storage (Janni and Cortus 2020). It could also affect the type of equipment that will be used for handling, collection, and land application of the manure. Approximately 85% of swine production systems in the USA produce slurry or liquid manure. In such systems, manure (feces and urine) can be collected in a storage area below the slotted floor and the manure can be stored either for a short (one day) or long term (greater than 6 months) period (Pagliari et al. 2020). Manure can be stored at short term in gutters or shallow pits or at long term in deep pits, above ground tanks and lined earthen basins. In long-term storage facilities, the manure is agitated to create a more uniform slurry before land application (Pagliari et al. 2020).

In poultry production, litters are stored under a stacking shed with concrete floor and walls (the walls can be either short or full and covered with a roof). The stacking shed helps to prevent nutrient seepage if the litter is wet and to keep the litter dry. Some poultry barns have manure belts below each level of cages that catches the manure and the belts transports the manure away for storage located outside of the barn. Manure from layer houses with manure belts is commonly removed from the layer house every day to every third day and then stored in a stacking shed. Some layer houses have flush systems that handle the manure as a liquid and the liquid manure can be stored in lined earthen basins, or steel or concrete structures for few months to a year before land application (Janni and Cortus 2020). Dairy operations generate manure in the form of solid, slurry, or liquid. Concrete floors and walls covered with roof are mostly used to store solid manure. Liquid and slurry manure from dairy operations are stored in similar structures, such as below-ground tanks, lined-earthen basins, and above ground tanks (Janni and Cortus 2020). These systems of storage may include multiple basins that provides separation of manure solids and also allow wastewater to be used for flushing manure alleys or manure flumes. Most liquid and slurry manure systems of storage are designed to store manure for at least a year before it can be land applied.

In beef production, feedlot runoff is often handled using a two-stage system. The first stage is the use of a smaller settling basin designed to

separate solids from the liquid. Afterward, the liquid portion is transferred to a larger, longer-term storage in a larger basin. Solids need to be periodically emptied from the settling basin. The basin needs enough storage to accommodate normal and storm-event weather conditions in all the entire feedlot area between the period of time when the liquid can be land applied. The basin may be referred to as a detention basin, holding pond, or evaporation pond in different areas and for different modes of management. The low solids and nutrient content of the basin liquid is liable to be distributed by irrigation. However, evaporation from the basin may be significant in dry climates (Janni and Cortus 2020). Furthermore, solid manure removed from open feedlots or barns with solid floors can be stored in uncovered stacks on impervious surfaces that prevent nutrient from leaching into the soil. Uncovered stacks are mostly required to have runoff collection systems and storage to prevent pollution of surface water. Also, solid manure from beef operations can be stored in covered stacks under sheds that limit runoff. Manure collected in deep pits needs to be agitated before removal. Most times, additional water may be added to reduce the solids content of the manure for easy removal by pumps. The manure is directly applied to cropland or soil according to nutrient management plans.

21.3.1.2 Technologies to Reduce Nutrient Excretion and Manure Treatment

Feeding Animals Based on Dietary Requirement

Nitrogen is an important element for proteins, amino acids, nucleic acids, and energy transfer in vertebrate animals; thus, large amounts of dietary N are required to produce profitable quantities of meat and milk and ensure successful stock procreation. When dairy rations are adequately balanced for energy, crude protein, and minerals, dietary N is metabolized and transferred to milk, urine, and feces in approximately equal proportions (Powell et al. 2011). However, feeding excess dietary nitrogen to cattle can lead to increased concentrations of urine-nitrogen, and to a lesser extent fecal-nitrogen and as much as 75–95% of nitrogen fed can be excreted (Cole et al. 2006; Selbie et al. 2015). For beef cattle, the nitrogen use efficiency (NUE) is generally low, of which 80–90% of the dietary feed N can be excreted in manure (Cole et al. 2006). When high dietary CP concentrations are fed to cattle, most excess N is excreted in urine (Waldrip et al. 2013). For example, Cole and colleagues (Cole et al. 2006) observed that urinary nitrogen content increased from 84 to 94 g/d, while fecal-nitrogen increased from 39 to 65 g/d, when dietary CP was increased from 11.5 to 13.0% (this is within the National Research Council (NRC) recommended CP levels for finishing cattle). Meanwhile, Cole et al. (Cole et al. 2005) reported 140% increased NH_3 emissions when beef cattle were fed 13.0% CP, compared to 11.5% CP. As a result, cattle NUE, and impact of diet composition on N use have gained a lot of interest for livestock managers. Interestingly, it was estimated that a diet containing 23% CP could facilitate optimum milk production (NRC 2001). Whereas, overfeeding protein nitrogen can have negative effects on milk nitrogen content. For instance, it was reported that increasing the intake of CP from 15 to 19% led to 18% reduction in milk nitrogen from 0.27 to 0.22 g/d (Groff and Wu 2005).

In contrast to nitrogen excretion, most excess phosphorus is excreted in cattle feces, rather than urine, which can be partitioned differently depending on diet and animal characteristics. The dietary phosphorus requirement for a feedlot steer is 0.30% of the diet dry matter (DM) (NRC 2000), but could be as low as 0.16% of dietary DM (Erickson et al. 2005). The phosphorus use efficiency of lactating cows is relatively low, and ~67% of total consumed phosphorus is excreted (Wu et al. 2003). The level of manure phosphorus excreted in feces can be reduced by decreasing dietary phosphorus levels (Feng et al. 2015), either by manipulating the amount of supplemental P or changing the ratio of silage to forage being fed. Cereal grains, silage, and other feedstuffs contain higher phosphorus levels than forages (Singh et al. 2018). For instance,

steam-flaked corn contains approximately 0.25% phosphorus, while meadow hay contains approximately 0.18% phosphorus (Wilson et al. 2020). Generally, grains consist of 3.5–4.5 g of phosphorus/kg DM, while straw contains about less than 1 g/kg DM (Singh et al. 2018). Knowlton and Herbin (Knowlton and Herbein 2002) reported that decreasing dietary P content from 0.67 to 0.34% DM decreased daily phosphorus excretion from 113 g/d/cow to 43 g/d/cow. Similarly, Wu and colleagues (Wu et al. 2003) observed that decreasing dietary phosphorus from 0.42 to 0.33% DM caused a 25% decrease in phosphorus excreted in the feces of lactating cows. The authors further reported that there was a positive linear relationship between the amount of phosphorus in the diet and feces-phosphorus, where increase in diet phosphorus content by 0.01% elevated feces-phosphorus by an average of 0.02% (Wu et al. 2000).

Inclusion of Feed Additives to Improve Digestibility

Feed additives may be beneficial for decreasing phosphorus and nitrogen contents of litter, as well as substantially reducing the odor of manure. One of the management practices to reduce phosphorus runoff from poultry litter is to decrease the amount of phosphorus in feed. In the past, more phosphorus was supplemented in poultry rations because most grains store around 80–90% of their phosphorus as phytate (Turner et al. 2002). Poultry birds cannot easily digest phytate-phosphorus because they are relatively stable. However, when phytase enzymes are added to poultry diet, it cleaves the phosphorus from the phytate molecule, making it readily available. Phytase can degrade digestible fibers from indigestible grain fractions and decrease the need for phosphorus supplementation, which in turn minimizes the phosphorus level in poultry manure. Furthermore, the addition of amino acids to poultry ration has been shown to reduce phosphorus excretion by nearly 50%, although this increases the production costs (Keshavarz and Austic 2004). Another diet modification technology that can be potentially used to decrease the amount of dicalcium phosphate added in the feed is the use of high available phosphorus (HAP) corn, which are varieties that have been selected or bred for their ability to store P in forms that is more bioavailable than phytate (Raboy 2002). Miles and colleagues (Miles et al. 2003) showed that poultry diets containing phytase and HAP corn produced manure with decreased phosphorus content resulting in lower phosphorus runoff (Smith et al. 2004). Distillers dried grains with soluble (DDGS) is a fermented product with low concentrations of phytate-bound phosphorus, that is mostly available as a by-product of ethanol production (Stein and Shurson 2009). It was reported that phosphorus concentrations in manure are mostly reduced when DDGS is added to the diet as long as the total dietary phosphorus is adjusted to account for the higher digestibility of phosphorus in DDGS (Stein and Shurson 2009).

There are other feed additives that have been used to mitigate methane (CH_4) emissions and improve feed efficiency, including seaweed (Vijn et al. 2020), secondary plant metabolites, such as tannins, saponins, essential oils, and flavonoids, as well as lipids, ionophores, nitrogen sources, and biocarbon (Ku-Vera et al. 2020; Villar et al. 2020). The most common lipids used for CH_4 emission mitigation are oil-rich seeds, such as cottonseed (Beck et al. 2018), linseed (Doreau et al. 2018), and canola oil (Villar et al. 2020). Ionophores are antimicrobials mixed with cattle feed to improve nutrient availability and prevent diseases like coccidiosis. Interestingly, when ionophores are mixed with cattle feed, it enhances feed efficiency and weight gain by selectively inhibiting methanogenic bacteria, thereby allowing the beneficial rumen bacteria to make more feed energy available to the animal. Monensin is the major ionophore used in ruminant diets to increase feed efficiency by limiting gram-positive bacteria and protozoa (Witzig et al. 2018).

Steroid hormone implants (estrogens, androgens, or their combination) have been commonly used in U.S. cattle production systems for a very long time, and are known to increase the synthesis of muscle protein, reduce protein degradation, and improve average daily gain (Beck et al. 2014; Webb et al. 2017; Cleale et al. 2018); as well as reduce the GHG emissions and resource use per

kg of beef produced (Webb et al. 2017). Implants have also been found to improve productivity in both feedlot and pasture-based steers, heifers, and bulls, which in turn improve their economic returns (Beck et al. 2014; Al-Husseini et al. 2014; Smith and Johnson 2020). Combining growth implants with ionophore feed additives has been shown to be effective in feedlot programs. It was shown that growth implants improved daily gains and feed efficiency while ionophore feed additives in combination with growth implants reduced the amount of feed needed for a given amount of gain by an additional 7–8% (Al-Husseini et al. 2014). Recombinant bovine somatotropin was among the first agricultural biotechnology products to be approved by the United States Food and Drug Administration (FDA). Somatotropin is a key homeorhetic control in regulating nutrient partitioning because when administered to dairy cows, it enhances milk production by15–20% (Etherton et al. 1993), improves milk synthesis efficiency by 10% (Bauman 1999) and at the same time maintains the health and overall well-being of dairy cows (Bauman 1999; NRC. National Research Council 1994). When recombinant bovine somatotropin was administered to growing pigs, carcass fat content was reduced by 70–80% and productive efficiency was improved by 15–35% (Buzby et al. 2006). However, hormone implants are not widely accepted in other countries and generally, there is negative public perception regarding the use of hormone implants in animal production.

Beta-agonists are a class of non-hormonal compounds fed to cattle. They work by binding to receptors on fat cells in the animals' body and redirect and reduce fat metabolism so that less fat is produced and/or stored in the carcass. Also, beta-agonists bind to receptors on muscle cells and redirect and increase the size of muscle fibers, which replaces some of the fat, thus increasing the percentage of lean muscle. In doing so, the energy supplied by the feed to produce weight gain is reduced. Therefore, more weight is produced by the same level of feed intake and feed efficiency is increased (Felix 2017). There are two compounds available to cattle feeders: Zilmax© (zilpaterol) made by Merck and Co. (Merck and Co Inc., New Jersey, USA), and Optaflexx© (ractopamine) made by Eli Lilly Co. (Eli Lilly and Company, Indiana, USA). Both products are fed at very low levels (200 mg/head/day for Optaflexx© and 60–90 mg/head/day of Zilmax©) for a short period of time just before slaughter (25–35 days) (Felix 2017). A recent report showed that 60–80% of feedlot cattle in the USA are fed a beta-agonist (Felix 2017).

Phase Feeding

Phase feeding involves formulating animal diet closer to their nutritional needs and this could reduce N and P excretions by 10–15%. It involves the adjustment of dietary CP to meet, but not exceed, animal CP requirements at different stages of growth and production. For instance, the nutritional needs of swine varies through different life stages (NRC 2012); thus, manure characteristics will change over time. To meet these nutritional changes, phase feeding is often employed. Swine diets are formulated based on amino acid balance needs of the pig. Although some feedstuffs like soybean meal provide the required distribution of amino acids, the addition of synthetic amino acids into swine diet can more closely meet the pig requirements, thereby reducing excretion of NH_4–N (Liu et al. 2017) and K (Li et al. 2015). In general, phase feeding can reduce N and P by approximately 5% (Sutton and Lander 2003). Knowlton and colleagues found that moving from a one-phase feeding to a three-phase feeding system, helped to better meet the exact nutritional needs of growing pigs, thus P excretion was reduced by 12.5% (Knowlton et al. 2004).

Manure Management to Reduce Nutrient Losses and Improve Production

Atmospheric emissions of compounds like NH_3 from animal manure cause production problems and environmental issues such as soil acidification, formation of fine particulate matter, and excessive N deposition into aquatic and terrestrial ecosystems (He et al. 2016). During the winter months, gaseous NH_3 concentrations can

reach very high levels in poultry houses, which can sometimes exceed 100 ppm. When atmospheric ammonia is deposited onto soil, it is converted to nitrate via nitrification, which is an acid-generating process (Ashworth et al. 2020). Presently, the only technology adopted by the poultry industry to decrease NH_3 volatilization from manure is acidification with acid salts, such as aluminum sulfate (alum), sold under the tradename of Al$^+$Clear or sodium bisulfate sold under the tradename PLT® (Ashworth et al. 2020). When litter is acidified, it pushes the ammonia/ammonium equilibrium toward ammonium, which is not volatile.

The two phosphorus fractions that are mostly abundant in cattle manure are water-phosphorus (H_2O-P) and sodium hydrogencarbonate-phosphorus ($NaHCO_3$–P). These two phosphorus fractions are generally considered labile phosphorus fractions and should be readily available for plant growth (Pagliari 2014). H_2O-P content is a critical indicator of the potential of phosphorus runoff (Kleinman et al. 2020). The higher amount of H_2O-P and $NaHCO_3$–P in cattle manure indicates that the management of P should focus on their immediate impacts on water quality and plant response. Cattle production systems generally capture and store manure. It has been shown that manure storage systems are effective at decreasing runoff potential (Janni and Cortus 2020). Hong and colleagues (Hong et al. 2018) characterized P in the sediment sludge and crust formed on retention ponds of a dairy manure storage by sequential fractionation method. It was reported that pond sludge and crust contained higher amounts of labile phosphorus (H_2O-P and $NaHCO_3$–P). However, there were lower levels of H_2O-P in sludge and crust than what was found in raw manure, which indicates that the use of sludge and crust rather than raw manure as a soil amendment could decrease phosphorus loss by surface runoff and leaching, as well as providing soluble P for immediate plant use. In addition, most of the organic compounds containing phosphorus in manure can highly interact with soil clay particles and they will bind to soil clay particles when the conditions are appropriate. When P binds to soil particles, it becomes more resistant to hydrolysis and therefore not readily available (Karathanasis and Shumaker 2009). Therefore, understanding the forms of phosphorus in manure can aid to develop best management practices, which could enhance the beneficial reuse of manure as a nutrient source in crop production.

Use of Water Extractable Phosphorus

Water extractable phosphorus (WEP) is used to predict the potential for manure applied on land, particularly manure applied to the surface of soil, to directly transfer dissolved forms of P to runoff water (Ashworth et al. 2020). Water extractable P can be used to adjust environmental recommendations for land application of manure (Elliott et al. 2006), and WEP is an essential factor in the most sophisticated computational models when considering (WEP) runoff (Vadas et al. 2009). Just as total P differs from one animal species to the other, so too does WEP. In a recent survey, Liu et al. (2018) reported that in average, WEP was highly concentrated in turkey manure and swine manure, followed by chickens (layers and broilers), dairy, beef, and horse manures. Generally, composted manures had lesser WEP concentrations. It was estimated that WEP comprised of 11–58% of total P in manure and compost.

Metal salts can be potentially used to reduce manure WEP. The most accepted metal salts is alum ($Al_2(SO_4)_3$), which is used in the production of over 1 billion broiler chickens in the United States alone. The use of alum in the broiler industry reflects its contribution to ammonia conservation, and improvement on the growth and health of housed birds (Choi and Moore 2008). Other examples of metal salts that have been experimented include ferric chloride ($FeCl_3$), ferric sulfate ($FeSO_4$), aluminum chloride ($AlCl_3$), and calcium sulphate (gypsum) ($CaSO_4$), all of which have shown great potential to lower WEP in manure but none of them gained widespread acceptance (Kleinman et al. 2020). In general, a decrease in the solubility of P in manure when salt is added does not significantly affect P availability to crops, although the added P adsorption capacity from salt amendments in manure can

also decrease P solubility in soils, as shown by long-term studies with alum-treated poultry litter (Huang et al. 2016).

Housing Management

The cleanliness of housing could affect the manure properties during storage. Li and colleagues (2017) compared dirty pig housing (sprayed with manure) versus clean housing (washed daily), and found that when stored in simulated deep pits, there was an increase in manure NH_3, nitrous oxide (N_2O), and hydrogen sulfide (H_2S) gas emissions from the dirty housing system. Manure is generally considered to be made up of feces and urine, but it also includes waste food and water. Food spillage can occur during pig feeding, and it is estimated that nitrogen and phosphorus in manure can increase by 1.5% for every 1% of food spilled (Ferket et al. 2002). Also, nipple drinkers have more wastage compared to cup drinkers or wet and/or dry feeders (Matlock et al. 2014) and it is estimated that adequate management and selection of appropriate drinkers could reduce water wastage by 30% (Muhlbauer et al. 2011).

Management of environmental factors within housing, like temperature and humidity, is also very important as this could impact manure properties. Temperature and humidity not only affect the food intake and manure production of pigs (NRC 2012) but can also influence emissions of gases and nutrient transformations of manure stored in pits. In a meta-analysis conducted on different types of swine production facilities in the United States, Liu et al. (2014) stated that NH_3 emissions from all types of swine facilities, such as deep pits and recharge pits increased with increasing temperature, but this does not affect H_2S emissions. However, Thorne et al. (2009) reported that H_2S emissions in barn were affected by number of pigs housed, wind, and relative humidity.

Handling of Manure and Treatment

Handling and moving manure into storage can affect manure characteristics, particularly nutrients and DM content. For instance, in flush systems, water is used for moving swine manure from temporary storage under the confinement building to storage outside the barn. When manure is flushed, lots of gaseous H_2S is emitted, but regular (daily) flushing compared to once weekly or bi-weekly flushing was found to reduce overall H_2S and NH_3 gas losses (Lim et al. 2004). In flush systems with pit recharge (the pit is partially filled with water for the manure to fall into), the rate of pit recharge (or how often manure is removed) can also impact H_2S emissions (Liu et al. 2014). For instance, if the manure stays for a long time in the pit before being flushed, the more H_2S is released. Agitation is often used to mix manure before crop or land application so that nutrients are redistributed uniformly. In a research carried out on a deep pit system, it was discovered that the average H_2S concentration in the barn increased by approximately 62 times while NH_3 increased by ten times before the manure was agitated (Hoff et al. 2006).

Manure disposal and management are among the most important issues facing producers, as improper manure treatment and management can lead to excessive odor, fly breeding, and environmental pollution. Anaerobic lagoons are system used only in warm climates for treating manure because the microorganisms are more active under warm climatic conditions to break down the manure accumulated in an appropriately sized lagoon. This is because, a small-sized lagoon with excess daily manure loading in cold temperature can overwhelm the microbial activity of the lagoon, which can lead to odor problems and poor treatment of manure anaerobically (Vanotti et al. 2020). Other manure treatment systems have been proposed that recover calcium-phosphorus (Ca-P) compounds. For example, in South Carolina, Vanotti and colleagues (2010) developed a full-scale, two-stage system for a swine production facility that can treat raw swine manure. This system uses a nitrification bioreactor to decrease carbonate and ammonium buffers, followed by the addition of calcium hydroxide ($Ca(OH)_2$) to precipitate Ca–P (Vanotti et al. 2005). Manure solids containing about 95% of the phosphorus are collected once the treatment process is completed and are exported to end users as compost or low-solubility fertilizer. This

system can also be used to remove odors and pathogens from manure. It is noteworthy that many calcium-based phosphorus recovery systems and anaerobic digesters generally volatilize much of the manure nitrogen content as they adjust pH to favor Ca-P precipitation unless recovery systems are included to capture NH_3 off-gassed (Karunanithi et al. 2015). Wei and colleagues (Wei et al. 2022) showed that nitrogen losses from land application were significantly reduced (52.6%) when compared to the level of discharge consent (75.9%). It was further stated that ammoniacal nitrogen (was the major source of nitrogen loss accounting for 72.9% and 50.2% in land applied manure and in discharge consent, respectively. It is imperative to control ammonia emission for sustainable manure management (Wei et al. 2022).

In-Field Stacking of Manure

Stacking of dry manure is a common short-term management practice in which dry manure is stacked in the field before land-application. Even though it is recommended to store manure under a permanently roofed structure, which could prevent litter from direct exposure to rain; however, it is still common to stack poultry litter in crop fields when the manure will be used within a short time frame (Kleinman et al. 2020). To minimize nutrient runoff from the manure stacked in the fields, most developed countries like USA states and Canadian provinces have established relevant management guidelines, which involves covering manure stacked on the field with plastic sheeting or with reinforced, ultraviolet-resistant cover (resistant to environmentally sensitive areas like streams, water wells, drainage ditches, and sinkholes), and with the manure stacked on lands with gentle slopes to prevent runoff (Kleinman et al. 2020). It is economical to use plastic sheet for covering manure stacks to reduce P and N runoff while better preserving the N value in the manure. Although some studies have several concerns associated with covering a manure stack under certain circumstances, including elevated nutrient leaching by water generated by microorganism respiration under aerobic conditions (Dewes 1995), most of the studies have also pointed out the benefits of covering the manure stacks (Doody et al. 2012; Liu et al. 2015). For example, in a field study conducted on poultry litter stacks, it was reported that although P losses from both covered and uncovered stacks were very low due to their high capacity to hold precipitation water, covering stacks reduced the total P leaching by 25–100 times such that leachate P losses from covered stacks was similar to the controls with no manure stacking (Liu et al. 2015). Moreover, it is worthy to note that manure stacking could result in the development of P "hotspots" in fields (Liu et al. 2015). Liu et al. (2015) observed that after 2 years of poultry litter stacking, WEP concentrations in upper 5-cm soils were increased (120–240 mg/kg) under the covered stack and under the uncovered stack (140–250 mg/kg). Therefore, it was suggested that relocating stack sites is necessary when field stacking of manure is mostly practiced.

Aerobic and Anaerobic Digestion of Manure

Aerobic digestion is described as a process in which animal manure is agitated with air or oxygen for a specific solids retention time at a set temperature, which could work as a batch or continuous system. The specifications for the needed mean cell residence time include 40 days at a temperature of 20 °C and 60 days at 15°C (Bekoe et al. 2018). Bekoe et al. (2018) reported that a 14-day aerobic treatment reduced the total solid content of swine manure by >15%, and the aerobic treatment of swine manure before anaerobic digestion showed a higher CH_4 yield. Anaerobic digestion is the microbial decomposition of organic materials void of oxygen, producing mainly CH_4 (55–65%) and carbon dioxide (CO_2) (30–35%) gases, commonly known as biogas (Gerber et al. 2013). Anaerobic digesters can be classified as passive systems, low-rate systems, or high-rate systems (Harrison and Ndegwa 2020). A passive system is when biogas recovery is achieved with an existing treatment system, that could be accomplished similar to a covered manure lagoon. A low-rate system consists primarily of manure as the major source of CH4-

forming organisms. Designs of low-rate system include complete mix and plug flow. A high-rate system traps CH4-forming microorganisms in the digester and includes recycling of solids, fixed film, suspended media, and sequencing batch digesters. Anaerobic digesters (AD) provide many benefits including: odor management, reduced emission of greenhouse gases, pathogen control, and production of biogas (CH_4) for use as fuel (Harrison and Ndegwa 2020).

Anaerobic digestion of livestock manure coupled with addition of biogas production is thus effective in decreasing CH_4 emission because this decreases readily available carbon for microbial processes to produce CH_4, either during subsequent storage or following land application of the digester effluent (Harrison and Ndegwa 2020). Furthermore, when CH_4 is captured and used as a renewable energy source, it can serve as an alternative to non-renewable fossil fuels, further decreasing emissions of GHG, nitrogen oxides, hydrocarbons, and particulate matter (Harrison and Ndegwa 2020). The economic benefit of converting fibrous materials, such as manure, food waste, and by-product feeds into CH4 is mostly linked to fuel production for generating electricity, transporting vehicles, and providing energy for home heating and cooking. In addition, the liquid after anaerobic digestion can be utilized as a nutrient source for crop production, while solids can be used either as bedding for animals or as a soil amendment. The environmental and societal benefit of AD is the diversion of wastes away from landfills (Gould 2012). Anaerobic digesters are used in the management of manure associated with dairy farming and waste water at swine and poultry operations (Harrison and Ndegwa 2020). In a recent study, Rajagopal and colleagues (2021) demonstrated that the liquid digestate (leachate) resulting from a two-stage liquid-solid anaerobic digestion (at 20 ± 1 °C) of chicken manure can be used to grow microalgae (Fig. 21.3). Microalgae are photosynthethic microorganisms with capability to grow and multiply rapidly by utilizing nutrients (e.g., nitrogen, phosphorus, and potassium) from water and producing organic exploitable biomass (e.g., biofuel) (Cai et al. 2013). Considering the high nutrient requirement by microalgae, Rajagopal and colleagues (2021) proposed that enhanced growth of microalgae at higher concentrations of manure digestate and better adaptation of microalgae/microalgae-bacteria consortia to high-N content wastes will positively influence the circulation bioeconomy framework.

Small-Scale Anaerobic Digestion in Developing Regions

Although developed countries have the concentrated animal density and infrastructure to promote the utilization of highly engineered AD systems, developing countries must make use of less sophisticated models (McCord et al. 2020). Common feedstocks for use in ADs in Uganda, Rwanda, and Bolivia include manure, food waste, slaughterhouse waste, and human waste (Vogeli et al. 2014). The designs often times consist of underground domes made of brick and cement, above ground poly-tanks, and bio digesters (Vogeli et al. 2014). Most of these digesters are simple pass-flow reactors that do not have mixing components, do not need elaborate continuous monitoring, and can be used in tropical weather conditions (Harrison and Ndegwa 2020). The most common use of the biogas is for cooking, which provides for improved indoor air quality since it is used as wood replacement (McCord et al. 2017). The replacement of wood with biogas reduces deforestation, which serves as a benefit for the environment. In addition, a further technology that has been adopted is the use of absorption coolers for refrigeration that are operated on biogas (Harrison and Ndegwa 2020).

Pasteurization

Pasteurization is the process by which manure is heated above a certain predetermined temperature for a short period of time. The pasteurization process is accomplished mostly with heated exchangers or by steam injection. Moreover, it eradicates zoonotic pathogens without spores, but the bacteria harboring spores are only decreased. The pasteurization method can be used as a pre-treatment method before the application of other known methods of manure treatment. However, pasteurization can be conducted

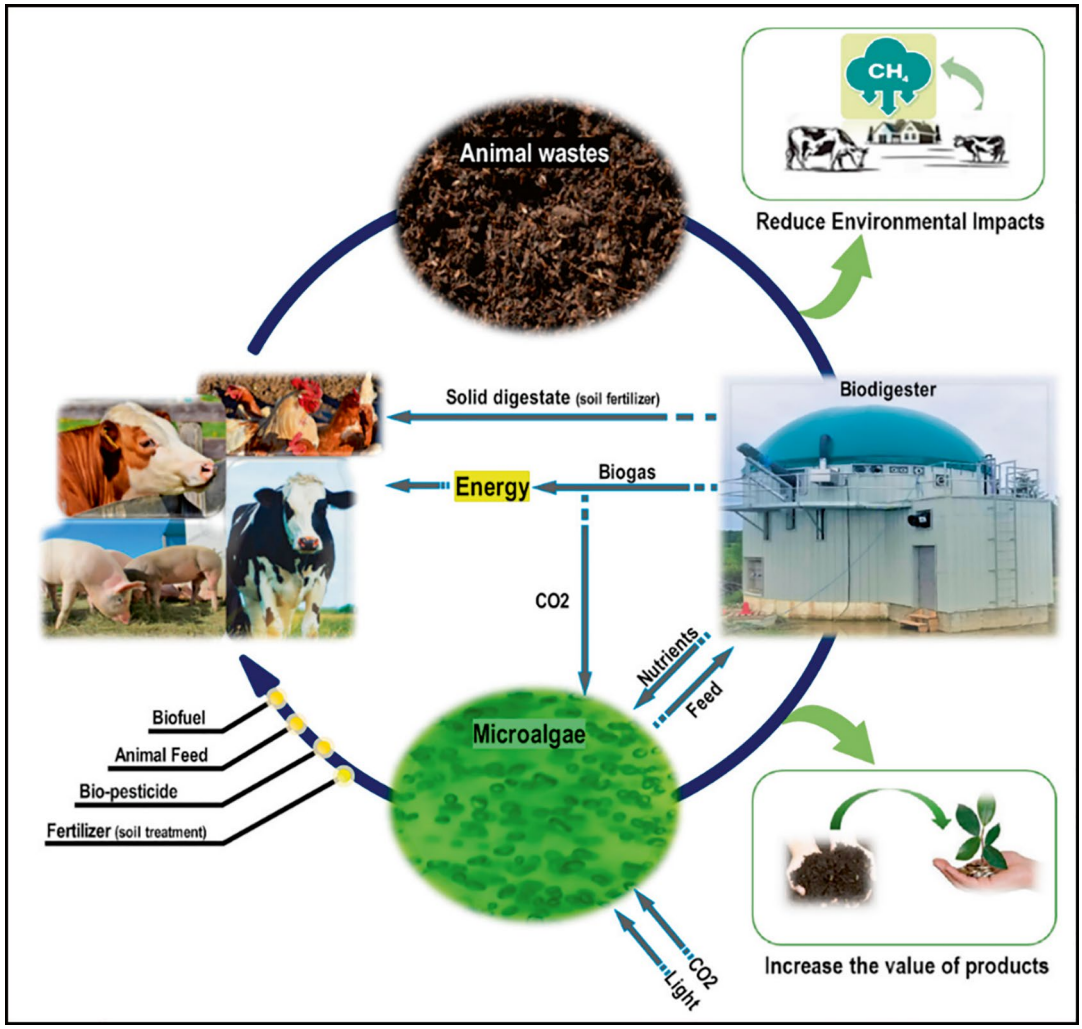

Fig. 21.3 Agricultural waste management toward a circular bioeconomy. Digestate (10% dilution) resulting from anaerobic digestion of chicken manure was used as nutrients for microalgal (strain *Chlorella vulgaris* CPCC 90) growth resulting in production of biofuel and bioproducts that can be used as fertilizer (for soil treatment), biopesticide and as animal feed. (From Rajagopal et al. 2021), licensed under CC-BY 4.0)

before or after anaerobic digestion in a batch or continuous mode. Mostly, the batch operation is usually recommended because the temperature and time can be controlled easily (Marañón et al. 2006). The pre-treatment of animal waste is done at 70 °C for 60 min or 30 min before mesophilic and thermophilic digestion, respectively (Colleran 2016). For example, Marañón et al. (Marañón et al. 2006) pre-pasteurized cattle manure for 2 h, followed by mesophilic anaerobic digestion in an up flow anaerobic sludge blanket and the result showed that some pathogenic bacteria (*Yersinia*, *Pseudomonas*, *Enterococcus,* and *Coliforms*) were removed without spores.

Liquid–Solid Separation

There are different methods used for liquid–solid separations and these include incline screens, rotary screens, screw presses, filter presses, rotary presses, and dissolved air flotation devices. Two liquid–solid separators were evaluated, a screw press separator (Eys, Daritech Inc., Lynden, WA), and rotating drum screen separator (DT-360, Daritech Inc., Lynden, WA) and it was reported

that nutrient partitioning after liquid–solid separation indicate a range in solids separation of 13–25%, in N separation of 4.3–12.9%, and in P separation of 9.2–21.5% (Vanotti et al. 2020). Church and colleagues (2016) demonstrated that up to 60% of P could be recovered from dairy slurry when liquid–solid separation technologies are used (screw press followed by centrifugation). Interestingly, it was reported that when these technologies were combined with chemical treatment, up to 99% of manure P was recovered in various solids, leaving a liquid effluent that kept more than 90% of the N in the manure (Church et al. 2016; Church et al. 2018). A mobile version of the solid separation and chemical treatment system, MAnure PHosphorus EXtraction (MAPHEX), was also developed to treat manure slurries on small dairies (Church et al. 2016; Church et al. 2018).

Natural flocculants (e.g., chitosan) may also have important roles in waste management due to increased cost of energy and renewed interest in organic farming systems. Chitosan is a polymer found in certain fungi and in the exoskeleton of arthropods such as shrimp and crab shell waste. For instance, it was demonstrated that naturally-occurring flocculants like chitosan can be as effective as synthetic polymers for separating solids and nutrients from concentrated dairy manure effluents (Garcia et al. 2009). The author used various rates of chitosan to flocculate mixtures of dairy manure and the lagoon supernatant used to flush free stall alleys. The flocculated manure was dewatered using 1-mm and 0.25-mm screens. The results showed that separation by screening only (1-mm screen) was not effective (average efficiencies were 60% for total suspended solids (TSS), 22% for total Kjeldahl nitrogen (TKN), and 25% for total phosphorus (TP)), as compared to the mixture of chitosan before screening, which significantly enhanced efficiency of separation (97% for TSS, 79% for TKN, and 58% for TP).

Use of Polyacrylamide

Organic polymers such as polyacrylamide are mostly used to increase separation of suspended solids and carbon compounds from liquid swine and dairy manure. Polyacrylamides are characterized as high molecular weight, long-chained, water-soluble organic polymers. The long polymer molecules affect the stability of suspended, charged particles by binding to them and building bridges between several suspended particles. Polyacrylamides have mostly been used to increase the performance of several mechanical and physical manure separators including incline screens, rotary screens, screw presses, filter presses, rotary presses, and dissolved air flotation devices (Vanotti et al. 2020). The maximum rate of metal coagulants (aluminum sulfate and ferric chloride) is 200–4000 mg/L, and it is comparatively higher than the maximum rate of application for organic polymers in swine manure (150 mg/L) and dairy manure (300 mg/L) (Vanotti et al. 2020).

21.3.2 Technologies to Reduce Greenhouse Gas Emissions

Greenhouse gases are referred to as gases in the atmosphere that absorb and emit heat (infrared radiation). As the sun's energy (i.e., solar radiation) travels to earth, some of it is reflected at both the earth's surface and atmosphere, while most is absorbed by the earth's surface, thus warming it. The warmed earth's surface then emits infrared radiation back into the atmosphere. Some of the infrared radiation escapes back to space, but the greenhouse gases, in the atmosphere, absorb some and re-emit it in all directions, which warms the earth's surface and the lower atmosphere (Harrison and Ndegwa 2020). The common GHG in the earth's atmosphere are CO_2, CH_4, N_2O, hydrofluorocarbons (HFCs), water vapor (H_2O), and ozone (O_3) (Harrison and Ndegwa 2020). The amount of heat trapped in the earth's surface depends on the concentrations of GHG in the atmosphere and recent increases in the global temperature has been associated with an increase in the release of these gases into the atmosphere. Particularly, agriculture contributes approximately 9% of GHG emissions, and this is majorly from livestock, soils, and rice production (USEPA 2017). Whether or not the soil acts as a

net source of CO_2 or a net sink for CO_2, can be influenced depending on soil management. When the level of soil organic matter is increased (process known as carbon sequestration), CO_2 can be decreased while increasing the soil carbon sink (Harrison and Ndegwa 2020). Soil organic matter levels can be increased by producing healthier crops and decrease soil tillage operations. It has been shown that healthy crops not only increase yield but they also decrease GHGs by trapping more carbon in their roots, some of which is converted to more stable soil organic matter. Reducing soil tillage operations increases soil organic matter levels by decreasing the amount of organic matter that is oxidized and released to the atmosphere as CO_2 (GM 2022).

The two major potential GHGs from dairy and swine facilities are CH_4 and N_2O. These two GHGs (CH_4 and N_2O) are extremely potent GHGs with global warming potentials of 25 and 298 times that of CO_2, respectively (Montes et al. 2013). The process of managing dairy and swine manures largely dictates the amount of CH_4 and N_2O emissions; hence, their respective contributions to GHG in the atmosphere. Nitrous oxide can be produced enterically in minute quantities; however, most N_2O is emitted from excreted manure. The manure or slurry accumulated in lagoons and retention ponds are often anaerobic and serve as the main source of N_2O produced from feedlots and dairies. Different methods of manure treatments and storage determines the amount of these GHG produced. The management of manure account for about 15% of the total GHG emissions from the agricultural sector in the United States (Harrison and Ndegwa 2020). The main methods for controlling GHG emissions from livestock operations are: (i) controlling decomposition of manure to reduce emissions of N_2O and CH_4; (ii) capturing CH_4 from manure decomposition and using it as renewable energy; (iii) nutritional changes that reduce GHG (e.g., increase forage quality, reduce age to harvest forage, use high edible oils and high energy grains, and rotational grazing); (iv) improve livestock fertility and survival rate; and (v) genetic selection for feed efficient and/or longer lived animals. The major impacts of anaerobic digestion in GHG emissions mitigations are from: (i) replaced fossil fuel consumption, and (ii) reduced emissions due to reduced fertilizer use and production (Kaparaju and Rintala 2011). Therefore, the technologies that maximize these processes, will ultimately lead to reductions in GHG emissions from livestock operations.

21.3.2.1 Composting

Composting manure is a process by which animal feces, urine, and bedding are stacked, turned, and managed in a way that enhances manure decomposition. The finished product has a soil-like texture and odor, and may be applied on crop land or as a pasture nutrient source. Composting is highly beneficial including destruction of harmful pathogens and weed seeds, and decrease in overall volume and odor emitted. The heat generated by composting manure can kill human and animal pathogens that are present in raw manure. This can help limit the risk of infection for animals and farmers that come in close contact with the manure; and also for members of the society that might encounter manure runoff that has escaped into a waterway or food source (Modderman 2020). Furthermore, composted manure has a less-offensive odor than raw manure. This makes composted manure more desirable to farmers with neighbors that might dislike the smell of raw manure. Composted manure helps prevent direct and indirect environmental nutrient pollution. The direct prevention of environmental pollution involves increasing the stability of nitrogen in the manure, thus reducing nitrogen emission to the environment (Eghball 2000). Indirectly, composted manure decreases the likelihood of pollution as a result of over-application on crop or pasture land. Manure can be over-applied to land when the actual nutrient content of the manure varies, and therefore, unknown; and raw manure has a high intensity of inherent differences both spatially and over time. However, composted manure's nutrients are more uniform and stable than raw manure (Lory 2008). Thus, the farmer is more informed on the actual nutrients being applied when using composted manure than raw manure, which leads to more-accurate calculations and rates of application;

resulting in decreased risk of over-application of manure (Rynk 1992).

There are biological, organic, and inorganic additives that alter the state of compost and aid in fast decomposition of manure, as well as increase the overall quality of the finished product. When compost is amended with these additives, components such as temperature, moisture content, pH, and nutrient availability may be altered. Inorganic additives are typically mineral and include chemicals, lime, clay, and industrial waste. Often, compost is amended with an industrial by-product, making it easily accessible and at low cost. Organic additives are mostly plant materials including residual straw from crops, grass clippings, bark, cornstalks, and biochar . These organic additives contain their own nutrients, so when using them, adequate care must be taken to prevent unbalancing of the overall calcium to nitrogen ratio of a compost pile (Doublet et al. 2011). At the same time, organic additives can be used to rectify an unbalanced C to N ratio. For instance, when the calcium/nitrogen of a manure pile is too low, carbon sources, such as straw or wood chips, can be added to the pile. On the other hand, if the calcium to calcium ratio is too high, nitrogen sources, such as grass clippings or hay, can be added (Rynk 1992). Biological additives are microorganisms that are added to a compost pile. These are usually commercial products that are marketed for aiding decomposition or removal of odor and gases. Using microbiological additives comes with lots of uncertainty since private companies are not obliged to disclose the active ingredients, and most of the times they describe their product with vague terms such as "over 60 strains of active bacteria" (Wakase et al. 2008). However, DNA assays have shown that most of the biological additives contain some bacterial genera like *Alcaligenes*, *Bacillus*, *Clostridium*, *Enterococcus*, and *Lactobacillus* (Sasaki et al. 2006).

21.3.2.2 Biochar and Biogas Production

This involves the thermochemical processing of animal manure (poultry litter, cattle manure, swine manure), and sewage sludge for the production of bioenergy and biochar. Animal manure consisting of high organic carbon and mineral nutrients is an available feedstock for bioenergy and biochar. Pyrolysis, gasification, hydrothermal liquefaction, and combustion are the thermochemical techniques used for converting animal manure into valuable bioenergy and biochar products (Guo et al. 2020). Dry manure solids range in energy density from 13 to 19 MJ/kg and can be combusted directly as an alternative to firewood. The major products produced from pyrolysis of manure are biochar and bio-oil; products from gasification are syngas and biochar; and products from hydrothermal liquefaction are biocrude oil and hydrochar. Biochar and hydrochar derived from manure carry significant nitrogen, phosphorus, and potassium nutrients, and both are promising soil amendments. Bio-oil, biocrude oil, and syngas derived from manure contain lots of impurities and this may pose challenges for subsequent upgrading processes (Guo et al. 2020). Thermochemical processing of manure may cause 100% of feed nitrogen loss, which is the main concern for such treatment. Pyrolysis at the temperature range from 400 to 450 °C is recommended for use in producing quality biochar from manure. Presently, thermochemical conversion of animal manure to bioenergy and biochar is technically feasible, but this process needs to be enhanced in order to be economically viable (Guo et al. 2020).

21.3.2.3 Mitigation of Odor and Gas Emissions

During the process of composting animal manure, unpleasant odors may be generated, which might not be palatable for neighbors. Ammonia and sulfur-containing compounds are the primary sources of foul odor in composting, and there are additives to mitigate these odors. Biochar added to compost can decrease ammonia emission and odor in manure containing high amount of nitrogen, such as poultry litter (Steiner et al. 2010). Organic additives that elevate aeration will catalyze microbial activity, thereby increasing ammonia loss and odor. It was found that biochar might potentially enhance ammonia production and odor because of increased microbial activity

(Waqas et al. 2018). Similarly, Jiang and colleagues (Jiang et al. 2015) demonstrated the same effect with cornstalk. Addition of inorganic additives to compost may produce better results since they typically are not bulking agents. For example, adding zeolite to compost has been shown to decrease both ammonia and sulfurous odors, with the concentration of added zeolite being directly proportional to the decrease in odor (Lefcourt and Meisinger 2001). Addition of sodium nitrate and sodium nitrite reduced sulfurous odors in swine manure composting significantly by lowering emissions of dimethyl sulfide and dimethyl disulfide (Zang et al. 2017). Furthermore, addition of magnesium hydroxide and phosphoric acid, along with other magnesium and phosphate salts to compost manure, have also been shown to reduce loss of ammonia and odor (Zhang et al. 2017).

21.3.2.4 Pelletizing Manure

Pelletization or granulation of manure provides a greater opportunity to fight against challenges faced in both on- and off-farm manure utilization by creating a product that is easier to handle, transport and apply to land or soil. Pelletizing animal manure removes its moisture, decreases its weight, volume, and odor, thereby creating a product that is more preferable than raw manure because of its reduced cost of storage, easy transportation, handling, and application. Blair et al. (Blair et al. 2014) compared the effects of pelletized poultry litter with inorganic Osmocote fertilizer on the availability of phosphorus nutrient and activities of enzyme over a period of growing season and reported that at high soil phosphorus conditions, pelletized poultry litter had higher activity of alkaline phosphatase and released more phosphate than the inorganic Osmocote fertilizer. Application of pelletized poultry compost causes greater availability of liable phosphorus in soil than the unpelletized form based on a 56-days lab incubation study (Takahashi et al. 2016). Poultry litter is the most common animal manure to be pelletized; however, cattle, swine, and horse manure have also been pelletized with the addition of bulking agents or other supplements.

21.3.2.5 Technologies to Recover Phosphorus

Use of Iron and Aluminum Phosphates

Metal salt is the main chemical used to precipitate phosphorus so as to remove phosphorus from municipal wastewater. The process has been confirmed for the removal of phosphorus from manure making use of different doses of metal salts. Other chemicals that have been considered for treating manure are aluminum sulfate or alum (Al_2SO_4), $AlCl_3$, $Fe_2(SO_4)_3$, and $FeCl_3$, which can be used singly or in combination with polymers; and can be applied both in wet and dry manure systems. The most common types of chemicals used in recovering phosphorus are alum due to its lower cost, and $FeCl_3$ because it is effective over a wide range of pH (4.0-12) (Chastain 2013). These two metal salts (alum and ferric chloride) can reduce phosphorus solubility but also destabilize colloidal particles through coagulation chemical process. Different methods can be used to apply these metal salts to precipitate phosphate from manure; these include injection, mixing, and separation by sedimentation (Vanotti et al. 2020).

Use of Calcium Phosphates

Lime is used to significantly remove carbon and ammonium interferences before precipitating phosphate as calcium phosphate. This results in distinct chemical equilibrium between phosphorus and calcium ions (Vanotti et al. 2020). The presence of bicarbonate in wastewater interferes with the production of high-grade phosphates. In wastewater containing high NH_4^+ concentration, huge amounts of hydrated lime are needed to increase the pH to required values because the NH_4^+ reaction could potentially neutralize the hydroxyl ions (Vanotti et al. 2020).

Other Phosphorus Recovery Methods

Other methods used to remove the inhibitory effect of inorganic carbon and to increase the dissolution of P conditions include: (i) chemical acidification, which is the process of adding mineral or organic acids to acidify the manure before

the P precipitation step with lime; (ii) biological acidification, which involves precipitating the P immediately after the acidification phase of anaerobic digestion during a multiphase anaerobic process of manure digestion (Barack 2013); (iii) physical acidification, which entails the addition of P precipitating compounds (calcium or magnesium) to the wastewater after the carbonate alkalinity and ammonia have been significantly decreased using gas-permeable membranes (Vanotti et al. 2018). It was reported that, when magnesium is added to wastewater after the removal of alkalinity and ammonia, the phosphates generated are very high grade (46% P_2O_5, >98% available), which is similar to the composition of the biomineral newberyite ($MgHPO_{4.3}H_2O$) found in guano deposits (Vanotti et al. 2017).

21.3.2.6 Technologies to Recover Nitrogen

Use of Air Scrubbers in Barns

One of the methods for decreasing or limiting NH_3 emissions from livestock production is the use of chemical and/or biological air scrubbers and biofilters, in which exhausted air from the animal houses is allowed to pass through a wet packed bed so that NH_3 and other water-soluble components can be removed (Van der Heyden et al. 2015). In a chemical air scrubber, an acid, e.g., sulfuric acid is added to the washing water to maintain pH < 4, shifting the equilibrium NH_3/NH_4^+ toward NH_4^+ as the dissolved NH_3 is captured by the acid, thus forming an ammonium salt (Vanotti et al. 2020). The suitability of acid salts, such as aluminum sulfate (alum), sodium bisulfate, potassium bisulfate, $FeCl_3$, and ferric sulfate have been confirmed, as well as strong acids (hydrochloric, phosphoric, and sulfuric) for capturing NH_3 (Moore Jr et al. 2018). In a biological air scrubber, NH_3 captured in the washing water is oxidized by bacteria using nitrification process according to nitratation by ammonium oxidizing bacteria and nitratation by nitrite oxidizing bacteria. In a biotrickling filter, these bacteria are immobilized in a biofilm on the packing material, while in a bioscrubber, bacteria are contained in a separated bioreactor where nitrification is performed. In the case of biofilters, they contain a humid filter bed of organic material, but not completely wet to support bacterial growth. Full-scale spray scrubbers have been produced for the recovery of ammonia at poultry facilities having a removal efficiency of 71–81% (Hadlocon et al. 2015), and also for deep-pit swine finishing facilities with ammonia removal efficiency of 88% (Hadlocon et al. 2014). It was found that ammonia removal efficiencies ranged from 91% to 99% when acid scrubbers were used, and from 35% to >90% when biotrickling biofilters were used (Melse and Ogink 2005).

Ammonia stripping by air or steam is a method that can efficiently recover ammonia from liquid manure. Ammonia striping by air or steam are similar gas-liquid mass transfer processes. Steam stripping is mostly a distillation process that uses higher temperatures than air stripping (Vanotti et al. 2020). The air stripping process involves the transfer of ammonia from the waste steam into the air, then absorbed from the air into a strong acid solution producing an ammonium salt. Nitrogen in liquid manure is mostly present as ammonium ions (NH_4^+) and aqueous ammonia (NH_3), which are highly volatile. The equilibrium between both forms of N strongly depends on pH and temperature. Ammonium ions are more dominant when pH is less than 7, regardless of temperature; while NH_3 increases as the pH increases, thus shifting the equilibrium. Similarly, the concentration of NH_4^+ reduces when the temperature increases, thereby favoring the production of NH_3. Therefore, high pH and temperature will favor the process of ammonia stripping. The quantity of NH_3 that can be gotten from liquid manure, or absorbed in the acidic solution depends on two equilibria: NH_3 gas/liquid equilibrium and NH_3 dissociation equilibrium in the liquid (Vanotti et al. 2020). It is stipulated that the efficiency of air stripping majorly depends on the following: pH, temperature, ratio of air to liquid volume, and characteristics of liquid. This process has been produced at industrial scale, involving the utilization of stripping towers, compressors, or pumps that are used to introduce air or steam into the liquid phase. Condensation or adsorption equipment are needed to recover

NH_3 from the gas phase when air stripping is used. For steam stripping, condensation or absorption equipment is used to recover NH_3, without requiring any further post-treatment of exhaust gases (Zeng et al. 2006).

Use of Gas-Permeable Membranes

The gas-permeable membrane process involves the transportation of gaseous NH_3 via a microporous hydrophobic membrane followed by NH_3 capture and concentration in an acidic stripping solution located on the other side of the membrane. The process can be used for the removal and recovery of nitrogen from liquid manures in storage tanks (Karunanithi et al. 2015), and from the air emitted from poultry and animal barns (Szögi et al. 2014).

Use of Ion Exchange–Zeolites

Zeolites are crystalline, hydrated aluminosilicates of alkali and alkaline earth cations, with infinite, 3D structures. They consist of varied properties, such as adsorption, cation exchange, dehydration–rehydration, and catalysis properties, contributing to a high variety of applications (Vanotti et al. 2020). For example, zeolite has been used in water and wastewater treatment, and also in animal waste treatment because of its high interest and selectivity for NH_4^+ ions. Addition of 6.25% zeolite to dairy slurry led to a 50% decrease in NH_4^+ volatility (Lefcourt and Meisinger 2001). Likewise, the addition of zeolite to swine manure before applying it to soil decreased NH_4^+ volatility between 65% and 71% (Portejoie et al. 2003). Similarly, when a layer of zeolite was added to the surface of composting poultry litter, NH_4^+ emissions was reduced by 44% (Kithome et al. 1999), and in a laboratory experiment, it was reported that application of a 5% (w/w) rate of zeolite to stored poultry manure caused 81% decrease in NH_4^+ emission (Li et al. 2006). Other authors have also confirmed that the addition of zeolite to cattle manure (2% rates) was able to counteract the inhibitory effect of NH_3 during anaerobic digestion (Borja et al. 1996), and when zeolite was used as air scrubber packing material and as a filtration agent in deep-bedded cattle housing (Milán et al. 1999).

Manure Pathogens Treatment

Indigenous microorganisms (a group of innate microbial consortium that live in the soil and the surfaces of all living things, having the capacity to biodegrade, bioleach, biocompost, fix nitrogen, improve soil fertility and produce hormones for plant growth) can prevent the survival of manure-borne pathogens because of predation, substrate competition, and antagonism (Chen et al. 2020). Therefore, enforcing a waiting period for raw manure application before harvesting crops (90 and 120 days for crops not in contact or in contact with soils, respectively) may be helpful in reducing the risk of exposure to manure-borne pathogens. Manure-borne pathogens survival in soils can last for few days to several months, indicating that a waiting period of 120 days may not be long enough to completely eliminate manure pathogens contamination in fresh produce. Thus, to further reduce the levels of pathogens in manure, pre-treatment of raw animal manure is required before manure is land-applied (Chen et al. 2020). The US Food and Drug Administration states that management of manure is acceptable before manure is land-applied if the amount of indicator pathogens in manure are decreased below the recommended levels (Chen et al. 2020). The threshold levels of manure-borne pathogens differ in many countries. For example, in France and the United Kingdom, the threshold level of *Salmonella* in manure is absence (not present) per 25 g fresh mass (wet weight basis) (Manyi-Loh et al. 2016). Whereas the threshold level for *Escherichia coli* is 100 and <1000 per g fresh mass (wet weight basis) in France and United Kingdom, respectively. Common methods for pre-treatment of animal manure include chemical, physical, and biological methods or the combination of any of the methods, which have all been found to be effective for reducing the levels of pathogens (Chen et al. 2020).

Exposure of Manure to Ultraviolet Irradiation

The sun is the main source of ultraviolet radiation. Ultraviolet radiation is a promising technology involved in the disinfection of cattle manure

for the control of pathogens. Ultraviolet radiation could be characterized into UV C, UV B, and UV A depending on the wavelengths and energy intensity. However, because of the high energy level of UV C, it is absorbed by the earth stratosphere ozone layer (Manyi-Loh et al. 2016). UV A and UV B (280–315 nm) radiations are used in the process of disinfection, but Willey and colleagues (2011) observed that UV radiation around 265 nm is somewhat lethal. Oni and colleagues (2013) reported that a 5 log decrease in *Salmonella* cells was noted when exposed to UV A (365 nm) in a control medium compared to a 1.5 log reduction in a manure dust matrix. The main significance of UV irradiation is that it is capable of disinfecting the manure without using any chemicals, consequently, no disinfection by-products are produced which could alter the physicochemical and nutritional properties of the manure after treatment (Spiehs and Goyal 2007). Interestingly, only the microbial cell that has absorbed the energy at the set wavelength is destroyed .

21.4 Growth-Enhancing Technologies in Meat Production, Processing, and Preservation

One of the major products of any livestock system is meat, which comes from an increase in size or multiplication of muscle fibers. Farm animal production has long had the objective of producing high-quality animal protein for human consumption and raw materials for the food industry, providing employment for millions on the meat supply value chain and sustaining livelihoods. In general, meat production in Africa has largely relied on extensive, subsistent, and unconventional traditional systems or tools using handed-down practices with little or no incorporation of state-of-the-art technologies. Current realities in terms of increasing human population, average per capita income, and urbanization changes have led to projected increased demand for livestock and livestock products, including meat, warranting the use of modern technologies to increase productivity. In this section, we review some of the technological innovations that can be targeted to achieve increased meat production in Africa.

Stakeholders led by national governments and non-governmental organizations have collaborated to find alternative means of increasing the growth performance of farmed animals. In the process, appropriate and relevant technologies have been encouraged worldwide, including crossbreeding, improved production systems and management practices, inclusion of approved growth promoters (probiotics and prebiotics), housing and keeping of improved breeds (disease resistant breeds), among others to increase growth rates and improve overall efficiency and product quality. The most extensively utilized growth promoters are feed additives, anabolic implants (both estrogenic and androgenic), bovine somatotropin, repartitioning agents (beta-agonists), and probiotics. The use of non-nutrient feed additives such as antibiotics and exogenous enzymes that improve animal growth (growth promoters) is fast gaining ground in Africa.

21.4.1 Use of Feed Additives: Probiotics and Prebiotics

According to the World Gastroenterology Organization Global Guidelines on Probiotics and Prebiotics of February 2017 (https://www.worldgastroenterology.org/guidelines/probiotics-and-prebiotics), probiotics are live microorganisms that confer health benefits on the host when administered adequately. Probiotics consist of various types of microorganisms that improve gut microflora and affect both the local and systemic immune systems by secreting beneficial enzymes, organic acids, vitamins, and nontoxic antibacterial substances upon ingestion (Popova 2017). Probiotics affect the host upon ingestion positively by improving the balance of the intestinal microflora. Not only that, probiotics stabilize rumen pH, reduce gastrointestinal tract-invading pathogens, increase volatile fatty acids production, and stimulate lactic acid utilizing protozoa, resulting in a highly efficient rumen

function. Probiotics release anti-inflammatory factors, downregulating pro-inflammatory cytokines and thwarting intestinal inflammation (Alfonsetti et al. 2022). Particularly, probiotics can improve phagocytosis and enhance the secretion of antibodies, generating increased immunological defenses against pathogens (Maldonado Galdeano et al. 2019). Probiotics interact with bile acids in the gut lumen, modifying bile acid metabolism and inducing cholesterol absorption (Plaza-Diaz et al. 2019). Probiotics positively affect digestive processes such as cellulolysis and the synthesis of microbial proteins (Uyeno et al. 2015). It serves as prophylaxes and therapeutic purposes in clinical and veterinary practices (Srinivas et al. 2017). They have shown the ability to secrete hydrolytic enzymes against bacterial toxins to inactivate toxin receptors that can cause toxin-mediated infections in livestock animals (Hossain et al. 2017).

Probiotics are widely used in animals to improve growth rate, increase milk yield, meat, and egg production. Yeast culture supplements, containing *Saccharomyces cerevisiae*, are known to be a rich source of enzymes, vitamins, other nutrients, and important co-factors, and have been reported to produce a variety of beneficial production responses (Markowiak and Śliżewska 2018). Beneficial responses include growth rate, feed intake, feed efficiency, milk composition, egg production, and reproduction in ruminants, poultry, pigs, and horses. The most commonly used probiotics are *Lactobacillus acidophilus, Lactobacillus lactis, Lactobacillus plantarum, Lactobacillus bulgaricus, Lactobacillus casei, Lactobacillus helveticus, Lactobacillus salivarius, Bifido bacterium* spp., *Bacillus* spp., *Enterococcus faecium, Enterococcus faecalis, Streptococcus thermophilus, Escherichia coli* bacteria, and other probiotic fungi such as *Saccharomyces cerevisiae* and *Saccharomyces boulardii* (Al-Shawi et al. 2020).

Non-digestible but fermentable food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon are known as prebiotics (Davani-Davari et al. 2019). Prebiotics are dietary substances consisting mostly of non-starch polysaccharides and oligosaccharides. Commonly used prebiotics are oligosaccharides, i.e., Mannan-oligosaccharides, fruto-oligosaccharides, galacto-oligosaccharides, chito-oligosaccharide, isomalto-oligosaccharides, pectic-oligosaccharides, xylo-oligosaccharides, lactulose, inulin, and breast milk oligosaccharides. Probiotics and prebiotics both act by modulating the balance of microbiota within the gastrointestinal tract (GIT). While probiotics add beneficial gut bacteria, prebiotics enable existing microbes to multiply. Butyric acid stimulates the proliferation and differentiation of epithelial cells in the GIT to increase surface area for nutrient absorption (Pierce et al. 2018). Probiotics are live microorganisms that can replace antibiotics in animal husbandry as a safe and viable alternative to antibiotics, which can confer health benefits on the host when administered in adequate dosage (Alayande et al. 2020).

Probiotics stabilize rumen pH, reduce gastrointestinal tract-invading pathogens, increase volatile fatty acids production, and stimulate lactic acid utilizing protozoa, resulting in a highly efficient rumen function. Probiotics release anti-inflammatory factors, downregulating pro-inflammatory cytokines and thwarting intestinal inflammation (Alfonsetti et al. 2022). Particularly, probiotics can improve phagocytosis and enhance the secretion of antibodies, generating increased immunological defenses against pathogens (Maldonado Galdeano et al. 2019). Probiotics interact with bile acids in the gut lumen, modifying bile acid metabolism and inducing cholesterol absorption (Plaza-Diaz et al. 2019). Probiotics positively affect digestive processes such as cellulolysis and the synthesis of microbial proteins (Uyeno et al. 2015). It serves as prophylaxes and therapeutic purposes in clinical and veterinary practices (Srinivas et al. 2017). They have shown the ability to secrete hydrolytic enzymes against bacterial toxins to inactivate toxin receptors that can cause toxin-mediated infections in livestock animals (Hossain et al. 2017).

The inclusion of probiotics and prebiotics has played a pivotal role in animal health thereby

contributing tremendously to the meat industry. Directly or indirectly, this technology has had some positive impacts on some key production elements such as growth performance and feed efficiency in farmed animals. Furthermore, the increase in meat demand has resulted in increased use of antibiotics as growth promoters and as prophylaxis and metaphylaxis in food animals, a situation worsened by inadequate biosecurity and good animal husbandry practices (Abdalla et al. 2021). Over the years, concerns have been raised on the risk of developing cross-resistance and multiple antibiotic resistance in pathogenic bacteria in both human and livestock, increase in foodborne allergies, negative impacts on the environment and their potential effects on human health owing to persistent use of antibiotics and chemotherapeutics in prophylactic doses used in animals (Popova 2017; Al-Shawi et al. 2020; Rai et al. 2013). An alternative to these problems is the use of growth promoters like probiotics and prebiotics which have positive effects on animal health and growth performance.

21.4.2 Impact of Growth Promoting Technologies on Meat Production

Growth performance is a combined result of several factors including but not limited to the genetic potential for growth, optimal environmental conditions, nutritionally complete feeds and good farm management practices. There have been several reports on improved growth performance, carcass yield, and meat quality owing to the use and application of growth promoting technologies in meat production, particularly with the use of probiotics and prebiotics (Valenzuela-Grijalva et al. 2017). Over the years, the effects of dietary supplementation of probiotics on growth performance of poultry have been extensively investigated. Most of the studies found that probiotics displayed great efficacy in promoting animal growth. For instance, Jin and colleagues (Jin et al. 1998) reported that dietary inclusion of probiotics *Lactobacillus* increased body weights and feed to gain ratio when compared to control broilers. In addition, intestinal immunity was increased in chickens fed with diets supplemented with yeast product and *Lactobacillus*-based probiotic culture (Gao et al. 2008; Higgins et al. 2008). Another study found that *Lactobacillus* inclusion in broiler nutrition resulted in higher broiler productivity index which was measured based on daily weight gain, feed efficiency, and mortality (Timmerman et al. 2006). Again, probiotics supplementation improved feed intake, feed efficiency, and carcass yield of broilers (Denli et al. 2003). Therefore, feed additive technology, in particular, the use of probiotics in animal feed should be encouraged by national governments and other key stakeholders to boost meat production in Africa.

Meat quality comprises of several factors including pH, tenderness, odor, tastes, flavor, characteristics, and intramuscular lipid content. The use of probiotic (*Lactobacillus fermentum*) in the water of broilers significantly increased the redness in breast, while there was no effect on the yellowness and lightness in breast and thighs (Popova 2017). Also, *Bacillus licheniformis* treatment increased significantly the protein content and respective contents of essential and flavor amino acids, while on the other hand, the fat content was decreased (Popova 2017). The use of probiotics in fresh and fermented meat products has been shown to reduce pathogenic and spoilage microorganisms and improve sensory characteristics (Al-Shawi et al. 2020). Additionally, probiotics improves feed efficiency, weight gain, and immune response with its overall effectiveness dictated by factors such as optimal selection of microbial strains, the use of a suitable dose, and the species and age of the host. Use of probiotics has led to improvement in product quality and safety, extending shelf-life, imparting unique sensory qualities, and providing health benefits. The use of probiotics has been shown to improve water holding capacity and tenderness in meat. Furthermore, the application of probiotics in animal nutrition aims to promote production performance and prevent diseases via the maintenance of a healthy gastrointestinal environment and improvement of intestinal function. The

mechanism of probiotic effect on animal health is primarily based on the competition between beneficial bacteria and pathogens, and the replacement of pathogens by probiotic bacteria.

Prebiotics have been shown to prevent the colonization of the digestive system with pathogens by creating unfavorable condition like altering the pH of intestinal content. Likewise, *Bifidobacterium* and *Lactobacillus* found in the digestive system has Manase enzyme used in breaking down polysaccharides. Plant extracts also known as phytobiotics are another potential alternatives for antibiotics because of their antimicrobial, anti-inflammatory, antioxidant, and antiparasitic activities, and they have been used successfully in poultry production for many years (Andrew Selaledi et al. 2020). In African countries, plant extracts from aromatic spices (cinnamon, clove, etc.), pungent spices (pepper, garlic, and ginger), and herb spices (rosemary, thyme, mint, etc.) have received increased attention over antibiotics because they are cheaper and naturally available, and they have been shown to improve poultry production and health status. Current research on alternatives to antibiotic use in food animals is slow, especially in the African continent. The available alternatives to antibiotics have a potential role in lowering dependency on antimicrobial substances. Failure to implement the WHO antimicrobial usage recommendations could deteriorate the situation and intensify the burden of diseases or increase the mortality rate in Africa and other continents (Andrew Selaledi et al. 2020).

Antibiotics function by eliminating all bacteria and depending on the spectrum of its activity, both beneficial and pathogenic microorganisms, and may lead to bacterial resistance (Michalak et al. 2021). Over the years the growth and health of food-producing animals have been enhanced by the use of antibiotics. These have helped reduce on-farm mortalities, lower incidences of diseases and more importantly improve productivity. Generally, the utilization of antibiotics in feed has been re-evaluated since bacterial pathogens have established and shared a variety of antibiotic resistance mechanisms that can easily be spread within microbial communities. Apart from developing antibiotic resistance, people can also develop allergic reaction or liver damage on consuming antibiotic residues in animal products (Andrew Selaledi et al. 2020). Therefore, antibiotics that are important for treating humans must be prohibited from being used in the feed as growth-promotants. Africa produces fewer antibiotics as compared to other continents. Nonetheless, many antibiotics can be bought over the counter in many African countries and this practice could play a key role in worsening antibiotic resistance. Most farmers in Africa purchase antimicrobial agents without consulting animal health professionals because they are not accessible/available, or farmers do not have the means to reach them. Antimicrobial resistance is prevalent in Africa and pose a threat to food safety and security. The one health approach concept simply emphasizes that the health of the environment, animals and people are connected and could be used to manage antimicrobial-resistant and food safety concerns (Andrew Selaledi et al. 2020). Alternatives to antibiotics which include probiotics, prebiotics, enzymes, and organic acids, among others are found to have the ability to replace antibiotics (Andrew Selaledi et al. 2020; Alayande et al. 2020).

21.4.3 Meat Processing and Preservation Technologies

The purpose of meat processing and preservation is to increase meat shelf life, ensure that the nutrient in meat is preserved and readily available for human consumption (Heinz and Hautzinger 2007). Meat processing involves a broad range of methods, including chemical and physical treatment. Thus, meat processing technologies include technical processes like cutting, chopping, or comminuting (i.e., reduction in size), mixing or tumbling, stuffing or filling of semi-fabricated mixtures of meat into cans, synthetic films, casings etc., and treatment with heat. Meat processing also includes biochemical or chemical processes, which are mostly used in conjunction with technical processes, such as salting, curing,

the addition of spices and additives, fermentation, drying, and smoking (Heinz and Hautzinger 2007; Balny 2002).

21.4.3.1 Technical Processes Involved in Meat Processing

In meat processing, especially red meat, most of the steps involved can be mechanized. Different methods of meat processing with various equipment are summarized below. Recently, a robotic workbench for poultry meat processing was described (Ahlin 2022). This system can accomplish disparate tasks at multiple stages of meat processing. Importantly, it allows the integration of flexible manufacturing into assembly line procedure, thereby promoting greater agility, scalable manufacturing, and hazard mitigation (Ahlin 2022).

Meat cutting/chopping/comminuting (reduction in size) are achieved by different methods: (1) mincing or grinding of lean and fatty meat, (2) chopping of meat in bowl cutter, (3) use of emulsifying machines for chopping meat, and (4) cutting of frozen meat and fatty tissues. Meat grinders are used for reducing meat sizes and interestingly, some meat grinders are also specially designed for cutting frozen meat while some grinding machines can automatically separate bones and tendons from soft tissues. Meat grinders are either manually or automatically operated and they work to forcefully push meat or meat trimmings through a barrel that is mounted horizontally (Sastry 2008).

Bowl cutters are the most commonly used equipment for chopping lean meat and fat tissues into small sizes (Zheng and Sun 2006). They are also used for mixing fresh or frozen lean meat and fatty meat with water (ice water), extenders, and functional ingredients (additives, curing agents, and salt) (Rivas-Cañedo et al. 2009). Chopping of meat by emulsifying machines is done by first premixing meat with functional ingredients, seasoning, and other raw materials and second, the premixed meat are pre-cut using grinders or bowl cutter. Afterward, the pre-cut meat are passed through emulsifiers, which is also known as colloid mills so as to attain the finely chopped or emulsified meat mix (Gola et al. 2000). Frozen meat tissues can be cut into slices, cubes, or flakes by frozen meat cutters. The frozen meat can be chopped directly in bowl cutters without thawing to prevent drip loss, meat discoloration, and bacteria growth (Gentry and Roberts 2005). Meanwhile, meat mixing involves the blending of coarse and finely chopped meat and spices together to achieve a desired meat texture and color. Another process involves stuffing or filling of meat into containers or casings followed by chopping to achieve finely comminuted fat or lean meat pieces (Knorr et al. 2004).

21.4.3.2 Chemical or Biochemical Processes Involved in Meat Processing

These involve the use of functional ingredients, smoking, fermentation, and drying (Heinz and Hautzinger 2007).

Salt is a very important ingredient in meat preservation. For example, salt (1.5–3%) is added to meat to increase the water holding capacity up to 5% (Beaufort et al. 2009). Spices used in meat preservation include pepper, paprika, nutmeg, mace, cloves, ginger, cinnamon, cardamom, chili, coriander, cumin, and pimento, which are added to meat to achieve a desired flavor. Pepper is the most used spice during processing of meat into sausage. Most spices used during meat processing are always in the ground form with particles size ranging from 0.1 to 1 mm (Diez et al. 2009). Smoking of meat using natural or liquid smoke is done to achieve meat and meat products of desired color and flavor. Smoking is a good source of antioxidant (phenols) and antimicrobial (phenols + acids) for meat (Bertrand 2005). Likewise, fermentation and drying are other non-technical methods mostly used during meat processing and for meat preservation.

21.4.3.3 Technologies for Meat Preservation

Meat preservation is another method of meat processing that is mostly used for the control or elimination of microbial agents that causes spoilage. The principles of meat preservation include (i) using aseptic techniques for the prevention or delay of microbial growth in meat, removing

microorganisms from meat, preventing microorganisms growth and activity by storing meat in the refrigerator, freezer, drying of meat, use of chemicals, storing of meat in an anaerobic condition, and killing of microorganisms by heat or irradiation (Andersen et al. 2014); (ii) destruction or inactivation of meat enzymes that cause meat decomposition using blanching methods or chemicals (e.g., antioxidant to prevent or delay oxidation) (Tassou et al. 2010); (iii) using chemicals or storing of meat in airtight containers to prevent insect or animal damage (Gupta and Gould 1997). The preservation technologies, such as freezing, heating, dehydration, chemical, cooking, fermentation, and hurdle technology of meat, are further discussed below.

Meat storage at low freezing temperatures (0 °F and below) can be used to stop or inhibit enzyme activity that causes meat deterioration or spoilage. Freezing meat also helps to inhibit the growth of microbes, yeasts, and mold that causes meat spoilage. It has been shown that freezing extends the shelf life of beef to 12 months, pork to 6 months, poultry from 3 to 6 months, and lamb from 6 to 9 months. There might be noticeable changes in red meat during freezing and these include lipid oxidation, recrystallization, meat dehydration (loss of water from meat to the environment), and enzymatic reaction (proteolytic and lipolytic enzymes) (De Mey et al. 2017).

Heat treatment is applied to kill microorganisms responsible for meat spoilage. Heat treatment methods include cooking and canning. The process of cooking uses very high temperature to heat meat and meat products in order to eradicate spoilage of microorganisms. Two main cooking methods are pasteurization and sterilization. Pasteurization involves the use of very high temperatures from 66 °C to 77 °C (150–170 °F) to kill most of the microorganisms found in meat (Sikes et al. 2010) while sterilization is the process of cooking meat under pressure to 121 °C (250 °F). In sterilization method, all the microorganisms are killed in meat and meat products, thus prolonging meat shelf life. The canning processes involves putting meat in cans or jars and heating at very high temperature to destroy all the microorganisms causing meat spoilage. The heating process ensures that air is completely removed from the container and vacuum sealed to prevent air from penetrating back into the container. This is because air is favorable for microbial growth. Two methods used for meat canning are boiling water bath method and pressure canner method. In the former, containers containing red meat are heated and totally covered with boiling water at 100 °C (212 °F) and cooked for some time while in the latter method, the containers containing meat are placed in about 2–3 inches of water in a specialized pressure cooker. The pressure cooker is then heated to a very high temperature of 116 °C (240 °F) and above (Hugas et al. 2002).

Chemical treatment is used to inhibit microbial growth, enhance meat flavor, color, and shelf-life. The chemicals used for meat treatment are salt, sodium nitrite, and sodium lactate. Salt has very good water holding capacity because it binds with water molecules, therefore acting as a dehydrating agent and at the same time preventing the growth of microbes. Meat can be dipped into water containing salt, or by hand rubbing of salt on meat or by injection into meat (Ahmed et al. 2003). Some chemical preservatives used in meat preservation are listed in Table 21.2. Microorganisms find it difficult to survive at low pH; thus, the use of acids like vinegar or citric acid helps to lower the pH of meat making it uncomfortable for microbial growth on meat.

The fermentation process uses bacteria or yeast to convert carbohydrate to organic acids in an anaerobic condition (i.e., very low or no oxygen). Fermentation inhibits the growth of bacteria in containers containing red meat. The container is void of air and or filled with nitrogen or CO_2 (Jeong et al. 2010).

Sugar is also used to preserve meat. When sugar is added to meat up to 65% and above, it can prevent the growth of microorganisms (Pawar et al. 2000).

Meat preservation by irradiation is a process of heating up meat by radiant energy. Irradiation, such as Gamma rays, electromagnetic X-rays, and ultraviolet radiations are commonly utilized in preserving food by killing microorganisms.

High-pressure processing or high hydrostatic pressure processing or ultra-high-pressure

Table 21.2 Some chemical preservatives for meat and target organisms

Chemical preservative	Target organism	Effect
Sulfites	Yeast and bacteria	Antioxidant
Propionic acid	Mold	Antimicrobial
Sorbic acid	Mold	Antimicrobial
Benzoic acid	Yeast and mold	Antimicrobial
Sodium nitrate	Bacteria	Antimicrobial

Adapted from Ahmed et al. (2003)

processing uses increased pressures of up to 600 MPa either with the use of external heat or without the use of external heat. High pressure is used purposely for inactivating microorganisms in meat and meat products (Carlez et al. 1995).

Microwave heating makes use of energy (300–300,000 MHz) that produces heat in dielectric materials, such as foods, through dipole rotation and ionic polarization. Microwave uses rapid volumetric heating which helps to decrease the amount of time needed to attain a temperature of interest, thereby decreasing the time needed for cumulative thermal treatment and at the same time preserving meat nutrients (Ramaswamy and Tang 2008).

Pulsed electric field processing is the use of a very high voltage electric field (20–70 kV/cm) for a few microseconds on meat. The processing parameters used in governing the microbial safety of the processed meat, e.g., red meat, include electric field strength, treatment temperature, flow rate or treatment time, pulse shape, pulse width, frequency, and pulse polarity (Yousef and Zhang 2006).

High power ultrasound processing or sonication is a technology used to inactivate microorganisms that promote meat spoilage. Ultrasound generates energy by sound wave if the frequency is more than 16 kHz. The wave penetrates via a medium causing compression and reduction in medium particles to create micro-bubbles. Acoustic cavitation is what ultrasound uses to exhibit their antimicrobial properties (Piyasena et al. 2003).

Hurdle technology is the process whereby known and novel techniques are combined together to improve stability of microbes, sensory quality, nutritional quality, and economic properties (Leistner 2000). Microwave and radio-frequency heating, treatment with pulse electric field, processing with high pressure, irradiation and oscillating magnetic fields, and ultrasonic applications are now mostly used to improve, replace, or use in conjunction with conventional meat processing techniques (Heinz and Hautzinger 2007; Brewer 2009).

21.4.3.4 Meat Packaging and Labeling

Packaging of meat involves the use of protective materials, such as plastic films or foils to wrap meat products. Packaging helps to conserve meat color, flavor, odor, and texture as well as prevent meat contamination with biological, chemical, or physical contaminants, maintain oxygen and water level in meat, prevent meat shrinkage, and has labels on which information like ingredients and nutrition facts are written (Day 1990).

Labeling is a way of displaying pertinent information about the meat product. The nutritional information on labels, for example, informs consumers about the nutritional contents of the meat product thereby helping them to make healthy food choices (Guthrie et al. 1995). Meat product labeling schemes are in place in most countries to help consumers make good food choices, and to prevent fake or misleading nutrition labels. Labeling encourages meat producers and processors to apply adequate principles of nutrition when formulating meat products.

21.4.3.5 Meat Preservation in Africa: Ethiopia as a Case Study

Ethiopia is the largest producer of livestock animals in Africa and the tenth largest world producer. Ethiopia has 59.5 million heads of cattle, 30.70 million heads of sheep, 30.20 million heads of goats, 56.53 million heads of poultry, and 1.21 million heads of camel (CSA 2017). Ethiopians make use of conventional methods of meat processing such as drying to make "quanta," application of salt on the meat surface, and use of honey and spices. In pastoral and nomadic systems, the main meat preservation methods are sun-drying and deep frying. Ethiopia however contributes only 0.2% of total world red meat production despite being the tenth largest world

producer of livestock (mostly sheep and goat). This is because the meat processing and preservation techniques are not optimal or do not support longer shelf life. As a result, they are ranked the 55th largest meat producing country in the world. Ethiopia like most African countries lacks novel techniques of meat processing and preservation thus reducing their capacity to meet international standards and the demand for meat and meat products (Filip 2006). However, in recent times, the Ethiopian government is using agriculture development led industrialization to improve their economic sector and the meat processing industry is growing gradually.

In conclusion, meat processing and preservation is a very vital part of meat production because it improves meat shelf life during storage, promotes meat quality, texture, flavor, and color. Therefore, it is expedient for developing countries, mostly African countries to establish proper meat processing and packaging facilities in order to achieve meat processing standard which can in turn improve public health.

21.4.4 Technology to Improve Product Shelf-Life Extension

The shelf life of the perishable animal and dairy products is limited by factors that generally bring changes in odor, flavor, color, and texture resulting in their complete unacceptability (Sridhar et al. 2021; Lee 2018). The most important factors are oxygen, light, spoilage bacteria/microorganism, enzymes, and inadequate cooling (Eie et al. 2007). Over the centuries, different processing techniques have been developed to secure a constant availability of food products through increase in shelf life. However, both intrinsic, as well as extrinsic factors influence the quality of food and thus its shelf-life (Lee 2018), which can be defined as the period a food maintains its safety and/or quality under reasonably foreseeable conditions of distribution storage and use (Singh et al. 2017). Intrinsic factors, among others, include pH, water activity, initial microbial population, redox potential value, and nutrient content. These determine the nature of the decay mechanisms of a food product.

On the other hand, extrinsic factors determine how fast decay mechanisms proceed. Typical examples include the atmosphere, climatic conditions, and illumination (Sridhar et al. 2021; Bauer et al. 2022). Packaging is the main tool that prevents product deterioration and prolongs shelf life (Bauer et al. 2022). The package protects these products against physical, chemical, and biological damage. It also acts as a physical barrier to oxygen, moisture, volatile chemical compounds, and microorganisms that are detrimental to these products. Packaging also acts as a mediator or separator between intrinsic and extrinsic systems. The traditional role of product packaging is restricted to the preservation and protection of quality from chemical, physical, and biological deterioration. According to this concept, spoilage retardation, shelf-life extension, and quality preservation of packaged food, meat, and dairy products are a priority. Choosing the right packaging material can positively affect quality maintenance and shelf-life (Eie et al. 2007).

Traditional packaging methods include air-permeable packaging (APP), vacuum packaging, and modified atmosphere packaging (MAP). These packaging technologies have been successfully devised for fresh and processed meat products. Vacuum packaging systems are primarily used for wholesale products, while APP is the most popular packaging method for retail products. MAP is also used for these purposes, though less frequently used (Sridhar et al. 2021; Lee 2018).

The packaging films used for vacuum packaging systems have low gas permeability. They are usually multi-layered, with a polyamide layer as a gas barrier and a polyethene layer as a heat sealer. Less frequently, however, polyethene terephthalate or polyvinyl chloride are used as layers of barrier, while polypropylene is used as the sealing layer. Ethylene-vinyl acetate and ionomer films are sometimes used for better seal ability. Ethylene vinyl alcohol and polyvinylidene chloride layers can also be incorporated to enhance

gas barrier properties (Sridhar et al. 2021; Bauer et al. 2022). Extraction, lamination, and/or coating are combined to create the desired properties. Recently, composite films incorporated with inorganic fillers (clay, glass flakes, and nanoparticles) are becoming popular in the market of fresh and processed meat products due to their advantages in microwave ability (Lee 2010). The advantage of applying a vacuum in fresh meat packaging is a longer shelf-life and improved tenderness. The increasing freshness of the retail market vacuum-packaged meat is due to its extended shelf-life (Sridhar et al. 2021; Lee 2018). In the air-permeable packaging system, wrapping films are typically made of plasticized polyvinyl chloride. The trays are mostly made of polystyrene paper, pulp mold, and rigid or foamed polyethene or polypropylene. These packages can also be produced from trays made up of relatively thick gauges of polypropylene and/or polyethene sheets that are hermetically sealed with a top film made of PP and high-density polyethylene. However, polyvinyl chloride films are still the most prevalent in the retail meat markets as wrapping films because of their superior mechanical properties and cheap prices compared to other alternative films (Eilert 2005).

MAP is a process where O_2 is often substituted by N_2. In MAP, CO_2 is the most important component in the gas mixture used because of its antimicrobial activity. Increased concentration of CO_2 leads to increased inhibition of bacterial growth. Three major gases are used in MAP, either individually or in combination. Carbon dioxide is used to provide an antimicrobial effect, that is, to suppress aerobic putrefactive spoilage bacteria, while N_2 act as an inert gas and is used in MAP as a filler either to substitute other gases or to prevent the package from deformation and O_2 is to convert purplish red myoglobin to bright red oxymyoglobin (Sridhar et al. 2021; Lee 2018). According to Bauer et al. (2022), argon was recently recommended for use in MAP because of its better effectiveness in retarding enzymatic activities, microbial growth, and chemical spoilage than N_2. Gas compositions used in MAP vary depending on the product species. Compared to vacuum packaging, MAP is less efficient because it needs more time to package the product and more investment in its operation. However, the application of MAP is expanding due to its value-added retail format, particularly regarding shelf-life, satisfying the requirements of both the consumer and the retailer (Sridhar et al. 2021; Lee 2018). The shelf-life of the vacuum-packaged product is preferentially influenced by factors such as storage temperature, size of meat cut, initial levels of contaminating microorganisms, and the O_2 permeability of packaging material (Koch et al. 2009). Longer shelf-life of fresh meat, processed meat, and dairy products can be achieved with a lower O_2 permeability of packaging film, storage temperature approaching a freezing point, and a lower initial bacterial load before the packaging (Lee 2018; Bauer et al. 2022).

However, these packaging technologies are continuously being developed to improve equipment, packaging material, and methodology. These packaging systems are typically characterized by the concentration and composition of gas inside the package and the packaging materials used. Recently though, various other innovative packaging methods have been introduced that utilize technologies such as barrier films, active packaging, nanotechnology, microperforated films, far-infrared radiations, and plasma treatment to extend shelf-life and preserve the quality of fresh and processed meat and dairy products (Sridhar et al. 2021; Lee 2018).

The positive effects of these various innovative packaging technologies for quality improvement and shelf-life extension have been verified (Lee 2010). The concepts of these technologies are characterized by how they regulate gas permeability or water vapor transmission rate, otherwise known as passive packaging, and how they incorporate bioactive ingredients into or onto the packaging materials, a technique known as active packaging. Some innovative approaches have also been developed by improving the control of gas permeability or water vapor transmission rate (micro-perforation of film, high gas-barrier film, nanotechnology etc.) by functional improvement in the packaging material itself (nanotechnology, plasma treatment, and

irradiation) and by the application of active packaging systems (Kanter et al. 2018). Active packaging systems can be classified in terms of the mode of application, which includes the direct incorporation of active agents into the packaging materials and the use of edible films and coatings with active agents (Lee 2018).

In milk and dairy products, it is generally accepted that riboflavin plays a major role as a photosensitizer. Riboflavin absorbs light in the UV region of the spectrum up to about 500 nm (violet and blue light). Studies have shown that the 400–500 nm region is the most harmful part of the visible spectral region regarding photo-oxidation in dairy products (Bosset et al. 1994). In addition to riboflavin, Wold et al. found that chlorophylls and porphyrins probably also act as photosensitizers in cheese (Wold et al. 2005). It was shown that the sensory-measured photo-oxidation in a cheese induced by red light did not differ significantly from that induced by blue light. Its most degraded quality was caused by violet light, while green and yellow light (500–600 nm) gave the least adverse effects. Similar results were reported for milk by Hansen, Turner and Aurand (Hansen et al. 1975). These results support the hypothesis that porphyrins and chlorophylls are active photosensitizers in cheese. Similar findings reported by Borle, Siebert and Bosset (Borle et al. 2001) indicated that green and yellow package material could protect milk products to a certain extent because none of these photosensitizers has pronounced light absorption peaks in the green and yellow part of the spectrum (520–610 nm).

Today's efforts to improve packaging performance with clear effects on raw and processed product quality are directed toward green polymers and active packaging. The performance expected from bio-plastic materials is to protect the product from the environment while maintaining its quality. It is obvious that to perform these functions. It is important to control and modify their mechanical and barrier properties, which consequently depend on the structure of the polymeric packaging material (Bauer et al. 2022). Active packaging is the most relevant innovative idea applied to consumer satisfaction recently. It has been defined as a system in which the product, the package and the environment interact in a positive way to extend the shelf life of the product or to achieve some characteristics that cannot be obtained otherwise. In many present-day active packaging technologies, the active agent is placed in the package with the food, in a small sachet, pad, or device manufactured from a permeable material, which allows the active compound to achieve its purpose but prevents direct contact with the food product, protecting it from contamination or degradation (Sridhar et al. 2021; Bauer et al. 2022).

21.5 Innovative Technologies for Livestock Nutrition and Feeding

Feed plays a vital role in various aspects of livestock production, including productivity, profitability, environmental impact, human food and nutrition security, animal welfare, and health. It constitutes a significant portion of variable costs in livestock production, up to 70% and even 90% in intensive systems (Makkar 2016). The global value of compound feed relative to total animal output averages around 30%, varying by species (FEFAC 2016). High-quality feed improves livestock productivity, leading to lower age at first calving and shorter inter-calving intervals, thus enhancing profitability. Proper feeding also boosts animal immunity, health, welfare, and reproductive performance. It contributes to environmental sustainability by converting nutrients from non-arable land and inedible by-products into nutritious food (Balehegn et al. 2020). Forage-based systems, including silvopastoral systems, can mitigate emissions from livestock, particularly CH_4 (Garg et al. 2013), which is crucial as feed production and enteric fermentation account for a significant portion of total emissions from livestock production (Garg et al. 2013; Rao et al. 2015). Despite its importance, challenges such as high feed costs, limited availability, and low adoption of feed improvement technologies persist in low and mid-income countries (LMICs) (Balehegn et al. 2020). Feed

development interventions must consider the complex socioeconomic contexts and systemic constraints faced by smallholders.

Successful feed enhancement interventions in LMICs have been achieved through technologies that align with local conditions and needs, often involving participatory approaches and collaboration between stakeholders (Balehegn et al. 2020). Commonly applied technologies include introducing improved forage varieties, enhancing the quality of crop residues and roughages, improving the production and utilization of processed concentrates and agro-industrial by-products, and involving the private sector in supplying inputs or processing, preserving, and marketing feeds (Table 21.3). The exploration and utilization of locally available, novel feed options that are economical, sustainable, and accessible are more sustainable options. These resources include agriculture remnants, invasive plant species, and food processing by-products (Table 21.4). Numerous studies have explored the utilization of unconventional feed sources in pig and poultry production (Baruah et al. 2022; Mbukwane et al. 2022) . Research has shown that incorporating ingredients such as rice bran, palm kernel meal, common vetch, duckweed, Azolla, baobab leaves and seeds, sweet potato vines, cassava leaves, marula seeds, and moringa leaves can enhance the growth and productivity of pigs and broiler chickens. Additionally, banana stems and oil palm fronds have been identified as beneficial fiber sources for both ruminants and non-ruminants (Liao et al. 2022). However, incorporating these novel feed sources requires careful consideration of factors like nutrient composition, antinutritional elements, digestibility, and palatability to optimize animal health and productivity (Chisoro et al. 2023). Also, attention must be paid to proper processing and feeding methods.

Some companies like Kenya's InsectiPro, Ecodudu, and Rwanda's Magofarm are leading the charge in using insects as alternative animal feed, converting food waste into nutritious black-fly larvae (TFF 2024). These larvae, rich in protein and nutrients like zinc, offer a sustainable and eco-friendly solution for feeding farmed fish and livestock. Although insect feed may currently be more expensive than traditional soy meal, it is considered an investment in the future of sustainable animal feed production (TFF 2024). Beyond insects, fungi-based meat alternatives are gaining traction, with Zambian research exploring the use of gourmet oyster mushrooms as a supplement for goats (TFF 2024). Additionally, synthetic biology companies are developing bacterial and fungus-derived proteins as alternatives to fishmeal, utilizing industrial waste and renewable energy sources for production (TFF 2024). Seaweed and algae are also emerging as valuable feed supplements, improving gut health in pigs and poultry while reducing CH4 emissions in cows (TFF 2024). The cultivation of seaweed and microalgae presents significant opportunities for the aquaculture sector. Further innovative solutions aimed at improving feed availability includes straw ammoniation, silage production, veld reinforcement, rehabilitation, and strategic destocking. In West African Sahel, the Common feed resources in West Africa Sahelian region are crop residues (millet, sorghum, etc.), rangeland herbaceous legumes, rangeland grasses, browse species, fodder banks, agro-industrial by-products (cotton seed cake, bran of millet, sorghum, maize, wheat, and concentrated feeds) (Amole et al. 2022).

Innovations in forage crops are enhancing the nutritional value of feed for grazing livestock, with initiatives like irrigated Napier grass proving beneficial for cattle productivity (TFF 2024). Technologies such as computational DNA analysis are driving advancements in breeding forage crops that can withstand the impacts of climate change (TFF 2024). The determination of nutrient requirements, development of the capacity for feed analysis using near-infrared reflectance spectroscopy, deployment of ration formulation apps/software, and examination of the effects of strategic supplementation on livestock performance are necessary elements to adopt (Balehegn et al. 2020). Feed Assessment Tool (FEAST) developed to involve farmers more directly in decision-making regarding livestock feed improvement is another innovative technology used for enhancing livestock feeding (Duncan

Table 21.3 Practical feed improvement technologies for smallholder livestock production systems and their expected or observed impacts

Category	Technology	Production system[a]	Description of technologies	Observed or expected impact	Ref
Improving feed availability/ productivity	Improved forage plants	Small holder mixed crop-livestock, semi-intensive and intensive	Introducing higher yielding and higher-quality forage species including legumes	Increase forage availability and or nutritive value, reduce seasonal fluctuation in availability	Foster et al. (2009); Alemayehu et al. (2017)
	Conservation-based forage development	Small holder mixed crop-livestock, pastoral	Introduction of forage plants in natural resource conservation structures such as gullies and terraces, which serve as a source of feed, while reinforcing soil and water conservation	Protect soil loss and land degradation while improving feed availability	Alemayehu et al. (2017)
	Silvopastures / agro-forestry	Small holder mixed crop-livestock, pastoral, semi-intensive peri-urban	Use pasture, farmlands, and degraded areas for growing trees that synergistically impact pasture productivity	Improved fodder biomass productivity by up to 500% compared to conventional fodder tree growing strategies	Balehegn et al. (2014)
	Food-feed crop integration	Small holder mixed crop-livestock	Intercropping or alley farming to exploit synergies in pest protection and soil and water conservation, while improving availability of forage	Improved soil fertility, reduced pest load to food crops, while improving feed availability	Lenné et al. (2003)
	Protected grazing (exclosures, zero-grazing, cut and carry, rotational grazing, deferred grazing	Small holder mixed crop-livestock, pastoral, semi-intensive peri-urban	Protection or prescribed grazing on range and grazing lands to protect degraded areas and allow for natural regeneration of forage and improvement of forage production	Improved grazing land productivity, forage biomass, quality of forage produced, and reduce grazing land degradation	Yayneshet et al. (2009)
	Protected agriculture, e.g., hydroponics, greenhouse forage production.	Semi-intensive urban and peri-urban	Producing forage under protected conditions in areas and localities where conventional way of production is not possible or ineffective	Enable forage production in small areas of land or in soilless agriculture. Improved availability of green fodder	Masud and Bhowmik (2018)
	Use of underutilized locally available feed resources	All systems	The use of underutilized locally available feed resources including indigenous fodder species, local brewery residues, etc.	Improved feed availability, reduced need for commercial concentrates, improved farm profitability	Balehegn et al. (2014)
	Improved human-food-waste processing	Intensive urban and peri-urban	The use of affordable drying, cleaning, sorting, and processing technologies that enable safe use of human food-waste for livestock feeding	Increased supply of feed in areas where there is resource limitation for growing forage	Makkar (2016)
	Agronomic interventions on cultivated pastures	All	These include the use of recommendations on sowing rates, spacing, species mixing and association, seed treatment, weed and pest control, irrigation land preparation, shading, control of water logging	Improved forage yields	Falvey (1999)

(continued)

Table 21.3 (continued)

Category	Technology	Production system[a]	Description of technologies	Observed or expected impact	Ref
Enhancing feed quality	Chemical treatment of crop residues	Intensive commercial, semi-intensive urban and peri-urban, small holder mixed crop-livestock	Involves treating crop residues with urea and spraying or soaking in dilute acid and alkaline solutions, etc.	Improved crude protein content (with urea treatment); improved intake and digestibility of crop residues	Sarnklong et al. (2010)
	Biological treatment of crop residues	Intensive commercial, semi-intensive urban and peri-urban, small holder mixed crop-livestock	Involves treating crop residues with enzymes, bacterial inoculants or white /brown rot fungi	Improved digestibility and intake of crop residues	Li et al. (2010)
	Reducing particle size of crop residues	Intensive commercial, semi-intensive urban and peri-urban, small holder mixed crop-livestock	Chopping and grinding crop residues	Improves intake by animals, reduces bulkiness	Hamed and Elimam (2009)
	Fertilization of crops	Intensive commercial, small holder mixed crop-livestock	Applying fertilizers to improve the nutrient content (mainly CP) of crop residues	Fertilization of crops improves quality (improve CP and digestibility and reduce crude fiber) of crop residues as livestock feed resulting in up to 40% greater milk production	Reddy et al. (2003); Haileslassie et al. (2013)
	Forage crop breeding	Intensive commercial, small holder mixed crop-livestock	Selective breeding of forages for developing high yielding and better-quality forage accessions	Improved biomass productivity, feed quality and thus improved livestock productivity	Den Hartog and Sijtsma (2013)

Maintain or conserve feed quality	Correct timing of forage harvesting	Intensive commercial, small holder mixed crop-livestock	Harvesting forages when the nutritional content of the forage is at optimal or when both nutritional value and biomass yield are optimal	Improved intake, digestibility, and livestock productivity	Makkar (2016)
	Silage making	Intensive commercial, semi-intensive peri-urban	Storing fresh fodder under anaerobic conditions to preserve the quality	Conserved fodder with minimal energy and nutrient loss and spoilage	Titterton and Bareeba (2000)
	Hay making	Intensive commercial, semi-intensive urban and peri-urban, small holder mixed crop-livestock	Reducing loss of nutrients from green fodder by drying	Conserved fodder with minimal energy and nutrient loss and spoilage	Klinner and Shepperson (1975)
	Using preservatives	Intensive commercial, semi-intensive urban and peri-urban,	Using microbes or chemicals that inhibit spoilage organisms and preserve the quality of fresh fodder	Conserved fodder with minimal energy and nutrient loss and spoilage	Wang et al. (2018)
Improve the nutritional status of animals	Balanced and or phased rationing or ration formulation	Intensive commercial, semi-intensive urban and peri-urban, small holder mixed crop-livestock	Feeding a balanced ration formulated to meet the nutrient requirements of the animal or targeting rations to animals at specific levels of performance	Improved milk yield by 2–14%, improve net daily income 10–15%; reduced emission of greenhouse gases by 15–20%	Garg et al. (2013)
	Supplementation with concentrates	All systems	Supplementing low quality basal diets of animals with nutritious concentrates	Improved intake, digestibility, body weight gain, and milk yield	Selemani and Eik (2016)
	Supplementation with multi-nutrient blocks	Semi-intensive urban and peri-urban, small holder mixed crop-livestock	Providing animals on low quality basal diets multi-nutrient blocks that provide needed supplementary nutrients	Enabled production of the same amount of milk when 50% less green fodder and 30% less protein supplement was fed; improved feed intake and protein supply, increased milk yield by 1–1.5 L per day and enhanced reproductive performance in cattle	Makkar et al. (2007)
	Supplementation with feed additives	Intensive commercial, semi-intensive urban and peri-urban	Enzymes, probiotics, yeast, and other products that are added to feeds to help improve the ability of an animal to digest and assimilate feeds	Improved feed intake, digestion and performance	Ramirez (2014)

(continued)

Table 21.3 (continued)

Category	Technology	Production system[a]	Description of technologies	Observed or expected impact	Ref
Analytical and operational technologies	Near infrared reflectance spectroscopy (NIRS)	Intensive commercial, semi-intensive urban, and peri-urban	The use of NIRS technology that enables a quick and affordable assessment of the nutritional quality of various types of feeds without reagents	Improved efficiency and cost-effectiveness of feed analysis; may be used to enhance feed marketing	Modroño et al. (2017)
	User friendly ration formulation tools	Intensive commercial, semi-intensive urban and peri-urban, small holder mixed crop-livestock	The development and use of simple ration formulation tools such as excel or mobile phone applications that enable farmers to formulate effective rations based on locally available feed resources	Make ration formulation easier and facilitate its adoption	Chakeredza et al. (2008)
	Livestock/feed management applications	Intensive commercial, semi-intensive urban and peri-urban	These are user friendly mobile phone-based applications to monitor, track, and analyze feed consumed, produced, wasted, etc.	Help improve livestock farm profitability	Hwang et al. (2011)

Adapted from Balehegn et al. (2020)

Table 21.4 Categories of some of the novel feed ingredients or supplements in livestock feed. Adapted from (Chisoro et al. 2023)

Category	Examples	Justification	Ref
Oilseeds and leaf meals of indigenous fruit-bearing trees	Neem seeds, baobab leaves and seeds, red sour plum seeds, Moringa leaves and seeds, etc.	Indigenous trees have many properties and most bear fruit that have been eaten and used since ancient times. Some have been used as food and medicine in African rural communities. They have great potential as feed resources in particular their seeds, leaf, and oilcake meals	Chisoro and Nkukwana (2020)
Grain and pulses crop leftovers	Rice, sorghum, millet, groundnut Stover, wheat hay, etc.	Crop leftovers are by-products obtained after crop harvest, especially for grain crops. These can be used as partial replacers for more expensive feeds like maize or wheat because they are excellent sources of fiber and carbs in livestock diets	Sebola et al. (2021)
Pasture and forage crops	Alfalfa, lucerne, rye grass, black clover, etc.	These are plants, the likes of legumes, grasses, and browse species, that are planted to be fed to livestock. Mostly they are utilized as significant sources of protein and other nutrients to enhance the nutritional value of livestock diets	Chioma et al. (2021)
Agro-industrial by-products	Dried distillers' grains, peanut shells, cottonseed cake, palm kernel cake, etc.	These are substances produced during the processing of agricultural products like, peanut butter production, cooking oil, and beer manufacture. They can be used to enhance livestock performance and in diets as valuable sources of fiber, energy, and protein	Girma (2019)
Insects	Black solider fly, silkworm, locust, crickets, etc.	These have taken the feed sector by storm, due to their high protein value, ease, and sustainable propagation from organic waste, insects have gained popularity as a source of protein in livestock feed especially for pigs and poultry	Khan (2018)

(continued)

Table 21.4 (continued)

Category	Examples	Justification	Ref
Aquatic plants and animals	Duckweed, azola, water hyacinth, water lettuce, etc.	These include plants, fish, and other aquatic creatures. In aquatic systems, they are often regarded as "waste or weeds"; however, they can be used as sources of nutrients for livestock	Mahgoub and Al-Mutairi (2015)
Leftovers of food processing and manufacturing factories	Biscuit meal, candy and potato chips by-products, etc.	In the making of candy, biscuits, potato chips, and other foods they produce a lot of by-products, and all the broken and deformed products that do not meet market and production standards are left behind (Mbele et al. 2019). They still contain valuable nutrients that are still useful for use in livestock feed	Mbele et al. (2019); Ominski et al. (2021)

et al. 2023). FEAST is a participatory tool that utilizes focus group discussions and individual farmer interviews to develop a comprehensive overview of the livestock farming system (Duncan et al. 2023). Over the past decade, FEAST has been extensively applied in various countries, including Kenya and Rwanda, notably within initiatives like the Accelerated Value Chain Development Project and the Rwanda Dairy Development Project. In these cases, FEAST informed feed options with substantial input from farmers. While FEAST primarily supports improved feeding strategies at the farm level, the data collected through the FEAST app and published in reports serve as valuable resources for understanding broader livestock feed issues at the system level (Duncan et al. 2023). FEAST exemplifies a participatory tool that empowers farmers in decision-making while providing insights to researchers across farming systems. Its widespread adoption highlights its significance in addressing gaps in livestock feed development. Its innovation lies in bridging the knowledge gap between livestock researchers and small-scale livestock keepers, contributing to more informed and sustainable livestock farming practices (Duncan et al. 2023).

Production efficiency can be improved by deploying automated systems or smart machines in livestock operations that can deliver a precise amount of feed to each animal to meet its nutrient requirement for that particular production stage. Precision livestock feeding or nutrition is part of PLF approach involving techniques that allow feeding of the proper amount of feed of suitable composition and in a timely manner to individual animals or groups of animals (Andretta et al. 2014; Niemi et al. 2010). Precision livestock feeding matches nutrient requirements with nutrient supply based on real-time factual data determined by sensors (Zuidhof 2020). Such systems combine specific management approaches to each animal such that the feed it receives (including appropriate use of any feed additive) contains the appropriate nutrients required at the correct dosage to the appropriate genotype and physiological stage while employing effective processing methods and minimal antinutritive factors (Banhazi et al. 2012). Apart from improved efficiency of feed utilization, other important benefits from these systems are being driven by increased animal productivity, profit maximization, and reduced negative impact on the environment via lowering nutrient content of

excreta. Using precision systems will reduce the oversupply of feed, which is a precursor to overfeeding and the over-excretion of wastes that exceed the animal's requirement. The lower cost of advanced technology has encouraged the exploration and applications of these innovative technologies in different livestock species. The application of precision feeding on-farm requires the design and development of measuring devices that determine animal feed intake and weight, computation methods that estimate the nutrient requirement of animals (based on actual growth of animal) in a timely manner and systems of feeding with capability to make available the required composition and amount of feed needed to achieve the desired production goal (Pomar et al. 2019).

There are factors affecting the adoption of innovative technologies, these includes (Baltenweck et al. 2020): (1) management of technology: Implementing feed interventions often requires specific skills and access to technology, extension services, and training. Farmers need to acquire and apply these skills effectively to adopt new feeding practices successfully; (2) perceived benefits and alignment with objectives: Farmers must perceive the benefits of adopting new feed technologies and understand how they align with their objectives. However, the link between improved feeding practices and financial gains may not always be evident to farmers, especially considering that livestock serve various purposes beyond meat and milk production. Development agents must recognize and address farmers' diverse objectives to promote successful adoption; (3) resource availability and trade-offs. The availability of key resources like land and labor, and the trade-offs imposed by feed technologies, significantly impact adoption. Adequate availability of resources, particularly labor, tends to facilitate adoption. However, in some contexts, farmers may prioritize allocating resources to non-livestock activities, requiring careful consideration of trade-offs when promoting feed interventions. Therefore, interventions for addressing sustainable feed resources should focus on understanding and addressing sociocultural and institutional factors, as well as ensuring private sector engagement and policy reforms. By prioritizing these aspects and developing innovative solutions, the livestock sector in LMICs can improve productivity, contribute to food security, and alleviate poverty (Balehegn et al. 2020).

21.6 Innovative Technologies for Livestock Health Management

Health in livestock is defined based on multifactorial indices to denote the different states of the animal. Hence, a more comprehensive definition is the "state of normal biological functions and homeostasis, the absence of physical and psychological stress with optimum productivity, including reproduction.". Health in animals is more than a mere absence of disease but encompasses an improvement of animal welfare through health and stress monitoring for sustainable output (Giannuzzi et al. 2022). One of the descriptors of animal performance includes the animal's live weight. This is influenced by nutrition, welfare, and disease (Key 2018). Other factors taking a toll on cattle production include environmental changes due to climate changes (El-Sayed and Kamel 2020). The rise in the global population has necessitated an increased demand for animal-based proteins, resulting in pressure on animal production globally, including in tropical and sub-tropical developing countries (Renaudeau et al. 2012). Another confronting factor in cattle husbandry with a somewhat negative impact is using antimicrobials as growth promoters (Ma et al. 2021). Adopting new and sustainable technologies to boost livestock production with animal welfare is imperative to satisfy the increasing demand for animal-sourced foods.

21.6.1 Surveillance and Disease Forecasting

According to the World Health Organization (WHO), health surveillance is "the continuous, systematic collection, analysis, and interpretation of health-related data needed for the planning,

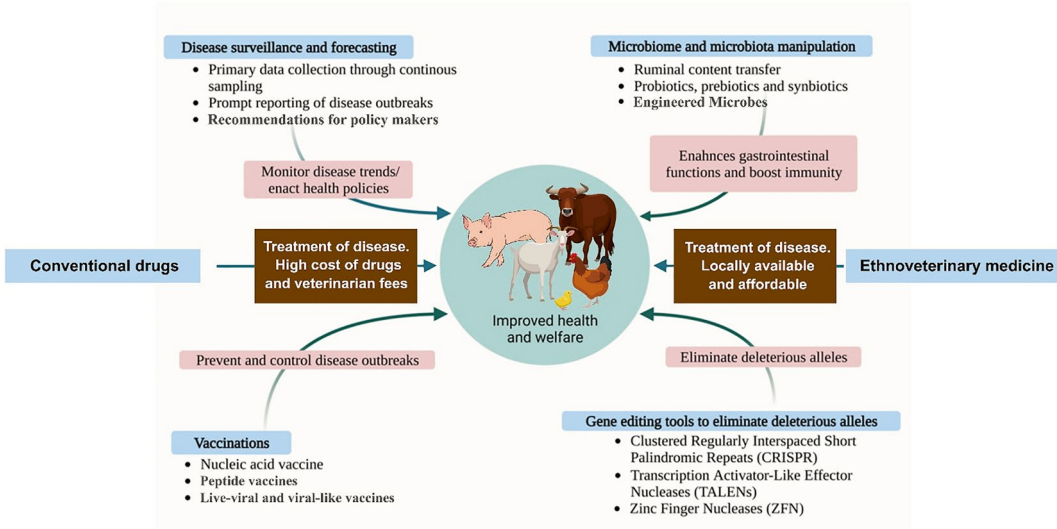

Fig. 21.4 Modern techniques for the improvement of livestock health

implemention, and evaluation of public health practice" (http://www.who.int/topics/public_health_surveillance/en/). In livestock, disease surveillance is planned to detect the early onset of diseases and evaluate the effectiveness of control measures. The data generated from disease surveillance is used to mount national control and eradication programs (Wakhusama et al. 2019). Disease surveillance is important in safeguarding animal and human health and welfare. Disease surveillance depends on notifiable disease reporting and secondary data analysis in humans. In livestock, primary data are obtained through active monitoring and sampling for the early detection of diseases (Wakhusama et al. 2019). Active disease surveillance in livestock aids in fulfilling trade requirements and certifications of animals and animal products to ensure safety (Comin et al. 2019). The current animal disease surveillance system in sub-Saharan Africa is inefficient because of its weakness, poor funding, and inability to provide quality and sensitive information on the status and trends of diseases. Hence, the need for urgent improvement in the specificity, sensitivity, and diagnostic flexibility for detecting silent epidemics and outbreaks (Abubakar et al. 2022). Animal disease surveillance requires improving the sensitivity of the reporting system, diagnostic accuracy, and disease containment activities using an integrated approach. It should be early alert and able to provide an understanding of disease dynamics with priority for intervention plans to prevent epidemics or pandemics and transmission of diseases from animals to humans (Abubakar et al. 2022). The ecology of Africa is complex and needs a specialized form of surveillance to document intervention impacts, track elimination progress, and monitor the epidemiological dynamics to determine health policy and practice. Disease surveillance is used to track and monitor the zoonotic transmission and progression of several diseases, such as bovine tuberculosis (Menghistu et al. 2018), schistosomiasis, leishmaniasis, helminthiasis (Fesseha et al. 2022), and brucellosis (Tadesse 2016) in humans. Therefore, mounting effective animal disease surveillance systems will help prevent and control disease transmission from animals to humans, boost production through improved health and welfare of the animals, and an overall increase in the gross domestic product through increased export of animals and animal products (Fig. 21.4). With the recent technological development and increased access to handheld computing devices such as smartphones, tablets, and portable computers, several

software are being developed to aid in effective disease surveillance and forecasting (Adepetun 2015).

21.6.2 Microbiome and Microbiota Manipulation

The rumen is a complex ecosystem with an intricate microbial community consisting of bacteria, viruses, archaea, protozoans, and fungi coexisting in a symbiotic manner (Ribeiro et al. 2017). These microbes interact symbiotically to break down complex fibrous substrates into volatile fatty acids and microbial proteins the host utilizes for growth, lactation, and general maintenance (Morgavi et al. 2013). The rumen microbiome digests dietary polysaccharides, which the rumen cannot break down. This process largely depends on the structure and diversity of the microbiota present in the rumen (Uyeno et al. 2015). The cattle rumen is an efficient system for degrading plant-cell walls to generate energy from forages. However, less than 50% of the carbohydrate from the cell wall are digested in low-quality forage (Ribeiro et al. 2017). Hence, improving carbohydrate metabolism in the rumen will produce adequate energy for health maintenance and enhanced productivity in the beef and dairy industries (Ribeiro et al. 2017). One way to improve the microbiome function is to manipulate the ruminal microbiota through probiotics administration or ruminal contents transfer.

Direct-fed microbes to ruminants manipulate the ruminal microbial community and alleviate dysbiosis. Probiotics enhance gastrointestinal health by stimulating and developing a healthy microbiome, inhibiting enteric pathogens, enhancing feed digestibility, lowering gastrointestinal pH, and modulation of mucosal immunity (Uyeno et al. 2015). The administration of probiotics in livestock has gained acceptance to replace low-dose antibiotics to improve animal health with benefits such as enhanced feed efficiency, body weight gain, and performance (Buntyn et al. 2016). Probiotics in adult ruminants are selected based on their ability to aid the breakdown of fibers, particularly cellulose (Uyeno et al. 2015). The actions of probiotics are associated with the microbial genera, species, or strains with multi-strain preparations recommended for a broader spectrum of action (Kwoji et al. 2021). Colonizing young animals with probiotics early in life is important as they modulate the expression of genes that support the establishment of beneficial commensals microbes (Siggers et al. 2007). The activities of probiotics are enhanced through prebiotics ingestion (Gibson et al. 2017). Common prebiotic substrates include carbohydrates, such as oligosaccharides or dietary fibers, with low digestibility (Uyeno et al. 2015). A combination of probiotics and prebiotics formulations are administered as symbiotics to animals to improve the survivability of the probiotics microbes (Gaggìa et al. 2010). The administration of probiotics in cattle, especially at the pre-ruminant stage, alleviates the incidence and severity of diarrhea and the carriage of pathogenic microbes (Gaggìa et al. 2010). Probiotics are used for prophylaxis and treatment of neonatal diarrhea in calves (Galvão et al. 2005). To protect probiotics during transit along the gastrointestinal tract, a single preparation of prebiotics and probiotics are formulated as synbiotics. A synbiotic is "a mixture of probiotics and prebiotics that beneficially affects the host by improving the survival and implantation of live microbial dietary supplements in the gastrointestinal tract, by selectively stimulating the growth and activating the metabolism of one or a limited number of health-promoting bacteria, and thus improving host welfare" (Markowiak and Śliżewska 2018).

Gastrointestinal microbial colonization is important during the rumen development of livestock (Sommer and Bäckhed 2013). This is because the rumen microbes supply approximately 70% of the daily energy needs of ruminants (Yeoman and White 2014). Different feeding programs are associated with variations in the microbial communities established in the rumen of young animals (Abecia et al. 2014). However, the composition of the ruminal microbiome may differ among cattle, even those fed with the same feed (Weimer et al. 2010a). Thus, indicating the possibility of the microbiome host-

specificity and likelihood of resistance to colonization by strains not adapted to the recipient host (Weimer et al. 2010b). Moreover the microbiome host-specificity, feeding method, and pre-weaning diets greatly influence the ruminal microbiome (Abecia et al. 2013). For example, introducing calves to solid feed early in life resulted in a diverse microbial community compared to those conventionally weaned at 6 weeks (Li et al. 2019).

21.6.3 Vaccination

Animal health is important for an efficient transition toward large, healthy, and sustainable food systems with animal welfare standards. Animal health is necessary for global food security, quality, and poverty alleviation (Pradere 2014). Therefore, preventing and controlling animal diseases, including zoonoses, and appropriately managing emerging diseases, pandemic threats, and antimicrobial and antiparasitic resistances in livestock are pertinent (FAO 2019). Vaccines in veterinary medicine are vital to preventing, controlling, and protecting animal and human health against diseases (Meeusen et al. 2007). Vaccines in animal disease control are sustainable and provide lasting protection without leaving pharmaceutical residues in the environment while reducing the need for antimicrobials (Hoelzer et al. 2018). The need for vaccines to prevent existing and emerging diseases in livestock has necessitated research in identifying protective antigens and virulence mechanisms using genomic, proteomic, immunological, biological, and bioinformatic techniques and suitable delivery methods (Charlier et al. 2022). Vaccines have reduced the burden of numerous diseases, such as smallpox, tetanus, polio, diphtheria, and measles (Younger et al. 2016). In cattle, several vaccines have been developed to prevent infections, including bovine tuberculosis (Vordermeier et al. 2016), contagious bovine pleuropneumonia (CBPP), bovine viral diarrhea (BVD) (Van Oirschot et al. 1999), and infectious bovine rhinotracheitis (IBR) (Nardelli et al. 2008) among others.

There is also the need for new vaccines with effective, long-lasting single shots to be developed due to the short lifespan of livestock (Charlier et al. 2022). For effective vaccine development, the host-immune mechanisms and means of immune evasion by pathogens must be understood (Entrican et al. 2020). Vaccinology is a dynamic research area whereby new technologies, including nucleic acid, peptide, live-viral, and virus-like particle vaccines, have been developed to induce high protection, and they constitute affordable vaccines (Francis 2018). Vaccines used for prophylaxis or therapeutics are grossly grouped as live attenuated (weakened microorganisms), inactivated (killed microbes), toxoid (inactivated bacterial toxins), and sub-unit (purified antigens) vaccines (Wadhwa et al. 2020).

21.6.3.1 Nucleic Acid Vaccine

Nucleic acid vaccines employ genetic material (DNA or mRNA) from a pathogen to elicit a specific immune response. Nucleic acid vaccines are becoming versatile and robust in their development and are potentially safe, cost-effective, and efficient in combating diseases (Qin et al. 2021). DNA vaccines are made from bacterial plasmids that encode immunostimulatory antigens such as Interleukin-2 (IL-2) and Granulocyte-macrophage colony-stimulating factor (GM-CSF) (Yankauckas et al. 1993). DNA vaccines are administered through various routes to the host, including intramuscular, transdermal, and intramucosal. These vaccines are efficient and elicit both humoral and cellular immunity in the host. Following administration, DNA vaccines are transcribed and translated into the nucleus and cytoplasm, respectively (Bai et al. 2017).

21.6.3.2 Peptide Vaccines

Peptide vaccines are subunit vaccines made up of mainly specific epitopes capable of inducing desirable B- and T-cells mediated immune responses (Li et al. 2014). The peptides are usually 20–30 amino acid sequences representing the immunogenic molecule of the specific antigen-binding site (epitope) (Li et al. 2014). Peptide vaccines can stimulate humoral and cellular responses because the epitopes are the anti-

genic determinants of a larger protein (Bijker et al. 2007). The development of peptide vaccines was birthed out of the discovery of the ability of major histocompatibility complex-I (MHC-1) to restrict the recognition of $CD8^+$ T-Cells by target cells (Zinkernagel and Doherty 1974) and the ability of the $CD8^+$ T-Cells to detect short peptide sequences of 11–16 in length generated from the proteolytic degradation of target antigen presented to MHC-I (Townsend et al. 1984). It was further discovered that the MHC-I recognizes even smaller peptides of the $CD8^+$ T-cells epitopes of eight amino acids (Rötzschke et al. 1990). The use of peptide vaccines reduces the cumbersomeness of multiple vaccinations because a conserved peptide sequence region of the epitopes from different strains, serovars, or species of a pathogen could be used in designing the vaccine (Li et al. 2014).

21.6.3.3 Live-Attenuated Vaccines

Live-attenuated vaccines involve the use of weakened microbes. The pathogen is weakened to reduce its disease-causing ability but retains its immunogenic ability (Kollaritsch and Rendi-Wagner 2012). During the formulation of live-attenuated vaccines, the microbe is passaged by serially culturing in cell cultures or animal embryos (mostly chicken embryos). Attenuating viruses is carried out by culturing on cells that have not been grown for so many generations (Dai et al. 2019). Live-attenuated vaccines can elicit higher immunogenicity than inactivated vaccines since the process mimics natural infection to stimulate cellular and humoral responses (Kollaritsch and Rendi-Wagner 2012). Also, the immunity conferred by live-attenuated vaccines is long-lasting and sometimes lifelong (Fuertes Marraco et al. 2015). However, safety is the major disadvantage of live-attenuated vaccines as the pathogens may revert to virulence through back mutations and cause classical diseases like the wild pathogen, especially in stressed or immunocompromised hosts (Kollaritsch and Rendi-Wagner 2012).

21.6.4 Conventional Drugs

Addressing livestock health issues requires a holistic approach considering the diverse roles and perspectives within livestock production systems and the challenge of access to drugs and cost of treatment. As an example, African animal trypanosomosis (AAT), caused by the protozoan parasite *Trypanosoma congolense*, poses a significant challenge to improving animal productivity and agricultural production in sub-humid zones, as evidenced by multiple studies conducted over the past two decades (Swallow 2000; Chanie et al. 2013). The FAO estimates the annual economic losses due to AAT in Africa at $1–1.5 billion (Swallow 2000). AAT poses a significant challenge to agricultural productivity and livestock welfare, especially given that 70% of agricultural land is infested with tsetse flies (vector of Trypanosome spp), putting over 60 million animals at risk (Ouédraogo et al. 2006). In Africa, the tsetse fly-infested zone spans approximately 8.7 million km (Enahoro et al. 2019), with nearly 46 million livestock animals affected (Swallow 2000). The use of trypanocidal products to control AAT is widespread, with over 35 million doses administered annually in Africa. A study in Burkina Faso showed promising results, with a 56% reduction in animal mortality rates achieved through combined trypanocide treatments and trapping (Kamuanga et al. 2001). In the Province of Kénédougou, it was revealed that the prevalence of sick animals plays a crucial role in treatment decisions, with farmers adopting a recursive strategy for treating trypanosomosis (Ouédraogo et al. 2006). A higher prevalence of affected animals prompt farmers toward seeking professional care. Likewise, resistance to trypanocides also influences this decision, with repeated ineffective treatments leading to professional consultation (Ouédraogo et al. 2006). Agropastoralism has a significant negative correlation with consulting animal health professionals for trypanocide treatment, with herders more likely to seek professional care than agropastoral farmers. The

size of agricultural households also plays a role, as larger farms tend to consult professionals due to lower labor opportunity costs. Socioeconomic and institutional factors such as the number of agricultural workers, transaction costs, and transport effectiveness interact with biological variables like disease prevalence and resistance to shape treatment choices (Ouédraogo et al. 2006). Therefore, it is important to consider these factors in rural development policies to enhance livestock health coverage and increase agropastoral farming productivity in the region.

In South Africa, granting farmers access to veterinary medicines without oversight addresses the scarcity of veterinary services and fostering sustainable farming. However, this practice assumes farmers can accurately diagnose and treat animals independently. Yet, like any medication, veterinary drugs can be used rationally or irrationally (Gulwako et al. 2023). Rational usage, endorsed by the WHO, involves appropriate drug selection, dosage, and cost. Conversely, irrational use risks ineffective treatment, harming animals, and wasting resources (Gulwako et al. 2023). Kirui et al. reported that many farmers in sub-Saharan African (SSA; Ethiopia, Malawi, Nigeria, and Tanzania) lack proper knowledge and training in administering veterinary medicines, leading to incorrect usage (Kirui 2019). Issues such as incorrect route of administration, drug storage, dose calculation, withdrawal periods, and disposal are prevalent, especially among those without formal education (Kirui 2019). Similar findings were noted in Bangladesh and Ethiopia, highlighting a global concern (Khatun et al. 2016). Misuse of veterinary drugs, particularly in food-producing animals, raises concerns due to potential residues in animal products, jeopardizing human health. This misuse exacerbates antimicrobial resistance, limiting treatment options and posing direct health risks. Understanding farmers' knowledge of safe drug use is crucial (Gulwako et al. 2023). Training programs, though beneficial, often fail to adequately cover food safety aspects like withdrawal periods. Therefore, farmers need to be properly trained for proper management of production animals to ensure the proper utilization of available medications. Targeted training on safety and storage aspects of drug use, along with strategic allocation of farm subsidies, could help address these challenges effectively (Gulwako et al. 2023).

In Uganda, Tanzania, Nigeria, and Kenya, veterinary drugs market remains peripheral in the global market for modern veterinary drugs (Gulwako et al. 2023). Unlike emerging Asian countries, SSA lacks appeal for international pharmaceutical companies. The market is characterized by weak regulation, fragmented supply chains, and a dual system for veterinary medicines. In SSA, the public sector supplies small-scale farmers in rural areas with limited resources, focusing mainly on vaccines and parasiticides through large-scale campaigns. In contrast, the largely unregulated private sector serves commercial and industrial livestock farming, relying on private veterinarians and various retailers predominantly located in urban and peri-urban areas. International efforts have been made to improve drug access and supply chain efficiency in SSA. These efforts include support for national legislation on veterinary drugs, harmonization of registration procedures, and arrangements to enhance availability through public-private partnerships (PPPs) and involvement of pharmaceutical companies (Gulwako et al. 2023). Jaime et al. emphasizes the need for policies informed by a better understanding of the drivers behind access to veterinary drugs (Jaime et al. 2022). The authors suggest analyzing factors affecting drug accessibility, including availability, quality, and economic affordability. Economic studies on affordability are crucial to understand pricing dynamics and stakeholder decisions. Additionally, assessments should consider the supply chain's capacity to handle epidemics and emergencies. The evolving international policy landscape highlights the increasing influence of commercial actors in drug availability decisions, necessitating a balance of stakeholders'interests. Furthermore, policies should avoid bias toward certain diseases at the expense of others important for veterinary public health, thus ensuring a holistic approach to animal health management in SSA (Organization, W. H 2004).

21.6.5 Ethnoveterinary Medicine

Ethnoveterinary preparations (EVPs) play crucial roles in maintaining the health and productivity of livestock in many developing countries, where access to conventional veterinary medicine may be limited (Wendimu et al. 2023). EVPs have been utilized for animal health management since ancient times. Historically, EVPs such as medicinal plants and herbs were prevalent before the industrial revolution but declined with the rise of conventional medicine. However, there is now a renewed interest in EVPs due to their sustainability, cost-effectiveness, availability, and environmental friendliness, particularly in addressing issues arising from conventional medicine use. This shift toward EVPs is driven by the need for organic solutions and a comprehensive approach to health problems (Tumasang et al. 2023). Plant materials and derivatives have a long history of use in human and animal health interventions, with extracts from plants being utilized to create remedies. Moreover, there is high demand for healthier organic alternatives in livestock products, driven by consumer preferences for pasture-fed livestock products free from synthetic residues. Additionally, there is a growing focus on ethically raised farm animals, prompting consumers to pay premium prices for products from certified farm sources, along with increased awareness from animal rights activism (Nwafor and Nwafor 2022). The rising financial costs associated with orthodox practices for treating livestock infections and diseases, including high drug and medication costs and fees payable to veterinarians and technicians, have further propelled the use of plant-derived remedies. With estimates from the FAO indicating significant losses due to livestock diseases among smallholder farmers in developing countries, the adoption of alternative practices involving plant-derived remedies presents a way to mitigate these losses (FAO 2018). This trend aligns with observations that animals in their natural habitat consume certain plants to alleviate ailments, and many farmers have witnessed improvements in livestock health after using medicinal plants or extracts (Nwafor and Nwafor 2022). Ethnoveterinary practices and products are widely utilized among rural smallholder livestock farmers in many SAA countries. These farmers often resort to herbal remedies when conventional knowledge is lacking, veterinary services are inaccessible or unaffordable, or when alternative remedies are more available and affordable. The availability and affordability of such alternative remedies are key factors driving the use of ethnoveterinary medicine among farmers. However, despite the availability of herbal remedies, some livestock owners still opt for orthodox treatments due to unsatisfactory experiences with herbal remedies or a perception that traditional practices are outdated and ineffective. Additionally, some farmers choose to use a combination of orthodox treatments and ethnoveterinary medicine for treating their livestock. This underscores the complex decision-making process involved in animal healthcare among rural smallholder farmers, who weigh factors such as effectiveness, availability, affordability, and personal experience when choosing treatment options for their livestock (Nwafor and Nwafor 2022).

The profile of users and adopters of ethnoveterinary products and practices varies based on socioeconomic factors and cultural perspectives. In developed economies, farmers may utilize phyto-therapeutic products to comply with organic livestock treatment directives. In contrast, in developing countries, ethnoveterinary practices are popular among rural livestock owners who practice extensive farming, rely on communal pastures, and face resource constraints. These farmers often gather herbs and plant materials from the wild due to their inability to afford conventional veterinary services and products, which may not be readily available in rural communities. Not only that, there are some smallholder or emerging livestock farmers who utilize a combination of bio-medicine and ethnoveterinary practices, known as medical pluralism. Among this group, ethnoveterinary practices are often used in conjunction with pharmaceuticals rather than exclusively (Nwafor and Nwafor 2022).

Ethnoveterinary medicine is rooted in traditional beliefs and indigenous knowledge and it is widely utilized globally to treat livestock diseases (Rahman et al. 2022). In a study conducted in Namibia's Omusati and Kunene regions, a total of 100 people were interviewed using a semi-structured questionnaire to identify ethnoveterinary medications used for treating livestock ailments (Eiki et al. 2022). The study identified 15 veterinary medicinal plant species from 10 families. Leaves were the most widely used plant parts for ethnoveterinary medicine (71%), followed by bark (14%), stem (8%), and root (7%). Fresh components were preferred in medical compositions. Oral administration was the most common method (42.76%), followed by cutaneous (topical) administration (36.18%) (Eiki et al. 2022). The majority of ethnoveterinary medications were administered orally or topically after being crushed and soaked in water. Specific plants like *Ziziphus mucronate*, *Combretum collinum*, and *Colophospermum mopane* are used to treat diarrhea, *Ziziphus mucronate* is used to treat mastitis, *Aloe esculenta* and *Salvadora persica* are used to treat skin infections and *Ximenia americana* and *C. imberbe* are used to treat eye infections in cattle, sheep, and goat (Eiki et al. 2022). The authors stated that further research is needed to determine the chemical components, minimum inhibitory concentrations, biological activities, and toxicities of these plants, as well as to explore plausible mechanisms for achieving the reported therapeutic effects (Eiki et al. 2022). Another field survey in the Wolaita Zone of south Ethiopia involving 90 proficient healers (Wendimu et al. 2023) revealed that 54 plants from 28 different families were used to treat 39 livestock illnesses. Leaves constituted the majority of plant parts used (49%), followed by herbs (9%). Remedies were administered through various routes including nasal, oral, topical/dermal, and ocular. Blackleg, bloat, and endoparasites showed the highest Informant Consensus Factor (ICF) values. *Withania somnifera* was identified as the most potent remedy for blackleg, while *Zingiber officinale* had the highest fidelity level (FL = 94%) for treating bloat (Wendimu et al. 2023). *Croton macrostachyus* was widely known and utilized in the community for various purposes. *Stephania abyssinica* had the highest mean cultural importance, followed by *Pentas schimperina L.* The main threats to medicinal plants in the study area were agricultural expansion, drought, and construction. Thus, conservation efforts for therapeutic plants are deemed essential, with responsibilities lying with local communities and other relevant organizations (Wendimu et al. 2023). In northern Nigeria, where modern veterinary services are scarce and costly, a study involving 50 livestock farmers, reported that traditional remedies, comprising plant extracts, seeds, leaves, tree barks, tubers, and roots, are widely used due to their local availability and affordability (Alawa et al. 2002). The combination of these ingredients suggested potential additive, synergistic, and nutritional effects in treating various animal diseases, highlighting the importance of indigenous knowledge alongside conventional methods (Alawa et al. 2002). In Cameroon, the use of EVPs among smallholder farmers declined following the introduction of orthodox veterinary medicine during colonization (Tumasang et al. 2023). However, there has been a resurgence of interest in ethnoveterinary practices in recent decades, with efforts to document and validate traditional knowledge (Tumasang et al. 2023). A plethora of studies from other regions of the world (Luo et al. 2022; Rehman et al. 2022) underscore the importance of ethnoveterinary knowledge in sustainable livestock production and highlight the potential of traditional herbal treatments in addressing livestock health issues globally.

21.7 Technologies for Housing and Milking Management in Various Input Systems

Housing is required to protect animals from inclement weather and provide clean, comfortable stay for good health and efficient management. Different housing systems exist for cattle, poultry, and pig. However, the evolution toward more sustainable farming systems is

occurring worldwide, and buildings are becoming an integral part of modern farming systems, which contribute greatly to the efficiency of operation, the quality of the products, and the health and comfort of livestock and workers. The sustainability of animal production depends on using modern housing systems, which ensure high productivity and quality of products (meat, milk and eggs) with the possibility of robotization of work, simultaneously minimizing the negative impact on the environment, including energy inputs. New technologies are rapidly integrating into agricultural systems and have altered the standard ways livestock, especially dairy cattle and chicken, are housed (Galama et al. 2020; Klopčič et al. 2019; Beaver et al. 2019).

21.7.1 Housing Innovations

Recent changes and expected developments in housing systems for dairy cows create an appropriate production environment for modern high-producing dairy cows and stimulate dairy farming-related developments (Klopčič et al. 2019). Before the 1970s, tie-stall (TS) housing systems were common (Fig. 21.5a). The TS system fits bucket milking systems and hay feeding and makes it relatively easy to keep the animals clean; however, it is not ideal for animal welfare because of the lack of freedom of movement, limited space per cow, and the potential for teat and leg injuries (Galama et al. 2015). Moreover, TS are not optimal for labor efficiency (Beaver et al. 2019). These factors explain the gradual change from TS to Cubicle barns (CB) since the 1970s (Bewley et al. 2017). Increased labor efficiency has been the most important driving force of the change from TS barns to cubicle barns (also known as free-stall barns). The transition to CB (Fig. 21.5b) was stimulated by developing parlor milking systems, milk cooling in a tank, availability of grass silages, and other innovations. Bewley and colleagues (Bewley et al. 2017) also described the ease of separating lactating cow groups and feeding in CB. The higher labor efficiency in CB has allowed for farms to be scaled up. Nevertheless, cows walk on a concrete floor, which can cause hoof problems (Kester et al. 2014). In addition, the manure product from these cows changes from feces mixed with straw and urine in TS to slurry in CB. Since the mid-1980s, after approximately 15 years of experience with CB, milk production has increased through improved technology, genetics, milking, and feeding management (Khanal et al. 2010). Still, animal welfare issues and minimizing ammonia emissions during field manure application increased in importance. The need for cow comfort was addressed by innovations such as mattresses in stalls; the use of deep sand, straw, and manure solids as bedding; innovative cubicle partitions that decrease cow injuries; open sides of barns; curtains to regulate ventilation; higher and insulated roofs; and wider walking areas (Galama et al. 2015). Sand is considered the gold standard for deeply bedded cubicles, but handling sand-loaded manure poses some challenges (Palmer and Holmes 2005). Environmental and cattle welfare requirements are becoming even more stringent in any production system. In addition to ammonia emissions, decreasing the emission of GHG (related to climate change) has gained importance (Steinfeld et al. 2006). New techniques, such as capturing emissions in the barn and separating feces and urine, are being tried. However, as the aesthetics of buildings in the landscape became an issue due to the con-

Fig. 21.5 Tie-stall barn (**a**), cubicle barn (**b**), and free walk barn (**c**) dairy cow housing systems

struction of larger barns and the need for more space per cow and increasing herd sizes, farmers started searching for alternatives to CB. As a result, the option of free-walk barns, such as bedded-pack barns, became a research focus. Proposed future housing systems with indicated benefits of animal welfare and manure quality as well as trade-offs (Galama et al. 2015) consider the following: (1) more space per cow versus more ammonia and nitrous oxide emission, (2) using waste materials as bedding versus increased food safety risk, (3) limited availability of bedding material (mostly wood chips or sawdust) at an affordable price, and (4) larger buildings versus landscape quality (Galama et al. 2020).

The natural behavior of cows, climate control, emissions of ammonia and GHG, reuse of waste, manure quality, the aesthetics of buildings in the landscape, and capital efficiency are now very important elements in modern cattle barns. Although technical innovations in feeding and milking made the transition to CB possible, the prevalence of lameness and hock lesions can be high in CB, especially on concrete flooring, including both slatted and solid floors (Leso et al. 2020). However, free walk (FW) housing systems, especially bedded-pack barns, have become of interest globally (Bewley et al. 2017) (Fig. 21.5c). Nevertheless, the implementation of FW systems is still in development. Even so, FW systems are spreading in several areas, where the evolution toward more sustainable farming systems is occurring worldwide.

Writing about future housing systems for cattle, Galama, et al. (2020) reported that approximately 55 Dutch farms as of 2019 have built an FW bedded-pack barn system, mostly with wood chips as bedding material. Half of these farms have adopted a greenhouse-type building, resulting in low roof construction investment to compensate for the greater area (m^2) per cow. A European Union Free Walk program involving eight European countries recently evolved due to knowledge exchange intensification between farmers. The project aims to develop further FW cattle housing systems, which are expected to improve animal welfare and soil structure, utilize waste products, and have greater public support than CB systems. The smart technology objectives of the FW system are climate-neutral development (20% reduction in GHG compared with 1990 data; 16% sustainable energy; energy-efficiency +2%/year); maintain grazing (81.2% of farms should use grazing); continuous improvement of animal welfare and health (70% reduction in antibiotic use; longevity +6 month compared with 2011); improve welfare scores (in operation by 2017); maintenance of the environment (100% use of responsible soy; national phosphate usage at 2002 level; and a 5-kt reduction in ammonia emissions compared with 2011); and improve biodiversity (biodiversity tool available in 2017) (Galama et al. 2015).

Other practices to increase milk production on dairy farms include nutrition, disease, and milking process management.

21.7.2 Milking Preparation

Since dairy cows are kept with the primary objective of producing milk, optimal milk removal from the udder is necessary. Under low input systems with few cows, milk removal is by hand or with portable milking systems. With increased herd size for medium and large operations or systems, more productive and efficient systems are used. An important step in the milking process, whether by hand or with the use of milkers, is udder premilking preparation, which is key to producing milk of high quality while minimizing the risk of contamination and infections. Therefore, methods for udder premilking preparation should ensure that teats are properly cleaned and dried beforehand milking or machine attachment to minimize sediments and high bacterial counts in milk. Procedures for effective udder cleaning with approved udder wash sanitizers are in effect in many high milk producing countries. For example, the majority of approved udder sanitizers by the Dairy Farmers of Canada have chlorhexidine acetate and/or iodine and/or glycerin and/or hydrogen peroxide, as the main components. Steps for pre-milking and post milking teat disinfection by the Canadian Mastitis Research Network (http://www.mastitisnetwork.org/) include: (1) clean teat thoroughly with clean water using wet wipes/paper towel (disposable)

Fig. 21.6 A typical portable milking machine

to remove surface dirt, which can reduce the efficiency of disinfectant; (2) submerge teats entirely in to an approved dip solution for at least 30 s; (3) wipe teats thoroughly with a disposable paper towel to remove the dip solution, followed by milking (attach milking unit or by hand); and (4) post-milking, coat the milk film on the teat by dipping in to an antibacterial solution (this prevents the transmission of pathogenic contagious bacteria (e.g., *Staphylococcus aureus*) and improves teat condition.

Before 1993, cows' udders were mostly hand cleaned in the USA, but in 1993, the udder washer system was developed which facilitated udder cleaning in the holding pen before entering the milking parlor (Khanal et al. 2010). Different types of udder washers include water heater with automatic teat spraying systems, spray guns, or teat dipping operations. In 1993, approximately 3% of US farms used udder washers and 71% of those farms had herd sizes of more than 300 cows (Khanal et al. 2010; Short 2000).

21.7.3 Milking Management Technologies for Small-Scale Farms

Depending on the size of the herd or scale of operation, various systems have been used to accomplish the milking process. For small-scale producers, the milking process can be accomplished using portable milking machines, barn milking systems or milking with automatic take-offs (ATOs).

21.7.3.1 Portable Milking System

Portable milking machine or portable milker (e.g., bucket milker) is an easy system of milking for small cow herds. It is an efficient way of milking cows that are reared in extensive production systems. It is also suitable for nomads or pastoral systems because the portable milking machine can be moved from one place to another. Also, this system can be used to milk cows in the barn, field or to milk sick animals in isolated pens (Patil 2013a). A typical portable milking machine (Fig. 21.6) has oil free vacuum pump that is controlled by an electric motor; vacuum regulator and a gauge that helps to monitor and maintain the vacuum level during the process of milking; and pneumatic pulsator that can be easily adjusted with an adjustment screw located on the pulsator. The pulsator is very reliable, precise, studded, and simple to use. It is recommended that the vacuum level for milking a cow with a portable milker should be 48–50 kPa and the pulsation rate should be set to 60 ppm. In places where there is no electricity, a diesel engine or batteries can be used to power the portable milker. The

milk can be collected in a sturdy stainless steel bucket mounted on a lightweight but very strong trolley for easy movement (Patil 2013a).

21.7.3.2 Barn Milking Systems

Barn milking systems are mostly used in tied stall barns having herd sizes of 100 or more cows. The milking is done by a portable milking unit, which provides pulsation and allows the vacuum to be delivered to the end of the teat. The portable milking unit is connected to the milking station and fixed on the milk line. In barn milking systems, a milking station can serve two cows. The milk moves to the milk receiving set or receiving vessel having a liquid control level, sanitary tap, milk pump, and milk filter. Afterward, the milk flows from the milk receiving vessel into the milking tank (Patil 2013b). The portable machine has vacuum pumps that is regulated by vacuum regulator in order to maintain a desired level. It is recommended that one vacuum line loop should be used for every 50 cows. This makes it easy for the milk to be pumped from the receiving set installed on the vacuum loop directly to the milk cooling tank. Automated washing system can be installed in the barn for adequate cleaning after milking to wash milking equipment that was used in milking including the portable milking machine. The water slug can be fixed in the milk line using air injector valve for proper washing (Patil 2013b).

21.7.3.3 Milking with Automatic Take-Offs

Mastitis, an inflammation of the mammary gland, can occur in cases where cow's udder is milked beyond the point where they have stopped releasing milk. Also, under-milking cows might cause reduction in milk yield and discomfort to cows. Therefore, ATOs are very essential because they have sensors that sense when milk flow has stopped. Once the milk flow stops, the ATOs switches off the vacuum and automatically removes the milking unit from the udder. Mechanical or electronic ATOs are used in milking parlors to ease human labor by reducing the number of times the operator needs to bend on the knees to examine if milk flow has stopped and it increases the number of cows to be milked (Tranel 2008).

21.7.4 Milking Management Technologies in Medium to Large Production Systems

21.7.4.1 Milking Parlors

Milking parlors are mostly used on medium-scale, large-scale, and sometimes on small-scale dairy milk production farms. In milk parlor system, cows are milked in stalls mostly raised above the ground for easy milking. Milking parlors are arranged in herringbone, swingover, rapid exit parallel, flat, or rotary manner. Milking parlors in general are cost-effective for large farms with 100 or more cows while automated flat parlors are used mostly by small dairy farmers wishing to change from stall to free stall housing (Tauer 1998). Milking by majority of farmers is done twice a day, in the morning and evening. In order to use milking parlors more efficiently and increase milk production per cow, milking can be performed three times daily. Research has shown a 6–19% increase in milk production when cows were milked three times per day (Gisi et al. 1986). Milking cows three times daily tends to maintain milk quality in late lactation stage (Sorensen et al. 2001). Another alternative to the milking parlor system is the bucket milkers or pipeline systems common in stanchion or tie-stall barns. Sample milking parlors are shown in Fig. 21.7.

Parallel Milking Parlor In this system, more cows can be loaded in the stall and within a short time. It consists of a vacuum operated gate lift and the building is very wide in length. This system can easily locate the exit gate in front of the cow stall making it a fast and efficient way of exiting and reloading cows (Patil 2013a). A recent parallel milking design by DeLaval company (DeLaval's P500 parallel parlor, www.delaval.com) has independently controlled, suspended, non-overlapping sequence gates, with ability to lift up during milking, allows easy and calm movement of cows (minimize stress on

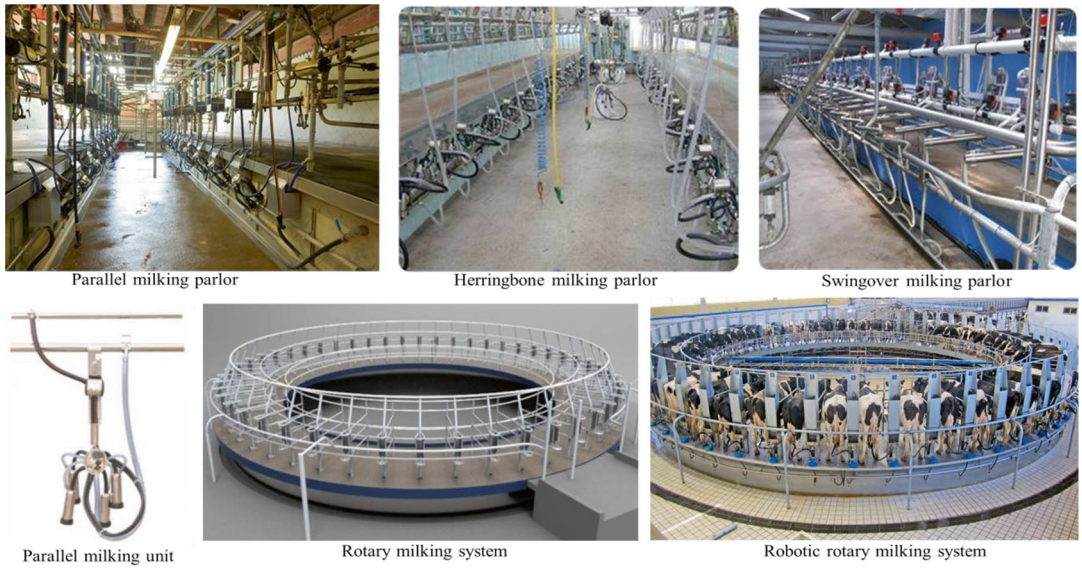

Fig. 21.7 Different parlor milking systems

cows) as well as reduce the size of parlor footprints.

Herringbone Milking Parlors This is the most used milking parlor in medium-scale dairy farms housing about 600 cows. With this system, the milkers or milking machines are positioned in the center or the spine (like spine of a fish) or center aisle, between two aisles with enough space or room for the cows. During the milking hour, the animals enter the parlor and line up between each spine, creating two rows of cows followed by milking by the milker. The milker washes the cow's udder and teats and then fix the cups to the udder from the rear of the hind legs. The size of the herringbone milking parlor ranges from a double 8/8 to 20/20, which means that both sides of the milking parlor have the same number of stalls, with each stall angle ranging from 30 to 90 degrees. Only one milking control is required for each stall in a double parlor (Patil 2013a).

Swingover Milking Parlor The Swingover parlor is similar to the herringbone parlor, except that two cows on the same row share a set of milking cups. This means that two cows can be milked at the same time and if one cow is done milking, it can be moved out for another to enter. In the swingover style, two sides of the parlor have the same control and therefore, it is mounted at the center of the pit. With the ram and the cluster fixed to it, it is able to move from one side of the parlor to the other side; hence, making it cost-effective for a double parlor. The swingover parlor is cheaper to install.

Rotary Milking Parlors The rotary milking parlor is a circular raised platform on which the cow stands, allowing attachment of the milking machine by the farmer or operator from below. During use, the system rotates slowly allowing cows to enter and exit the platform easily when a stall is free or at regular intervals. The rotary milking parlor is the least labor-intensive form of milking, and it is suitable for medium to large farms. It is bigger (can milk more than 1000 cows) and milking is also quicker than in the herringbone parlor. Herringbone parlor mostly accommodates 20–40 points per side whereas a typical rotary parlor is made up of a turntable having 12–100 individual stalls for cows around the outer edge (Patil 2013a). The turntable is controlled by an electric motor drive and it is designed in a way that one turn represents the time in which a cow is totally milked. Once an empty stall passes through the entrance, a cow

steps on it facing the center and then the turntable rotates with the cow. This is repeated until all the cows are milked. The milker washes the cow udder before fixing the milking machine cups. Afterward, the cows are milked as the platform rotates and once the udder stops releasing milk, the ATOs or milker removes the cups from the cow's udder, and the cow is allowed to exit the stall just before the entrance. Two operators can milk 250 cows per hour on a 60 point platform (Patil 2013a).

Pipeline or Milkline Milking System The pipeline milking system is commonly used in tie-stall barns and milking parlors. It is a portable milking unit that provides pulsation, delivers vacuum to the teat end and at the end of milking, delivers the milk directly to the cooling tank through a pipeline or milkline system. In organized milk recording systems, a milk meter flask-based is installed at every milking stall for the measurement of milk produced by each cow.

The pipeline milking systems are the most predominant type of milkline systems on dairy farms while some producers make use of a less common milking system known as weigh jar systems. The pipeline milking systems can perform two functions at a time including vacuum supply and the movement of milk from the milk unit to the receiver in milklines. While in weigh jar milking systems, only milk can be transported from weigh jars to the receiver while vacuum lines move only air from weigh jars to the sanitary trap. Furthermore, the milk is transported from weigh jars via the sanitary trap by the air pressure in the weigh jar and vacuum pressure in the milk receiver. Another sanitary airline provides milking vacuum to the weigh jar during the process of milking cows and also supply water to the weigh jar during cleaning (Reinemann 2013). The weigh jars are placed below or almost at the same position of the cow udder for easy milking. Even though the size of the milk transfer lines does not affect the milking performance, because they are only used to empty weigh jars after milking and also looping (enhances cleaning process and emptying of weigh jars), it is expedient that the capacity of the milk transfer line is as large as the line supplying water used for cleaning the weigh jars and milk meters (Reinemann 2013).

In dual-purpose milk pipeline systems, the pipeline uses gravity to transport milk from the milkline to the receiver. Low-level, high-level, and mid-level pipeline systems are used in milking parlors and they are located under the cow udder, a little above the cow udder and high above the cow udder, respectively. The dual milk pipeline systems are also used in round-the-barn milking system, which is a type of facility that milks cow in the same place (tie-stall or stanchion barns) where the cows are kept (Reinemann 2013).

21.7.4.2 Computerized Milking Systems or Robotic Milking and Feeding Systems

Computerized milking systems also known as automated robotic milking systems is a system that automatically attaches cups to the udder teats of cows. AMS allows voluntary milking of motivated cows three to four times daily as it pleases them, which has been shown to increase milk production by 5–10% (De Koning 2010). AMS help cows to relieve the pressure of milk in their udders. However, if there is no milk in the cow udder and the cow enters the AMS, the cow will be automatically turned away. The AMS are also connected to automatic feeding and cleaning systems. Lactanet (www.lactanet.ca), a Canadian Dairy Production Center of excellence and established by the Dairy Farmers of Canada, has introduced a new electronic milk recording service called electronic Dairy Herd Improvement, which allows farmers to record herd data remotely without the help of a technician, but this service is only available to farmers using AMS and milk parlor systems on their farms (Lactanet 2021). In New Zealand, the AMS was used on cows reared in paddocks or on pasture-based systems following the Greenfield project in 2001 at DairyNZ's Greenfield Project farm. In this scenario, the cows on the Greenfield farm move from the paddock to the AMS and then back to the paddock (Science Learning Hub 2017). The movement of the cows is directed by installation of temporary

fences and computer-controlled gates. Also, the cows are moved to the robotic milking stall paddock by giving them incentives, such as water or fresh grass. The AMS is used in identifying individual cows, milking cows, recording individual cow behavior, milk quality and quantity, and cow's health status. After the 2001 Greenfield project, several farms (organic pastoral farms, fully housed systems, and herds ranging from 180 to 800 cows) in New Zealand are now making use of AMS for milking their cows (Science Learning Hub 2017).

In Sweden, a large Swedish producer of dairy and farming equipment, DeLaval International installed 24 AMS (Robotic Voluntary Milking System) that are capable of milking 1500 cows at TDI Farms LLC (Westphalia, Germany) (Amelinckx 2016). The producer installed the AMS to increase the efficiency of his farm through low cull rates and high cow longevity, since the AMS has been programmed to monitor udder health and identify mammary gland infections at an early stage. This firm also installed another 64 Robotic Voluntary Milking Systems in Los Angeles that can milk 4500 cows (Amelinckx 2016). In Michigan, there are presently 243 AMS installed on 55 farms (Michigan Department of Agriculture and Rural Development data (Malacco 2022)). The reasons for adopting AMS are different from one farm to the other. Small dairy farms adopt AMS to attain more flexibility in work schedules and better well-being of their workers while large dairy farms adopt AMS because of shortage of labor as well as to reduce the number of hours spent on cows per day (Malacco 2022). In general, the use of AMS on farms has resulted to reduction in the cost of labor (84.6%), improves welfare of cows (76.9%), reduce human labor (69.2%), improves overall cow well-being (50%), improves cow reproductive performance (36%), and improves herd performance (73.1%) (Malacco 2022). Although the use of AMS is very efficient, the decision to transit from conventional methods to AMS depends on the size, needs, and objectives of the farm operation (Malacco 2022).

The production of AMS is undertaken by many companies including Lely (Lely 2022), DeLaval (Amelinckx 2016), and GEA (GEA 2022a). For instance, GEA Farm technologies, a German company has built DairyProQ, a robotic rotary system that is in use on two dairy farms in Germany and two in Canada (GEA 2022b), and also GEA Dairyrobot 9500 robotic milking system that has been engineered to improve the milking process (GEA 2022c). Due to the flexibility in the machine design, it supports voluntary milking of cows and the milking of cows in group at specific times of the day. The system can also be used in milk parlors. The GEA's in-liner performs all the steps involved in milking cows, such as stimulation, teat cleaning, fore-stripping, milk harvest, and post-dipping just in a single attachment. The GEA DairyMilk M6850 sensor technology monitors individual cow udder quarter during milking without using chemical consumables or reagents. This machine facilitates early detection of infected quarter(s) (infected with mastitis pathogens) due to their pioneering sensor-based technology (GEA 2022c).

At the University of Melbourne Dookie Dairy Farm, daily milk production, milk temperature, milk quality (somatic cell count, milk fat, and protein%), cow weight, and concentrate intake are collected automatically using a Lely Automatic Milking System, which also identifies individual cows via RFID ear tags (Osei-Amponsah et al. 2020). Additionally, each cow is fitted with a transponder (Qwes-HR, Lely) that contains a rumination monitor. The rumination monitor uses a microphone to detect chewing sounds and differentiates between eating and rumination time (Osei-Amponsah et al. 2020).

21.7.4.3 Using a Feed Nutrition Expert

In large-scale milk production, it is very essential to understand and provide adequate nutrition to improving cow health and milk yield. Proper feed management practices can help to reduce the excretion of specific nutrients in manure. The USDA-Natural Resources Conservation Service defined feed management practice standard as managing "the quality of available nutrients fed to livestock for their intended purpose." As a result, it is important to have an animal nutritionist with experience in dairy feed formulation and

Fig. 21.8 Sample pasteurization system for large-scale use (Tubular Aseptic UHT Pasteurizer with Vacuum Deaerator)

nutrient management to improve animal health and promote milk yield.

21.7.4.4 Technologies for Pasteurization, Cooling, and Storage in Low to High Input Systems

Milk pasteurization is a process by which milk is subjected to heat treatment to kill or inactivate organisms that cause spoilage, which in turn extend milk shelf life and promote food safety. Different thermal processing methods are commonly used, such as thermization (57–68 °C for 15 min), batch pasteurization (63 °C for 30 min), flash pasteurization (72–74 °C for 15–20 s), ultra-high temperature (UHT) pasteurization (135–140 °C for 2–4 s) (Fig. 21.8), canned pasteurization (115–121 °C for 10–20 min), and high temperature short time (HTST) pasteurization (72 °C or 161 °F for 15 s or above) systems (Aryal 2019). Generally, the steps in milk pasteurization include chilling of milk (2–5 °C) (to arrest bacterial growth), pre-heating (40 °C), and standardization to separate butter fat, clarification (to remove milk sediments), homogenization (to break down the milk fat globules into tiny droplets to prevent milk separation), heating (from 60–72 °C in order to kill microbial spores, such as *Clostridium botulinum* spores), milk holding (where milk is held at a constant temperature for at least 16 s in the holding tubes) and milk cooling/chilling of pasteurized milk to 4 °C before pumping to the packaging machines for aseptic packaging and storage in the cold room (Aryal 2019). Pasteurization systems for small scale use are also available, such as P-3000 SafGard 2 gallon and Milky FJ50PF multipurpose 12-gallon milk pasteurizers (Farmandranchdepot.com). There are different types of commonly used cooling systems including direct expansion cooling system with pre-cooling of milk, ice bank cooling system without pre-cooling, ice bank with pre-cooling of milk, and solar thermal solutions (Upton et al. 2015).

21.8 Technologies to Improve Competitiveness in Pastoral Production Systems

Pastoral farming, also known as nomadic farming, refers to a farming system whereby farmers rear animals (e.g., cattle, sheep, goat, camel and donkey) on a large scale and move them from one place to another in search of water and food (see Chapter 2 for more information on pastoralism in Africa). Pastoralism is a traditional system of livestock farming mostly practiced in the arid and semi-arid areas of East Africa, Southern Africa, North Africa, West Africa, and Central Africa. Pastoralism is mostly practised by persons belonging to some ethnic groups including the Tuareg, Fulani, Mbororo, Peul, Maure, Ababdeh, Afars, Beja, Berbers, Borona Oromo, Dinka, Gabra, Karamojong, Maasai, Mrazig of Tunisia, Nuer, Pokot, Rendille, Sahrawis, Samburu, Somali, Toubou, Trekboers, and Turkana. More than 90% of meat and over 50% of milk produced in East Africa comes from pastoralists (FAO 2022). Pastoral livestock (e.g., cattle) is not only meant for food production, but also for social status satisfaction, domestic fuel, and farm power (Suleiman et al. 2015). Countries such as Sudan, Kenya, Somalia, and Ethiopia generate revenue from exporting livestock from pastoralists to Gulf countries (FAO 2022). However, pastoral farmers are faced with a lot of challenges because pastoral farming is mostly practiced in the dry areas where crop production is less favorable, thereby causing an increase in livestock competition for land use. The growth in human population has resulted in an increase in the use of land meant for livestock grazing for other purposes, such as infrastructure, intensive crop agriculture, and housing. Clashes between pastoralists and crop farmers are becoming more rampant mostly when cattle feed on crops cultivated for human consumption or when a grazing land has been converted to cropland. Likewise, irrigation farming can reduce access to communal water and prevent dry season grazing for pastoral farmers. This has triggered the migration of some pastoralists to other parts of the country where they can have access to green pasture and water for their animals. For example, in Nigeria, the movement of cattle from the northern parts to the southern tsetse fly-infested zones may increase exposure of the animals to tsetse fly bites and eventually trypanosomiasis. The animals can also be exposed to other diseases like foot-and-mouth disease, mastitis, pneumonia; therefore, reducing animal productivity, and numbers through death of animals (Suleiman et al. 2015). The improvement of pastoral farming is therefore necessary for optimum animal performance and income generation.

21.8.1 Best Management Practices for Pastoral Farming

Rotational grazing is one of the best management practices that pastoral farmers can utilize for better animal management (MacPhail and Kyle 2012). It is a situation whereby cows are moved from one area to another with the intent of allowing only a portion of the grazing area to be grazed at a time while the other portions rest (Undersander et al. 2002). This is to give the pasture and soil enough time to recover. Rotational grazing helps to increase pasture quality, promote cattle health, and lead to sustainable environment. For good pasture management, the number of animals must be balanced with available forage supply, livestock must be evenly distributed but should be excluded from sensitive areas when conditions are not suitable for grazing (pastures too wet or dry), and there must be balance between the period of grazing and rest to maintain the pasture. Paddock (an enclosed field of grassland that is meant purposely for pasturing or grazing livestock) is increasingly finding being adopted for pastoral livestock management. Fences, such as permanent page-wire, barbwire, or high tensile strength electric fences can be used to surround the grazing field while temporary poly-wire fences can be used to subdivide fields into smaller paddocks (MacPhail and Kyle 2012). There must be access to drinking water situated in close proximity (about 800 feet is rec-

ommended) in each paddock. Windbreaks can be planted around the paddocks. Also, mixture of forages should be grown in each paddock because every forage has their own susceptibility and resistance to insect, disease, or environmental conditions (mixture of legume and grasses) (MacPhail and Kyle 2012; Undersander et al. 2002).

In Africa, pastoral cattle feed mostly on native pastures; therefore, there is a need for adaptation of the technology that can improve pasture quality, preserve natural resources, and boost soil health. Farmers in New Zealand are the first adopters of technologies to improve forage quality (Caradus et al. 2020). This is because farmers in New Zealand practice more of pastoral farming when compared to other developing countries. For instance, the cultivation of the herb, chicory, is gaining importance in New Zealand because it can be used to improve soil fertility. Chicory has high mineral content, and it is deeply rooted and can take up minerals and nutrients in the soil for proper growth and development. The perennial ryegrass is also another forage crop used by pastoral farmers for cattle feeding (Caradus et al. 2020). It lives in a symbiotic relationship with a fungus known as "endophyte" to protect itself from insect pests (such as argentine stem weevil, black beetle, root aphid, pasture mealy bug, and porina). AR37 is the most recent endophyte of ryegrass commercialized in New Zealand. It does not produce alkaloid compounds lolitrem, peramine, or ergovaline, but it production of indole diterpene like compound, epoxy-janthitrem, makes it unique when compared to another endophyte, AR1 endophyte which produces more of ergovaline. Re-grassing of ryegrass with AR37 only requires 8 years interval. Research has shown that there was a 12% increase in the DM of ryegrass containing AR37 endophyte. Likewise, cattle fed with AR37 ryegrass had increased production of milk solids with no adverse effect on animal health (Caradus et al. 2020).

21.8.2 Precision Livestock Technologies for Better Productivity in Pastoral Farming

Precision livestock farming is the proper use of data analysis and modeling for the purpose of informing management about animal reproduction status, feed regimen, and productivity status. All the information gathered can be used to understand and predict animal health and welfare (Neethirajan and Kemp 2021). Precision livestock technology is a powerful tool that can improve pastoral farming in terms of animal productivity capacity, welfare, or management (Odintsov Vaintrub et al. 2021). Recently, technologies, such as biometric sensors, have been developed to monitor behavioral and physiological parameters of livestock. These enable farmers to monitor animal's health and welfare remotely. Biometric sensors can either be invasive or non-invasive. Invasive sensors are used for monitoring the internal behavior of the animal, such as the rumen health, body temperature, and vaginal pressure. However, they are not mostly used in animal production, because they are typically swallowed or implanted in the animal. The predominant sensors used in the livestock industry are non-invasive sensors which are also suitable in pastoral livestock farming. These include surveillance cameras, sensors to measure the feeding system of the animal, and to monitor animal weight gain and feed intake (Neethirajan and Kemp 2021). Other technologies that can be adopted by pastoral farmers include drones for checking fence lines, water-troughs, and for monitoring pasture quality more effectively through aerial images and video; RFID for identifying or tracking tags on animals, to monitor human-animal or cow-calf interactions, image analysis for detecting excessive mounting, accelerometer for estimating locomotion, and so on. However, all the information gathered by this technology needs proper interpretation for the

purpose of making informed decisions (Odintsov Vaintrub et al. 2021).

21.8.2.1 Electronic Animal Identification, Sensors, and Automatic Drafter and Weighing Systems in Pastoral Farming

Electronic identification, like RFID system, is used in pastoral farming for independent identification of individual animals for the purpose of collecting data and storing them for decision making (Odintsov Vaintrub et al. 2021). The RFID operates on divergent level of radio frequency (noise to signal ratio): low frequency (LF, 125–134.2 kHz), high frequency (HF, 13.56 MHz), and ultra-high frequency (UHF, 860–915 MHz). The HF and UHF allow anti-collision, longer distance, less noise, and stable connection. However, LF is less stable, but it can pass through obstacles when compared with HF and UHF if a larger antenna is used (Odintsov Vaintrub et al. 2021). Passive EIDs tags can be used for identifying animals and it involves the use of copper coils that charge transmitters through the energy that passes through an active reader to store information. Passive EID does not require a battery, and this makes it ideal for pastoral farmers (Holje 2012). However, ear tagging is the most common method used by farmers for animal identification because it is easy to use, less costly, and does not require a high level of expertise. The EID can also be enclosed in a ceramic bolus and inserted into the rumen. This bolus EID is permanent and cannot easily get lost or malfunction. However, bolus EID is only suitable for matured animals, while smaller boluses can be inserted in smaller animals for greater efficiency (Hentz et al. 2014).

Sensors (discussed in Chapter 20), are increasingly used in pastoral farming. For example, sensors can be used to create virtual fencing for pastoral livestock management. Virtual fencing serves as electronic barrier in place of physical barrier. Animal movements are restricted by a visible and/or audible system attached to an electric stimulus. Virtual fences are used in moving animals wearing a sensor remotely from one area of pasture to another (Campbell et al. 2020). However, the use of virtual fencing may pose risk to animal due to their long-term exposure to the electric stimulus; thereby affecting their welfare and also arousing public concerns (Lee et al. 2018). With the use of global positioning system, collar sensors connected to the global system for mobile communication or connected to a Sigfox network, and with low-cost Bluetooth tags, animals' movement in the grazing area is tracked remotely using a software, thereby keeping farmer informed of animals' behavior and location at all times.

Automatic drafter, weighing crates, or walk overweight are examples of stationary tools that are placed in the gate of a paddock for the purpose of distinguishing and directing the movement of animals. Automatic drafter recognizes the EID of individual animals which facilitates data collection, feeding control and labor efficiency during animal selection for sale, treatment of diseases, and sheering. Other systems like walk overweight, which only allows animal to pass through one way for the purpose of weighing, is placed at a specific angle of a paddock for communication with individual animal EID for data collection.

21.8.2.2 Machine Learning and Artificial Intelligence in Pastoral Farming

Machine learning (discussed in Chapter 20) is valuable in pastoral farming in the areas of animal monitoring, data capture, and prediction of disease and soil properties for pasture management. Regression algorithms are the backbone for predicting soil properties, weather, and crop yield. Deep learning algorithms (convolutional neutral network) and machine learning (support vector machines and random forest) can be used in identifying disease and weeds in forages planted (Sharma et al. 2021). Machine learning algorithms can be used to determine the maximum amount of fertilizer to be applied to soils before planting forages for animal grazing. Cameras attached to drones are used for monitoring pasture growth, spray pesticides, and for drip irrigation. Deep learning can therefore be used to

examine all the images captured by drones for the forages grown, for disease and weed identification. The drones can then be used to spray pesticides on infected grasses and weeds. Drip irrigation attached to drones is an effective system of irrigation because they can denote weather pattern and can reduce water problems for farmers drastically. Likewise, robots can be used alongside with drones for field monitoring (Sharma et al. 2021).

There are different technologies that can also be used to monitor soil and pasture quality. Internet of Things (IoT) is a smart farming system that can be used to monitor soil nutrients and soil moisture content using sensors (Sharma et al. 2021; Tekin et al. 2021). The use of remote sensing, such as unmanned aerial vehicle, manned aircraft, and satellite imagery can be used to predict grass yield and quality. Automated grass measurement system, Grasshopper (GH), is another tool for pasture management (Odintsov Vaintrub et al. 2021). It evaluates herbage mass by means of a microsonic measurement device and transmission of real-time data. The GH is used in measuring the time of return of a sonic transmission from its reflective circulate plate that is placed on a grass emitter (Odintsov Vaintrub et al. 2021). Global positioning system is used for the integration of data that provide information needed for the planning of animal movement and pasture availability for the year (di Virgilio et al. 2018).

21.9 Challenges, Future Perspectives, and Conclusion

Livestock farming is the cornerstone of agriculture in Africa, engaging about 90% of Africa's rural population. However, sustainable smallholder livestock farming is hindered by many factors hitherto discussed in Chapter 20 (Section 20.2) including (1) limited access to modern technologies and information; (2) limited technical and technological capacity; (3) poor/lack of supporting infrastructure; (4) limited access to markets and/or lack of market orientation and/or lack of market infrastructure and/or weak market linkages; (5) inefficient/insufficient input and service delivery; (6) limited feed resources and grazing lands; (7) limited and/or lack of private sector investment; (8) limited financial capacity; (9) limited government support; (10) weak regulatory institutions; (11) lack of supporting government policies; (12) limited or lack of robust collaboration structures among relevant stakeholders (farmers/producers, research institutions, agro-industries, and Government) in the livestock sector; (13) climate change, other environmental factors, etc. (Gebreyohanes and Mwai 2021). The adoption of modern technologies and in particular, genetic technologies have been responsible for majority of improved gains realized in several livestock traits. For example, genetics selection alone accounts for 85–90% of the changes in growth rate of broiler chickens irrespective of the significant improvements in poultry nutrition and management (Havenstein et al. 2003). Moreover in year 2001, a typical broiler chicken was ~5 times as large as a 1957 broiler at 42 days of age (Havenstein et al. 2003). In general, the adoption of modern technologies in all areas of livestock management and breeding will positively impact animal agriculture in Africa. For example, the results of a recent study of 291 smallholder livestock producers in four communities in Zimbabwe, indicated that emerging technologies have significant and positive impacts on risk management activities since the use of digital technologies enhanced risk mitigation and value chains in smallholder livestock farming, thus indicative of a strong need for the adoption of emerging technologies in smallholder livestock farming (Gwaka and Dubihlela 2020). The outcome of this study is not surprising since Delgado and colleagues suggested in 1999 that progress in technological innovations in the production, processing, and distribution of livestock products will be central to achieving a positive outcome of the "Livestock to 2020 : the next food revolution" (Delgado et al. 1999). Within the Africa Union Agenda 2063, increasing livestock productivity is a key component and the adoption of innovative technologies will be crucial in attaining objectives of the livestock sector.

The efficient application of modern technologies in enhancing animal productivity requires a commercial setting. The dominant smallholder systems in the livestock sector in African possess a challenge in terms of the cost-efficient application of these technologies due to high cost and inadequate technological skills. However, several pilots of these technologies or application of these technologies have been attempted for the dairy, beef, and poultry sectors in Africa.

Over the past decades, the adoption of innovative modern technologies has seen transformation in various livestock sub-sectors including a four-fold increase in broiler chicken body size with the same amount of feed input and doubling in the amount of milk produced by a Holstein cow due to implementation of technologies, discussed in sections above, to improved feed efficiency and milk production (Ibeagha-Awemu and Yu 2021). It was indicated recently that improved livestock productivity relies on enhancing the rate of genetic gain for target phenotypes or outcomes and breeding programs, for example, will embrace enhanced measures that increase selection accuracy, intensity of selection, and genetic diversity while reducing the generation interval, such as improved management practices, improved nutrition, improved health care, improved genetic/genomic selection, and reproduction technologies (Ibeagha-Awemu and Yu 2021)..

In some African countries, the introduction of modern technologies has resulted in increased livestock productivity and farm incomes. In Senegal, the implementation of a dairy processor and a milk collection center, representing a new format of smallholder livestock development, created a new dynamism in production activities such as extension services and a consistent market opportunity through increased local productivity and increased incomes (Habanabakize et al. 2022). To harness the growth and opportunities, however, it is imperative to establish robust and continuous collaboration structures between the Government, agro-industries, and producers or farmer clusters in a public-private partnership that will help producers lower the cost of inputs and services and increase productivity while boosting local dairy production (Habanabakize et al. 2022).

The African Chicken Genetic Gains (ACGG) program, now Tropical Poultry Genetic Solutions (TPGS) (https://africacgg.net/) is a practical example of how modern technologies and technical know-how with the participation of relevant expert institutions harnessed in a farmer-oriented manner delivered and achieved increased livestock productivity and farm incomes. The ACGG was initiated in 2014 in Ethiopia, Nigeria, and Tanzania, and recently extended to include Kenya, Ghana, Zimbabwe, Cambodia, Myanmar, and Vietnam, leverages numerous partnerships and innovation platforms to engage farmers, private sector actors, policymakers, and professionals (geneticists, human and animal nutritionists, and social economists) to deliver better and more contextually appropriate chicken genetics to smallholder farmers. The TPGS is working to characterize chicken ecotypes based on farmer preferences in order to develop chicken lines that are better-producing birds with low inputs and environmentally resilient (Dessie 2021).

Given the limitations of the smallholder system, large scale and cost-efficient application of modern technologies will require public-private partnerships between farmers, private industry, and embryo transfer practitioners as the case in Brazil (Viana et al. 2017) to drive productivity in the livestock sector. In addition, the formation of farmers' co-operatives will facilitate large scale and efficient applications of modern technologies among members and provide market outlets for their products. More in-depth practical examples of the application of modern technologies in African livestock production systems are discussed in Chapters 22, 23, and 24.

These practical examples in Africa and described technologies in sections above demonstrate that the modern technologies necessary to advance African livestock productivity are available and applicable in African livestock production systems.

In conclusion, the modern technologies presented above and technical know-how have been key drivers to increased livestock productivity in Western countries, and practical examples in

Africa demonstrates that their adoption is feasible and can facilitate rapid progress in efforts to increase livestock productivity in various African livestock production systems. The presented technologies are not an exhaustive list of existing and future technologies but presents opportunities for their implementation for sustainable livestock production within the various livestock production systems in Africa.

22 Prospects for Utilization of Modern Technologies for Cattle Improvement in Africa

Sunday O. Peters, Eveline M. Ibeagha-Awemu, Iliya D. Kwoji, Raphael Mrode, Michael O. Ozoje, David A. Mbah, Isidore Houaga, Moses Okpeku, Peter O. Fayemi, Daniel Trocmé, Oluyinka Opoola, and Matthew A. Adeleke

Abstract

This chapter discusses the prospects of the utilization of modern technologies for cattle improvement in African livestock production systems. The first section gives a general overview of modern technologies and their application for improving cattle in the African continent. Section 22.1 discusses the general overview of how different molecular information improves the development of large ruminants in Africa. The section outlines some practical case studies where molecular information has been used for the detection of genomic variations in African cattle and buffalo, the use of genetic markers to assign individuals to breeds, and parentage identification. It concludes with the use of molecular information in gene editing and transgenic animals in animal production. In Sect. 22.3, the prospect for the application of modern technology in developing livestock feeds and feeding

is discussed with practical examples. The subsequent sections discuss the application of modern technologies in improving livestock housing and husbandry systems (Sect. 22.4). Other modern technological advancements, including the development of diagnostic tests for detecting genetic defects using single nucleotide polymorphisms (SNPs), using genomic markers for selective breeding, and genome editing to improve productivity and control of deleterious alleles in livestock, are also discussed. The chapter also reviews the application of modern technologies to improve livestock health. In each case, practical examples are outlined as case studies where the technologies are applied in the African setting. The chapter concludes by looking at challenges and constraints in the implementation of modern technologies in cattle and buffalo production in Africa. Potential solutions are suggested.

22.1 Introduction

The development and application of modern technologies in science have been instrumental in driving every sector of human endeavours for sustainable development and understanding complex processes. The application of technologies has made everyday work easier in the agricultural sector 1. An extensive review of modern technologies and how they are being applied to improve productivity in the livestock sector in Africa and worldwide is presented in Chap. 21. Advancements in molecular biology have aided in understanding the genome and its influence on phenotypes. Further developments in the milking process have led to the introduction of milking robots, which have brought new advantages to the farmers, such as labour efficiency and automatic recording of several animal-related parameters (Groher et al. 2020). Today, farmers are faced with a wide range of new technologies and the uncertainty of their effects on the sustainability of farming systems (Anderson 2010; Frezal et al. 2021). Technological innovations and developments are rapidly evolving. Sensors of various kinds are being developed to monitor real-time milk quality, health, and pregnancy hormones. In addition, virtual fences can remotely move animals wearing these sensors from one pasture area to another. Even robotics is advancing fast in the livestock industry, addressing the challenges of labour shortages in livestock farms. About 12% of dairy farms are using robots, which is expected to grow to 20% in the next 5 years, according to Collado et al. (2018). However, several factors facilitate the adoption of new technologies in sustainable farming systems.

There is a significant interest in applying advanced technologies for the improvement of livestock production in Africa. Demand for animal-based source foods (ASFs) such as meat, milk, and eggs in Africa is increasing (Opoola et al. 2022) and therefore the current ASFs produced do not meet the supply for the growing human population. However, the level of productivity of most African livestock is low, and the adoption of modern technologies will help to drive sustained growth in cattle under different input systems. This chapter reviews the practical application of modern technologies like genomic information, reproduction technologies, growth technologies, and phenomics technologies in cattle production in Africa and other developing countries. References are made to buffalo where appropriate.

22.2 Application of Genomic Technologies in Large Ruminant Production

Traits of economic importance in livestock in terms of productivity, disease resistance, behaviour, and adaptability are the product of the actions and interactions of many genes combined

with environmental factors. Understanding and identifying the genetic basis that controls genetic variation at the DNA level and incorporating such molecular information in animal breeding programmes represent the optimum path for the rapid implementation of livestock improvement. However, unravelling the genetic control of such complex traits at the genome level remains challenging. Still, tremendous progress has been made in the last few decades, especially from the attempts to sequence the genomes of many livestock species. Recent advances in genomic technologies have been presented in Chap. 20. This section examines their various application levels and potential roles in driving genetic improvement and the genetic basis of the adaptation of African indigenous breeds. African cattle breeds have been extensively covered in Chaps. 3 and 4.

22.2.1 Detection of Genomic Variations in African Cattle and Buffalo Populations

The discovery of SNPs during the sequencing of the human genome shifted attention to their use as markers due to their abundance in the genome. With the completion of the first human genome draft in the early 2000s (Wakeley et al. 2001), much effort was exerted to sequence the genomes of commonly farmed animal species. Starting in December 2003, the efforts of Richard Gibbs and George Weinstock (Baylor College of Medicine's genome sequencing centre, Houston, Texas, USA) culminated with the sequencing and publication of the first draft of the Herford genome in 2009 (Sequencing et al. 2009). In the same year, another group at the University of Maryland published the genome sequence of the domestic cow (Zimin et al. 2009). Following were the publication of the Bos indicus genome in 2012 (Canavez et al. 2012) and the genomes of the Asian buffalo leech and Egyptian water buffalo in 2019 and 2020, respectively (Canavez et al. 2012; Tijjani et al. 2022). Subsequently, cattle genomes of different breeds have been sequenced including initiatives like the 1000 Bull Genomes project (Hayes and Daetwyler 2019) which resulted in the genome sequencing of animals from different cattle breeds in an attempt to better understand cattle genomes and complex traits. The incorporation of this information into breeding strategies to improve the rate of genetic improvement. More recent efforts include building the pangenomes of cattle breeds to better catalogue genomic variations in cattle and buffalo populations worldwide (Zhou et al. 2022; Smith et al. 2023).

Depending on the species and population, SNPs, the most abundant form of genomic variation, occur in every 1000 nucleotides on average, implying that there are approximately four (4) to five (5) million SNPs in a typical bovine genome. The abundance of SNPs and the plausibility of genotyping SNPs in large numbers makes them very useful as biological markers in mapping quantitative trait loci (QTL) that are associated with traits of economic importance in livestock and in improving the accuracy of breeding value prediction.

Consideration for the inclusion of genetic marker information in breeding programmes requires knowledge of the available genomic variation and their relationship with traits of interest (Ibeagha-Awemu et al. 2004). Therefore, the first step in deciding to include genetic information in breeding objectives and plans is detecting sequence variations and association with traits. Genomic variations in the form of SNPs, microsatellites, and copy number variants have been detected in some African cattle and buffalo populations and, in some cases, are associated with production traits.

22.2.1.1 Case Studies

Characterizing 28 autosomal markers (microsatellites, SNPs) in *Bos indicus* and *Bos taurus* cattle breeds of Nigeria and Cameroon Ibeagha-Awemu et al. (2004) reported high genetic polymorphisms amongst the breeds, as well as close relationships due to high gene flow between breeds. Rushdi et al. (2017) evaluated polymorphism at eight polymorphic microsatellite loci (BM143, ETH2, BM1706, ETH131, BMS711, BM415, BM6438, and BM1443) and showed their association with milk production

traits in the Egyptian buffaloes (Rushdi et al. 2017). Whole genome SNP panel (Illumina BovineSNP50 BeadChip) genotyping in six South African cattle breeds (Afrikaner, Nguni, Drakensberger, Bonsmara, Angus, and Holstein) indicated that ~56% of SNPs (21,290 SNPs) were polymorphic in the breeds. In contrast, 41% exhibited a high degree of polymorphism (minor allele frequency ≥0.05) (Makina et al. 2014). Furthermore, 33 genomic regions harbouring putative signatures of selection and genes associated with adaptation to tropical climates (KRT25, KRT24, KRT26, KRT27, KRT222, and HSPB9), immune response (CDC6, CYM, and CDK10), and production (MTPN, AJAP1, TGFB1, and IGFBP4) were identified in the same South African cattle populations (Makina et al. 2015).

Further genome characterization of cattle breeds from North Africa, West Africa, East Africa, and South Africa with Illumina BovineHD or BovineSNP50 Genotyping BeadChips revealed high levels of genetic polymorphisms, candidate genes for various traits and positional positive selection regions harbouring genes and QTL for reproduction traits, milk traits, immunity, heat stress, skin and hair properties, genes associated with adaptation to marginal environments and copy number variations (Gautier et al. 2009; Bahbahani et al. 2018). Using the method of whole genome sequencing to characterize the genomes of five indigenous African cattle breeds: Ankole (African Sanga cattle), Boran (East African zebu), N'Dama (West African taurine), Kenana (East African zebu), and Ogaden (East African zebu), Kim and colleagues Kim et al. (2017) reported a high number of genomic variations (mostly SNPs), as well as SNPs specific for the breeds. Compared with three European breeds (Holstein, Angus, and Jersey) subjected to intensive selection for various traits over generations, the African breeds presented higher nucleotide diversity (Kim et al. 2017). From these reports, high levels of genome variation are evident within African cattle and buffalo populations attributable to domestication, migrations, selection, and environmental adaptation to diverse environmental exposures (cold, dry, hot, or humid tropical climatic conditions) and indicative of their potential application in breed improvement for dairy, breed and environmental adaptation traits.

Evaluation of genotyping-by-sequencing (GBS) data of 193 Nigerian cattle from different breeds against whole-genome sequencing data, Mauki (Mauki et al. 2022) and colleagues recorded a high rate of sequence variations and genomic regions harbouring imprints of adaptation and genes associated with growth, reproduction, the immune response, efficiency of feeds utilization, and thermotolerance.

22.2.2 Application of Genetic Markers for Breed Group Assignation and Parentage Identification

African cattle and buffalo populations are mostly under traditional management systems where breeding is not controlled, and gene flow between breeds is high. Recent studies have reported high levels of gene flow and admixtures between African cattle populations (Ibeagha-Awemu et al. 2004; Gebrehiwot et al. 2020). Moreover, the introduction of exotic cattle breeds (e.g. Holstein, Ayrshire, and Montbeliarde) for increasing the productivity of indigenous African populations in the last seven decades has resulted in high levels of exotic genes in local populations. As such, many individual cattle in the continent are of uncertain genetic composition, even when main physical characteristics qualify assignation to specific breed types. With a lack of structured genetic evaluations of the cattle populations (indigenous breeds and the crossbreds) and pedigree records, as well as the inability to assign individuals to specific breed types based on visual traits, genomic variation has been used to assign individual cattle to their respective breed groups or compositions, parentage verification and to make informed decisions on breeding programmes for specific traits.

22.2.2.1 Case Studies

Using SNP genotype data (Illumina BovineSNP50 and BovineHD Beadchips) on 4231 individual animals from various cattle populations in Africa (African *Bos taurus* and *Bos indicus*, European *Bos taurus* and crossbreds), Gebrehiwot et al. (2020) identified 200 SNPs with high prediction accuracy for breed composition. Applying SNP data generated with Illumina BovineHD Beadchip followed by admixture analysis provided accurate information on the genetic composition of breeds and the breed composition best suited for different smallholder production environments (Alexander et al. 2009). A study on the admixture, population structure, and levels of inbreeding in Baoulé and Baoulé x Zebu crossbreds under traditional management systems in Burkina Faso using data on 38,207 SNP genotypes, correctly assigned analysed individuals to their main genetic backgrounds (*Bos indicus* and *Bos taurus*) as well as defined their levels of admixture (Ouédraogo et al. 2021).

In pure breeds of beef cattle, especially those with herd books, accurate pedigree information is essential for the success of their seed stock market and the accurate ranking of breeding stock. For example, using microsatellite markers for parentage identification, incorrect and incomplete parentage recording of up to 14% of individuals was found, resulting in significant re-ranking of the Angora goat sires (Visser et al. 2011; Garritsen et al. 2015). Similarly, Kios et al. (2012) 55.2% of the misidentification of sires and 2.3% of dams in the Boran seed stock in Kenya were reported using DNA-based testing. Visser et al. (2011) reported that about 35% of cattle breeders use DNA parentage testing on a routine basis, especially in larger herds where multi-sire mating is performed.

Working with crossbred dairy cattle in Senegal, genotyped with the Bovine 50 K SNP assay and using population Structure analysis, Tebug et al. (2018) assigned animals to different proportions of ancient Zebu, recent Zebu, ancient Taurine, and recent Taurine, and subsequently defined different breed groups. Based on the breed-composition assignment, Marshal et al. (2017) undertook a trade-off analysis for the various household dairy systems and determined the most productive bred type for each management or production system.

Similarly, for crossbred dairy cattle in Eastern Africa, Strucken et al. (2017) developed an assay of 200 SNPs to determine the breed composition of animals. However, the number of SNPs would increase to 400 if parentage verification was to be incorporated. Also, using SNP data, Al Kalaldeh et al. (2021a) estimated breed proportions for genomic prediction for smallholder crossbred dairy production in India and in determining the performance of these crossbred animals under different environments.

22.2.3 Application of Genetic Markers for QTL Mapping, Marker-Trait Associations, and Detection of the Signature of Selection

Linkage mapping of QTLs using molecular markers is commonly used in conventional breeding. With developments in MAS from the 1980s, information on QTL was incorporated into linear models for genetic evaluations (Weigel et al. 2017). Typically, the estimated breeding value (EBV) of a candidate under selection is determined by summing the estimated effects of several QTLs. Thus, QTL information was employed in MAS of young sires or breed introgression programmes, especially for loci that alter performance attributes or disease resistance/susceptibility (Mitra et al. 1999). Moreover, by determining the coupling linkage relationship between specific alleles at marker loci, breeders can identify genetic markers and QTL that confer favourable traits of interest, increasing the accuracy of selection and the rate of introgression of favourable alleles into desired populations (Soller 1994).

From the 1980s to the early 2000s, genetic markers used for QTL detection were mostly microsatellites and restriction-length fragment polymorphisms. With the developments of next-generation sequencing technologies and the availability of whole genome genotyping assays,

more sequence variations, mostly SNPs and copy number variants, are now applied to map QTLs, detect-market trait associations, and signatures of selection at unprecedented depth.

22.2.3.1 Case Studies

The application of QTL mapping to guide the selection and genetic improvement of African cattle is exemplified by the study of Hanotte et al. (2003) involving the crossing of tolerant West African N'Dama (*Bos taurus*) and trypan-susceptible East African Boran cattle (*Bos indicus*) to identify QTL controlling resistance to trypanosomiasis. To test their hypothesis, 177 F2 animals and their parents and grandparents were genotyped at 477 microsatellite loci covering 29 autosomes. Several identified QTLs were mapped to 18 autosomes, and individual QTL effects ranged from 6 to 20% of phenotypic variants of the trait (trypanotolerance). Results of the study suggest that selection for trypanotolerance within F2 populations could produce synthetic breeds with higher trypanotolerance levels than their parents.

Vohra et al. (2021) Vohra and colleagues conducted a genome-wide association study (GWAS) in Murrah Indian buffalo using 38,000 SNPs obtained by double digestion restriction associated DNA (RAD) tag genotyping-by-sequencing and identified genomic regions associated with lactation (305-day milk yield, lactation persistency, breeding efficiency) and fertility (postpartum breeding interval and age at sexual maturity) traits (Vohra et al. 2021). The same study identified many other potential genomic regions associated with milk yield and fertility in Murrah buffalo.

Following Illumina BovineSNP50 genotyping in East African Shorthorn Zebu, Butana, and Kenana zebu breeds, several regions under selection and intersecting with genes and QTL for reproduction performance, production and environmental adaptation to stress (heat stress and immunity) and dairy traits were found (Bahbahani et al. 2015, 2018). Analysing the whole genome sequences of indigenous breeds of cattle from East, West, and Southern Africa, Kim and colleagues (Kim et al. 2017) identified signatures of selection as well as genes and pathways controlling anaemia, drinking behaviour, feeding behaviour, and circadian rhythm in the N'Dama, heat tolerance or thermoregulation and tick resistance in Ogaden, Boran and Kenana cattle and horn development and coat colour in Ankole (Bahbahani et al. 2018). Investigated the trypanotolerant basis of the Following genotyping of the Sheko breed of Ethiopia (the breed shows better trypanotolerance than other breeds) with Illumina BovineHD Genotyping Beadchip, Mekonnen et al. (2019) reported that the Sheko genome is an admixture of taurine and indicine genomes or ancestries (Mekonnen et al. 2019). Moreover, 99 genomic regions harbouring 364 signature genes and several pathways related to oxidative stress response, which possibly modulates oxidative stress following trypanosome infection, were identified (Mekonnen et al. 2019).

22.2.4 Application of Molecular Markers for Marker-Assisted Selection

By discovering genomic diversity and identifying important genes and genomic variations controlling traits, it is now feasible to implement more informed selection programmes for cattle and buffalo improvement. Therefore, the availability of molecular information, environmental factors, generation intervals, and the cost of rearing cattle or buffalo to a specific age before phenotypes are manifested have all been removed from the selection challenge. Thus, MAS is based on detecting connections between genetic markers, linked QTL, and traits. The distance between the marker and the target trait impacts the marker-QTL relationship. Once QTL markers have been identified, they may be used in selection procedures. Generally, molecular markers find applications in MAS, marker-assisted introgression (MAI) breeding, screening undesirable traits, cross-breeding, and genomic breeding.

Marker-assisted introgression is based on the tandem selection in a multigenerational backcrossing programme, in which a marker based on the presence of donor breed alleles at or near the

target gene is used in the first selection step (foreground selection), followed by background selection of markers based on the presence or absence of recipient alleles at markers spread across the genome, on phenotype, or a combination of the two (Montaldo and Meza-Herrera 1998). Backcrosses with molecular markers may also introduce a significant gene into a population through introgression (Hayes and Daetwyler 2019). When used with targeted selection for specific advantageous alleles known to exist in the donor line or with closely related markers, traditional introgression strategies (introgressing specific QTL alleles) are most likely to succeed (Barton and Keightley 2002). Genomic selection may be used to select all marker alleles in linkage disequilibrium (LD) with beneficial QTL; this method may be especially effective when several QTLs underlying the genetic variation of the trait are of interest (Hayes and Goddard 2001). Marker-assisted selection deployment necessitates developing and integrating procedures and logistics for DNA collection and storage, genotyping, and data processing. Response to MAS is usually at its greatest in the first generation (Goddard 1996). Still, there is a steady drop in response to MAS in succeeding generations, possibly due to increased recombination events leading to linkage equilibrium.

22.2.4.1 Case Study

A case study of MAI was reported by Rothschild et al. (1994) a researcher who found evidence for a QTL affecting litter size in a cross between Large White and Chinese Meishan pigs, which increased litter size by one piglet per litter. This QTL for litter size was found to have originated from the non-commercial Meishan breed. It would benefit commercial populations if introduced into commercial lines, which are superior for meat traits. Other studies involving non-commercial Meishan pigs have found a QTL on chromosome 7 that decreases the backfat depth (Walling et al. 1998). This finding is interesting because the Meishan is significantly fatter than leaner commercial Western breeds; hence, the allele is 'cryptic' (i.e. the allele improved a trait despite being at a high frequency in a breed with poorer commercial performance for the trait).

22.2.5 Application of Molecular Markers for the Detection of Genetic Defects

In addition to genetic selection, genomic variants have rapidly facilitated the detection and prediction of carriers of genetic defects (Biscarini et al. 2016). This has led to the development of various diagnostic tests that offer stud breeders and livestock producers the tool to identify carriers of undesired mutations and select them out of the population. Some methods for detecting genetic defects include haplotype-based predictions (Pirola et al. 2013) and linear discriminant analysis (Biffani et al. 2015). The utilization of lower-density SNP chips for detecting genetic defects has yielded accuracies comparable to those from the 54K Bovine SNP array (Biscarini et al. 2016). Based on SNP genotypes, several diagnostics tests have been developed for cattle. Examples of such tests (Table 22.1) available in South Africa for cattle were summarized by Visser et al. (2011). The tests are relatively cost-effective and find application in both the commercial and emerging farmer sectors in South Africa.

22.2.6 Application of Molecular Markers for Genomic Breeding

While MAS strategies consider one or a few markers with mostly large effects on a trait, whole genomic selection considers thousands of markers and even whole genome data. Thus, genomic selection (GS) involves estimating breeding values using markers spanning the entire genome. Genomic selection implementa-

FreeMartin	Unistel
Cytogenetics: 1/29 Translocation	Unistel

tion in developed countries has consequently resulted in rapid genetic improvement in all traits, particularly lowly heritable traits (e.g. health traits, fertility, and lifespan), selection of animals at an early age, higher rate of genetic gain, shortened generation interval, higher intensity of selection and increased reliability of predicting breeding value (Miglior et al. 2017). Genomic selection also resulted in more artificial insemination (AI) active sires in the United States (Hutchison et al. 2014). For example, in 2007, adolescent bulls accounted for 28% and 25% of Holstein and Jersey inseminations, respectively. Still, these percentages jumped to 51 and 52% in 2012 due to the use of genomic-verified young bulls (Hutchison et al. 2014). In many countries, well-established conventional genetic evaluation procedures have given a solid foundation for the success of GS.

22.2.6.1 Case Studies

Several case studies of GS on African cattle have been reported. Brown et al. (2016) used milk test day information on 1034 cows and genotypes (Illumina BovineHD BeadChip) within the Dairy Genetics East Africa (DGEA) project to investigate the accuracy of genomic predictions for cows of various breed compositions (crosses between indigenous African cattle—N'Dama (*Bos taurus*), and Nellore (*Bos indicus*) and exotic dairy breeds (*Bos taurus*)—Holstein, Friesian, Ayrshire, Jersey, and Guernsey) using genomic best linear unbiased prediction (GBLUP) and Bayes C models (Brown et al. 2016). The study found that genetic prediction accuracy ranged from 0.30 to 0.40 (Brown et al. 2016). Mrode et al. (2018) looked at models with dominance impact and a multi-trait approach that fit breed proportion as independent traits using the same dataset. Although the dominance effects were zero, presumably due to the small size of the dataset, the multi-trait strategy resulted in a tiny improvement in the model's predictive ability, though not in prediction accuracy, when compared to the results of Brown et al. (2016). Another study on genomic prediction of crossbred cattle in Tanzania and within DGEA, consisting of 134,987 test day milk records of 14,741 cows (from 8735 herds) and genotypes obtained with Illumina BovineSNP50 Beadchip reported moderate to high levels of genomic prediction accuracy (0.53–0.83) for body weight and milk yield (Mrode et al. 2021). Similar genomic predictions in crossbred dairy cattle in India have been reported for daily milk yield using only genotypic data (Al Kalaldeh et al. 2021b).

22.2.7 Application of Molecular Information for Gene Editing and Transgenic Animal Production for Livestock Improvement

Developments in gene editing or genetic engineering techniques have increased their application in livestock animals (Perisse et al. 2021; Rieblinger et al. 2021; McFarlane et al. 2019). Gene editing (see Chap. 21) involves the introduction of single or multiple edits (insertions or deletions) or long DNA sequences into specific genome locations simultaneously and precise nucleotide transitions and transversions. Meanwhile, genetically modified or transgenic animal/livestock production is a method by which 'new' or modified genes and DNA sequences can be rapidly introduced into animals without crossbreeding or hybridizing (Wheeler et al. 2003). Transgenic livestock is used to (1) produce new animal products, (2) study the genetic basis of physiological systems, (3) improve animal production, (4) health, reproduction, and adaptation traits, and (5) build human genetic disease models. Thus, in addition to the obvious scientific interest in the study of genes and their regulation, transgenic animal technologies have been proposed as a way to accelerate livestock improvement by introducing new genes or modifying the expression of endogenous genes that regulate economically important traits like milk production traits (Wheeler et al. 2003). Therefore, livestock genome editing and transgene technologies will allow breeders to improve animal health, welfare, performance, environ-

mental adaptation, and efficiency at unprecedented speed, opening the path for more sustainable livestock farming in Africa.

Many livestock traits have been targeted for genetic modification, including traits for disease resistance, nutrient enhancement, milk composition, growth rates, carcass composition, environmental impact, reproductive performance, hair and fibre quality, animal welfare, and climate change (Perisse et al. 2021; Karavolias et al. 2021; Van Eenennaam et al. 2021). While gene editing has been successfully implemented for crop improvement in Africa and proof of concept has been established for resistance to trypanosomiasis in goats, no specific example exists for African cattle (Karavolias et al. 2021).

22.2.7.1 Case Studies

Examples of gene editing applications and transgenic production in cattle are summarized in Table 22.2. For instance, using the CRISPR/Cas12a system, a polled Celtic variant from the genome of an Angus cow was extracted and integrated into the genome of fibroblasts derived from a horned bull, followed by somatic cell nuclear transfer (SCNT) (Schuster et al. 2020). The work effectively established CRISPR/Cas12a's practical application in dairy farming. Furthermore, Sun et al. (2018), generated DNA-free β-lactoglobulin (BLG) bi-allelic knockout cow by ZFNs mRNA, which produced hypoallergenic milk (Sun et al. 2018). ZFNs and other genome-editing methods can establish alternatives to transgenic (genetic modification)-based methods for the genetic improvement of livestock and the production of 'designer' milk for human health benefits.

22.3 Application of Modern Technologies in Feeds and Feeding

The humped (*Bos indicus*) and non-humped (*Bos taurus*) cattle breeds are raised in many agroecological zones for milk, meat, manure, hide, and draught power generation. Details of breeds and classification of cattle have been provided in Chaps. 3 and 4. Bovine meat is the third muscle food consumed worldwide, following pork and chicken. As global meat production is projected to reach 44 M tonnes by 2030 (Frezal et al. 2021), the aggregate consumption of beef veal remains on an upward trajectory. Global milk production is estimated to grow at 1.7% annually and reach 182 M. tonnes by 2030 (Frezal et al. 2021). These estimates considerably depend on the nutritional worth of feedstuffs that constitute the bovine ration at different stages of growth across breeding seasons. Invariably, bioactive compounds in the diet do not only affect feed intake but also the welfare of the animal and the biological value of its by-products. Producers that would spend 55–75% of the total cost of production on feeding would opt for an ideal feeding regime and metabolic modifiers that can inhibit pathogenic invasion, enhance feed efficiency, boost average body gain, carcass weight, milk yield, and profitability of the enterprise (Lamb and Maddock 2009).

Aside from the estimated breeding values**,** feed efficiency (expressed per unit of dry matter consumed, per hectare of pastureland, per unit of nitrogen fed, and per methane produced) is a key performance indicator to determine the genetic merit of each trait and profitability of beef-dairy cattle husbandry. To optimize beef-dairy productivity indices, metabolic modifiers that can aid ruminal microflora, the bioactivity of beta-adrenergic agonists, and hormone-like growth enhancers have been prioritized in beef-dairy cattle feeding regimes.

22.3.1 Probiotics and Prebiotics Supplements

Maintaining microbial balance in the gastrointestinal tract (GIT) is vital in nutrient utilization. On a broad scale, the dynamics of the GIT network interact with the circulatory, endocrine, immune, and nervous systems to modulate the immunologic and metabolic markers of the host (Alfonsetti et al. 2022). The significance of gut-intestinal microbiota in health promotion makes the utilization of probiotics, prebiotics, and symbiotics, a better alternative for realizing feed effi-

Table 22.2 Examples of gene editing application and transgenes in cattle

Transgenic animal and gene manipulation outcome	Technique	Trait	References
Human recombinant lactoferrin expressed in bovine milk	Somatic cell nuclear transfer (SCNT)mmm	Innate host defence, milk composition	Van Berkel et al. (2002)
Milk with higher levels of CSN2 (β-casein) and CSN3 (κ-casein) proteins	Gene knock-in	Milk composition	Brown et al. (2016)
Cows secreting lysostaphin in milk	Somatic cell nuclear transfer (SCNT)	Enhance mastitis resistance	Wall et al. (2005)
Expression of human recombinant lysozyme in bovine milk	Somatic cell nuclear transfer	Animal health, disease resistance, milk composition	Yang et al. (2011)
Dairy cows expressing omega-3 fatty acid desaturase gene	Nuclear transfer	Tissue and milk fatty acid composition	Wu et al. (2012)
MiRNA-directed depletion of β-lactoglobulin (BLG) (an allergen) results in the production of BLG-free milk with high-casein content	Gene knockdown	BLG-free milk, milk composition	Jabed et al. (2012)
Animals expressing shRNAs targeting the myostatin (MSTN) gene	Suppress MSTN expression by RNA interference and somatic cell nuclear transfer	Enhance muscle development	Tessanne et al. (2012)
Beef cattle expressing omega-3 fatty acid desaturase (FAD3)	Somatic cell nuclear transfer	Muscle tissue fatty acid composition	Cheng et al. (2015)
Cattle with site-specific knockin of transcription activator-like effector (TALE) nickase-mediated nuclear body protein gene (SP110)	Transcription activator-like effector nuclease (TALEN)-mediated editing (gene knockin)	Enhance resistance to tuberculosis (tuberculosis-resistant cattle)	Wu et al. (2012)
Cattle with Cas9 nickase (Cas9n) induced generation of the natural resistance-associated macrophage protein (NRAMP1) gene	CRISPR/Cas9n mediated gene knocking and SCNT	Enhance resistance to tuberculosis	Gao et al. (2017)
Cow-producing BLG free-milk	zinc-finger nuclease (ZFNs) knockout of BLG and nuclear transfer	Hypoallergenic milk, milk composition	Sun et al. (2018)
Cattle harbouring knockout alleles of the Nanos C2HC-Type Zinc Finger *2 (NANOS2)* gene	CRISPR-Cas9 editing and spermatogonial stem cell transplantation	Male germline ablation, surrogate sires for genetic dissemination	Nigam and Bhoomika (2022)
Polled offspring with Polled Celtic variant (202 base pair insertion-deletion (indel) on bovine chromosome 1)	CRISPR/Cas12a knock-in and SCNT	Polled dairy cattle	Schuster et al. (2020)
Deletion of three bp in pre-melanosomal protein 17 genes (PMEL), the causative variant of semi-dominant colour dilution phenotype	gRNA/Cas9-mediated editing	Adaptation to climate change	Laible et al. (2021)

ciency in cattle production (Atılgan Türkmen 2020). Bifidobacteria, Enterococci, Lactobacilli, yeasts, and combinations of different beneficial strains are viable probiotic bacteria and gut modifiers commonly used to stimulate efficient feed conversion and average daily gain in feedlots (Varankovich et al. 2015). *Aspergillus oryzae*, *Saccharomyces cerevisiae*, *Lactobacillus acidophilus*, and other multistrain probiotics are known for stabilizing gut microbiota, improving ruminal fermentation, limiting the risk of pathogen colonization, enhancing growth and the pro-

duction of milk during early-lactation in cows (Singh et al. 2015). For instance, *Lactobacillus acidophilus* BT-1386 has been used in finishing feedlot cattle to increase feed efficiency, average daily weight gain, and reduce diarrhoea in ruminants and milk yield (Lambo et al. 2021).

A plethora of investigations have reported on the benefits of supplementing the diets of livestock with various feed supplements (Singh et al. 2015). Despite the derivable benefits from the incorporation of probiotics in the diets of ruminants, very little exists in the literature on the implementation of this technology in ruminant production on the African continent apart from a few reviews (Ibeagha-Awemu et al. 2024). However, the use of probiotics in poultry (Reid et al. 2014) and swine (Ohimain and Ofongo 2012) production is more popular in Africa. Research efforts to implement the use of these supplements in ruminant production in Africa are much needed.

With proper compliance to standard practices, conformity to ethical practices, and effective consumer cum stakeholder orientation, a beef-diary enterprise (Kwoji et al. 2021) can meet the millennial goal of meeting dietary proteins by all categories of consumers in 2030. This is also poorly explored in cattle production systems in Africa, hence should be encouraged to improve productivity.

22.3.2 Technologies for Dry Season Feed Production

The demand for improved pasture, especially for milk production and sustenance of the African beef industry, has grown considerably. A thriving but ancient traditional method of combatting dry season feeding challenge for ruminants is planting deciduous trees, which produce lots of green leaves all year round from where leaves are harvested to supplement feeding for cattle. Although this is very productive in keeping animals alive, it is more suited for raising small ruminants like goats, which are more sure-footed in climbing trees to reach even the farthest leaves. Nevertheless, this is less suitable for dairy products as the nutritive value of such tree plants begins to decline with prolonged periods of the dry season.

A large portion of the grazing areas in Africa are subjected to numerous climatic challenges that limit the year-round quality and quantity of available pasture and forages, especially in the dry season, which is more prolonged in some African countries than elsewhere in the world. Adopting local preservation technology, such as silage-making (Ntakyo et al. 2020), from crop residues and farm waste in a time of plenty and kept for future use is common and very helpful. However, making well-preserved silage requires skills and experience; the acidity level in the final product must be right to avoid acidosis. Bacteria treatment and incorporation of nutritive additives provide quality material for storage and extended shelf life. Quality and shelf life depend on the feeding value of ensiled materials. One big challenge would include storage space and the availability of quality storage materials, especially in rural agricultural systems. The technology is common in all ruminant-producing regions of Africa and is the oldest and most explored technology in ruminant production (Ntakyo et al. 2020).

22.4 Application of Digital and Milking Technologies in African Large Ruminant Production Systems

Advances in digital technologies are helping modern farms optimize economic contribution per animal, reduce the drudgery of repetitive farming tasks, and overcome less effective isolated solutions. Farm management and operations will drastically change due to access to real-time data, real-time forecasting, and tracking of physical items in combination with Internet of Things (IoT) developments to further automate farm operations (Akbar et al. 2020; Nasirahmadi and Hensel 2022).

Many new technologies intended to increase the effectiveness of milk generation, improve

livestock administration and management, and increase the productivity and profitability of farm animals and animal products (Groher et al. 2020; Petersburg-Pushkin 2015), Joshi et al. (2019) such as Robotic/Automatic milking systems (AMS), cow activity sensors, rumination sensors, programmed calf feeders, Blockchain, Artificial Intelligence (AI), and machine learning (ML) are among other precision technologies becoming progressively popular in the operations of dairy farming in developed countries and in some parts of Africa. For instance, the Africa Asia Dairy Genetic Gains (AADGG) programme utilizes digital technologies to ensure cutting-edge genetic (and genomic) technologies, farmer training, digital monitoring, and mobile phone technology that supports thousands of farmers across Tanzania, Kenya, Ethiopia, Uganda, and Nepal to rear productive, adaptive and resilient dairy cattle (Mwai et al. 2023). The use of sensor (wearable) technologies for digital monitoring of dairy cattle can greatly impact Africa's extensive cattle production systems by decreasing operational costs due to timely upkeep and monitoring of cattle's welfare and health such as illness, lameness, feed efficiency, and rumination effectively and accurately.

The Digital Twins (DT) in dairy farming hold significant promise to greatly shape the future of animal welfare, production efficiency, sustainability, and management practices (Schillings et al. 2021) if deployed for cattle production systems in Africa. The DT can address key constraints and challenges related to the intensive nature of livestock production systems, which are typically characterized by high levels of input and output (Zhang et al. 2023).

Automated milking systems (See Chap. 21) drastically reduce the labour needed for milking cows. It also allows farmers to maintain a sanitary milking procedure, milk cows at any time of day, and increase milk output. Automatic milking systems are popular in the intensive milk production industry in South Africa and some southern and eastern African countries.

22.4.1 Feasibility of Application

One of the biggest challenges our society is facing and will continue to face is the ability to feed its growing population while minimizing environmental impacts and ensuring human health because, by the year 2050, it has been estimated that the world population will be about 9.7 billion and food production will need to increase up to 60% more to meet the demand (Symeonaki et al. 2024). Similarly, global meat production is expected to double by 2050. This increase in production will only be achieved by a combination of expansion in animal numbers and increased productivity (Food; Organization., A 2018). Livestock production would likely intensify, increasing animal density and lowering the stock person per animal ratio. This will result in less time to monitor and properly manage individual animals. An increase in animal numbers could make their management more challenging, especially if, as was observed in the EU recently, the number of farmers continues to decrease by (Cook 2020). In the UK, while livestock numbers remained stable between 2018 and 2019, the labour force on commercial holdings decreased by 0.3% (DEFRA, U 2020). Having fewer farmers to look after larger numbers of animals likely makes it more difficult to address animal health and welfare challenges. Therefore, farmers need reliable and affordable technologies to assist them in daily management, guaranteeing accurate and continuous individual animal monitoring.

Farmers have always looked to new technologies to increase production efficiency and reduce costs.

There is a growing interest in automating productivity, animal health, and welfare using precision livestock farming (PLF), which increases the farmer's ability to keep contact with individual animals in the growing livestock production intensification (Vranken and Berckmans 2017). PLF technologies are designed to support farmers in livestock management by monitoring and

controlling animal productivity, environmental impacts, and health and welfare parameters in a continuous, real-time, and automated manner, offering the opportunity to improve productivity and detect health issues early. The premise of PLF systems is that fully automated continuous monitoring of individual animals will enhance the ability of the producers to detect and manage animal health, productivity/reproduction, and environmental aspects of their livestock operations (Berckmans 2017). Various systems using technologies such as sensors, cameras, or microphones can directly alert farmers via connected devices (e.g. phones, computers, or tablets) about detected anomalies, thus allowing farmers to intervene early. Research is pointing toward the great potential for these 'smart technologies' to help livestock farmers monitor the welfare of their animals, and several countries are already investing in their development, reflecting their potential to be part of strategies to move toward sustainable agriculture (Rose and Chilvers 2018). Silvi et al. (2021) recently reported on the various levels of adoption of precision livestock technology in Brazil and concluded that understanding the perception of dairy farmers regarding precision livestock technologies is crucial for creating strategic actions that will increase the adoption and usage rate of such technologies.

Understandably, adopting technologies for sustainable farming systems is a challenging and dynamic issue for farmers. The agricultural sector needs to employ a wide range of evolving technologies and farm practices across many different farming systems and structures to meet various changing and heterogeneous demands for food products. Farmers need reliable and affordable technologies in modern livestock production systems to assist them in daily management tasks, guaranteeing accurate and continuous individual animal monitoring (Groher et al. 2020). Undoubtedly, the scientific way of farming and the adoption of viable technologies will enable the farmers to match the pace with the changing agricultural scenario. Livestock farmers want each animal to receive the right care at the right time, place, and amount. These new technologies will help make this happen. When precision livestock farming technology is implemented and understood, farmers can create their data to manage their herds better (Nasirahmadi and Hensel 2022; Krpalkova et al. 2021).

Technology adoption, however, does not guarantee that the technologies will be used optimally. However, the potential of PLF to help reduce the duration and/or severity of diseases and injuries in livestock farming systems is a promising technology that can detect health issues at an early stage and help ensure optimal environmental conditions (Nasirahmadi and Hensel 2022; Buller et al. 2020).

While genetic engineering/transgenesis in cattle improvement is at the commercialization level, gene editing is not yet at that level. The regulatory status still needs to be completed. Genetic engineering/transgenesis may have concerns/risks, but technical and regulatory mechanisms exist in many African countries (CBD 1992) (https://www.cbd.int/doc/legal/cbd-en.pdf). The regulations consider the stipulations of the related Cartagena Protocol and its supplementary Nagoya-Kuala Lumpur protocol to the CBD.

22.4.1.1 Case Study: Genetically Modified Dairy Cattle

Wall et al. (1997) reviewed transgenic methods for improving livestock and dairy cattle. The goals included the search for new products and production efficiency and cost. The strategy was the production of pharmaceuticals for human health and engineering of the mammary gland of cattle to change milk composition for human consumption: alteration of protein and fat levels as well as alteration of milk composition to be similar to that of humans. This could reshape the compensation given to dairy farmers. Since then, several laboratories and companies have pursued these goals and objectives.

The main problems involved the long generation interval in producing transgenic cattle, the very high cost of producing a transgenic cow, inefficiencies (low gene integration rates, low survival of embryos, and unpredictability of the behaviour of the transgene involved.

The bovine somatotropin gene was isolated and inserted in bacterial cells for massive produc-

tion of recombinant BST, and cows injected with 30 mg of it increased milk yield by 10–30% (Wall et al. 1997). This increase was more dramatic in the zebu cattle (Mbah 2006).

Brophy et al. (2003) showed the potential to enhance milk composition and processing through increased casein proportion. The introduction of additional copies of genes encoding cattle beta-casein (*CSN2*) and cattle kappa–casein (*CSN3*) into cow fibroblasts resulted in 11 transgenic calves. Analysis of hormonally induced milk from these transgenics revealed high levels of transgene–derived caseins in the milk. Nine cows of the high expressing lines gave milk containing an 8–20% increase in beta-casein and a two-fold increase in kappa–casein. These results indicated the potential to alter major milk components by transgenic methods and improve milk composition.

Assessment of differences in the composition of milk and cheese from transgenic and cloned cattle has been made by Laible et al. (2021). The components involved were amino acids, fatty acids, minerals and vitamins, and colostrum. Results indicated that levels of these components in milk were similar between transgenic and non-transgenic cows. Colostrum IgG levels were also similar. In cheese, fatty acid levels were lower than in non–transgenic cheese. Salt levels were higher in transgenic cheese than in non-transgenic cheese. Amino acid levels showed small differences between transgenic cheese and non-transgenic cheese.

Yang et al. (2008) reported using cattle mammary bioreactor to produce recombinant human lactoferrin (rhLF) through transgenic cloning. Using 2 transgenic cows secreting rhLF at good levels, they found that glycosylation was similar to that of the lactoferrin of man (hLF). Its proteolytic susceptibility was also similar to that of man. Further analysis revealed that the properties of iron-binding/releasing were similar to those of non-recombinant hLF. Thus, the resulting bioreactor led to the production of rhLF at an industrial level.

Furthermore, Yang et al. (2008) characterized human lysozyme expressed in cloned transgenic cattle milk. Lysozyme, a bactericidal protein highly produced in human milk but very little in cow milk, protects infants from microbial infections. Focusing on 4 transgenic cattle expressing recombinant human lysozyme, they reported an expression level of 25,96 mg/l. The physicochemical properties (molecular mass, bacterial lysis) were similar to those of the natural (human) lysozyme, and there were no significant differences between transgenic and non–transgenic cattle milk in composition (lactose level, total protein, total fat, total solids). They concluded that milk from transgenic cattle has similar nutritional value as human milk.

Jabed et al. (2012) experimented with decreasing the level of beta-lactoglobulin, an allegen, in cow milk. Using RNAi technology, they produced a transgenic calf expressing miRNAs. Analysis of hormonally produced milk from the transgenic calves showed the absence of beta-lactoglobulin and increased milk casein proteins. It was concluded that miRNA mediated the elimination of the allergen effectively and that miRNA expression is an effective strategy to change/improve milk composition (and perhaps other characteristics).

The transgene's effect on milk components was further assessed by Wu et al. (2012). They compared proteins and colostrum from transgenic cloned cattle (TC) expressing α–lactalbumin (TC-LA), lactoferrin (TC-LF), lysozyme (TC-LZ) and cloned non-transgenic cattle (C), and conventionally bred cattle(N). The results indicated an altered expression level in the profiles of 37 proteins in the TC and C groups relative to the N control group. Evaluation of the transgene effect and variability in milk protein profiles indicated that variability in the TC was similar to that of control groups. At least 50 parameters of colostrum and milk were used to compare TC and control cows. Results indicated that the average values of the parameters in RC cows were similar to those of N cows. It was concluded that milk components were not affected/modified by the transgene.

On the prospect of using transgenesis/genetic engineering/genomic technology to improve cattle productivity and production, African Science Academies (NASAC) has taken a position on

modern agricultural biotechnology (NASAC 2015; www.nasaconline.org). This could have a positive effect on animal/livestock biotechnology. African countries are parties to the Convention on Biological Diversity and related protocols on biosafety and access to genetic resources. As parties to these, they have developed regulatory mechanisms to enable sustainable use of the resources and use of genetic modification (genetic engineering) on a case-by-case basis based on risk analyses. However, while easily accepting this in the health sector, public acceptance has concerns with the food sector's technology. Hence, the utilization of genetic engineering/genomic technology in African cattle production systems may not be immediate but may change with problem-free use of it in the health sector.

Capacity (human resources skilled in genetics, reproductive physiology, nutrition, health, and economics and infrastructural developments (such as laboratories) must be improved for effective implementation of genomic technologies in African livestock improvement. Public policy must be in place, guided by stipulations of the Cartagena Protocol to the Convention on Biological Diversity (CBD 2000; https://www.cbd.int/doc/legal/cbd-en-pdf).

22.5 Application of Modern Technologies in Reproductive Efficiency in African Cattle

The inefficiency of reproduction is one of the most significant causes of economic losses in animal husbandry globally (Bianchi et al. 1986). Although there have been significant developments in reproductive physiology in recent times, the issues of infertility caused by low conception rates and high rates of embryonic mortality continue to be a major concern (Hafez 2015). The need to increase animal productivity per animal unit without increasing the herd population size necessitates using modern technology applications to ensure sustainable livestock production. Introducing three cutting-edge reproductive technologies—zygote electroporation, recombinant adeno-associated virus (rAAV) zygote transduction, and surrogate sire technology give cattle producers a new toolkit of genome editing delivery options (Wheeler et al. 2003). The ease with which these technologies may be integrated into present breeding methods will enable extensive on-farm adoption in African livestock species. Therefore, modern reproductive technologies, including artificial insemination (AI), multiple ovulation and embryo transfer, and embryonic micromanipulation, described in Chap. 21, are being advocated.

22.5.1 Artificial Insemination

The most widely applied reproductive technology in African cattle and buffalo populations is AI. The application of AI was made possible through advances in semen technology including collection and facilities, evaluation, processing and packaging, and preservation/storage. Practical AI service in the field involves heat detection, semen handling, insemination, and advice to farmers. The delivery chain includes AI services/centres, cooperatives, farmer organizations, and products (milk, meat, semen). Services at the management level include records and economics, heat detection, insemination and motivation, pregnancy diagnosis, and recording (Verma et al. 2012).

22.5.1.1 *Case Study 1*: Kenya National Artificial Insemination Service

The historical perspectives of AI of cattle in Kenya are well documented in these reports by (Joint 2005; KDDP/SDP 2004; Competition Authority of Kenya (CAK) 2014). Artificial Insemination (AI) was first introduced in Kenya in the 1940s and has risen to become the most relevant approach for breed improvement. According to Duncanson (1977), the AI of cattle in Kenya started with the collection of semen from sires on private farms for use in the same farms. In 1941, an AI scheme was set up based on a community bull scheme, followed by a farmer association (Limuru Cattle Breeders

Association) in 1942. With AI for breed improvement, semen is imported mainly from South Africa, Europe, and North America or locally produced semen collected from locally bred bulls. The dominant breeding method applied by farmers is the natural service whereby cows are bred by local bulls. Currently, AI services are provided in partnership between County Governments and the Kenya Animal Genetic Resource Centre (KAGRIC). The utilization of AI in Kenya is to optimize productivity, which will translate to income and revenue for farmers. The Kenya AI service is funded by the government of Kenya and various Swedish grants and expertise organized as follows:

The main goals of the AI service include increasing milk and meat production, improving cattle productivity nationally, upgrading local zebu cattle, and controlling diseases transmitted through natural breeding. The service has two sections—the field services section and the planning and development section. Each section is well equipped (human and infrastructural capacity and logistics). Located at Kabete, the National AI Station has bulls composed of exotic dairy breeds (Holstein, Jersey, Ayrshire, and Guernsey) and beef breeds (*Bos indicus*: Boran, Sahiwal; *Bos taurus*: Simmental, Hereford, and Charolais). Semen from top bulls are also imported for use on top-producing cows. Semen produced at the station is mainly for national use while only about 1% is exported. From 1993, about 20% of collected semen was frozen in liquid nitrogen, while 80% was kept at room temperature and delivered to schemes twice a week.

The impact of the AI service is significant given that its annual production of improved dairy heifer calves by farmers is reported to be 100,000 crossbreds and upgrades. Furthermore, this is at a low cost to the farmers, who pay only 4.5% of the total cost. Hence, adequate funding will enable the sustainability of the service.

Suggestions for the way forward include the need to use cars for daily activities (i.e. the need to increase efficiency), use deep frozen semen only, and improve recording (AI and milk).

22.5.1.2 *Case Study 2:* Tadu Dairy Cooperative Society Artificial Insemination Service, Cameroon

According to Shange (2021), the Tadu Dairy Cooperative Society (TDCS), located at Kumbo in the Northwest Region of Cameroon is composed of about 200 male and female members and was founded in 1990 by pastoralists interested in AI as a tool to improve cattle. It is a multipurpose cooperative through which farmers can access new breeds through AI for greater and better-quality milk production, transformation, and commercialization of dairy products.

Structurally, men handle cattle while women handle milk and related products. It comprises 2 clusters: (i) five groups of grassroots cattle farmers interested in AI services, and (ii) five (5) dairy women groups affiliated with the cattle farmers groups.

The 5 cattle breeders groups live in 5 different TDCS Districts. Each district is provided with a crossbreeding station. AI services are delivered at the station managed by TDCS. Each station has a multipurpose corral and grazing land and is equipped with a 20/20 cryogenic container and a loaded AI breeding kit. The resident inseminator/herdsman resides at the station.

Cooperative members provide cows for insemination. The cows are held for a month, during which time they are observed. After insemination, they are held for another month. Those indicating heat are given a second insemination and returned to their owners. Members presenting cows for insemination pay 50% of the cost of AI, and the rest is paid when the calf is born.

The management of each station is by the inseminator/herdsman trained and paid by the cooperative, which also furnishes them with AI equipment, supplies, and logistics. The animal recording is at 3 levels: on arrival at the AI station, after successful insemination, and when a calf is born. According to advice from research personnel at the Institute of Agricultural Research for Development (IRAD) Bambui and Wakwa

Centres, the TDCS Dairy Performance Enhancement Strategy involves the insemination of local Gudali and Red Fulani females with Holstein semen. The TDCS beef improvement strategy involves the insemination of Gudali and Red Fulani with Brahman semen. All semen is imported from the USA.

The funding partners of TDCS activities include USAID, IFC, World Bank and Land O'Lakes, IRAD, and the Cameroon Ministry of Livestock, Fisheries and Animal Industries. USAID and Land O'Lakes, in particular, supported the training of inseminators in semen technology in the USA.

The success of the service is reflected by the results obtained within and outside the cooperative. Within the TDCS, the AI performance is 85.05% AI success, 2.03 straws per insemination, 90.78% calving rate, 89.84% calf weaning rate and 2.49 straws per calf weaned. Outside the cooperative (contract to produce crossbred calves at the state ranch, SODEPA), the performance is 89.3% AI success (significantly less than 2 inseminations), 94.9% calving rate of cows confirmed pregnant, 91.5% weaning rate of calves born and 8.5% pre-weaning calf mortality. The crossbred animals produce 3 to 4 times more milk than the local zebus and are more adapted than the purebred exotics.

The major challenges include an absence of a coherent cattle crossbreeding strategy. This leads to potential genetic erosion, dysfunctional crossbreeding regulatory mechanisms, seasonal fluctuation of feeding resources, high cost of AI inputs, sporadic access to electrical power, non-replacement of the equipment pool, absence of a functional cold chain between the milk factory and market outlets, high taxes, inadequate access to key inputs such as starter cultures and prolonged regional socio-political crisis. The way forward includes establishing a coherent national cattle breeding policy, improving access to electrical power, strengthening links with the Livestock Research Department of IRAD, and introducing a cold chain between the dairy processing factory and marketing outlets.

From these examples, it is feasible to apply AI upon observation of natural or synchronized heat in private and state farms to facilitate crossbreeding local cattle with exotic semen or semen of improved local Zebu males on improved local females. This requires mastery of semen processing technologies like semen collection and preservation, multiple ovulation, and embryo transfer among others. These technologies are also essential in conservation/regeneration/repopulation efforts for breeds at risk of extinction or synthetics/upgrades.

22.5.2 Multiple Ovulation and Embryo Transfer

Multiple ovulation and embryo transfer (MOET) technologies are regarded as second-generation reproductive biotechnologies. The MOET involves the super-ovulation of improved females (donors, which can yield 10 eggs each per oestrus with an average of 5–7 eggs for dairy cows and 6-6 for beef cows), followed by AI and transfer of fertilized eggs into surrogate mothers (recipients) (Mbah 2006; Kidie 2019). There are two methods of producing embryos from the donors: in vivo and in vitro techniques (Kidie 2019). MOET programmes require two or more nucleus herds (donor herd, and receiver herd). The genetically improved embryos are disseminated through transfer or IA or young bulls for natural service.

22.5.2.1 *Case Study 1:* Multiple Ovulation and Embryo Transfer in Kenya

In a simulation model, Sagwa et al. (2019) concluded that an increase in the rates of reproduction of both male and female dairy cattle increases selection response. They used conventional semen (CS), and X-chromosome sorted semen (XS) and compared them with the most used strategy in Kenya, AI as follows: AI-CS, AI-XS, MOET-CS, and MOET-XS. About 5% of cows were in the nucleus herd and 95% were in farmers' herds. The improved genetic material in the nucleus herd was disseminated to all the strategies while dissemination in farmers' herds was based on AI–CS only. Results indicated that

MOET-CS and MOET-XS increased the reproduction rate of both males and females. This led to an increased response to selection. This was evident in annual genetic gain and economic benefits/cow/year.

While MOET has grown fast since the first successful case in 1973, it is still at an embryonic stage in Africa relative to the number of countries engaged in embryo production and transfer (Brophy et al. 2003). In 2015, two out of 57 African countries submitted data on MOET, while Europe (71.8%) and North America (100%) were at the top. Only South Africa produced in vivo derived (IVD) from in vitro fertilization (IVF) (0.84%) of world embryo production, while North America produced 54.5% and Europe (19.4%). In the same year (2015), Africa transferred 183 embryos (fresh and frozen) while North America, South America, and Europe produced 97,871, 22,887, and 14,502, respectively. Countries exporting IVD cattle embryos include South Africa (659), Canada (12,758), the USA (15,896), Australia (2426), New Zealand (28), Argentina (2946), and Canada (1228, IVF) and Dominican Republic (590, IVF) (Brophy et al. 2003).

It is evident that embryo transfer in Africa is below demand. This is due to challenges such as capacity (human, infrastructural, funding, policy) insufficiency. Apart from South Africa, Ethiopia has affected ET at the Animal Research Centre (Adanu Tulu) (Brophy et al. 2003). Despite the potential for multiplication and dissemination of genetic material, regeneration of breeds at risk, etc., the prospect for utilization for cattle improvement in Africa is not yet realized.

22.5.2.2 *Case Study 2:* Multiple Ovulation and Embryo Transfer in Burkina Faso

Through a Ceva (Ceva Santé Animale) and CMAP (Centre National de Multiplication des Animaux Performants) partnership, F1 calves were produced using MOET technology under the auspices of the Vache du Faso project (Bianchi et al. 1986). The CMAP is a public centre under the Ministry of Livestock with the mandate of genetic improvement of the national cattle herd in Burkina Faso, while Ceva is a multinational animal health company established in 1999 in France that undertakes research, development, production, and marketing of pharmaceutical products, vaccines and equipment for ruminants, poultry, swine, and companion animals. The transfer of pure Montbéliard and Tarentaise embryos was performed on local cows at the CMAP station in Burkina Faso. Over 3 years, 31 embryo transfers were undertaken leading to the birth of 7 live calves (23% calving rate), of which only three survived (one male Tarentaise, one female Tarentaise, and one male Montbéliard). Despite the low survival rate, the experiment paved the way for the feasibility of MOET in local cattle breeds in Burkina Faso.

22.5.2.3 *Case Study 3:* Sperm Sorting at First African Sorting Lab

The first African sorting lab has been recently established in South Africa through a partnership between Sexing Technologies® (ST) and RAMSEM (STgenetics, 2021). RAMSEM is a pioneering livestock artificial insemination company in South Africa, while ST is a global livestock semen sorting leader and innovator. The new sexing lab is at RAMSEM's facility near Bloemfontein, South Africa, and will produce fresh and frozen sex-sorted semen from sheep, goats, and cattle. This will provide customers with semen that is more than 90 percent accurate for the desired gender, with conception rates comparable to conventional (unsorted) semen used for AI. This introduction of semen sorting into the African continent is set to revolutionize the breeding industry for African cattle, sheep, and goats.

22.5.2.4 *Case Study 4:* Birth of Live Calves by in Vitro Embryo Production in a Commercial Herd in South Africa

A successful story of bovine in vitro fertilization and the birth of live calves under typical South African conditions has been reported (Arlotto et al. 2001). Oocytes for in vitro fertilization (IVF) were collected from six slaughtered Bovelder beef cows. The oocytes produced 43

blastocytes from five donors using frozen Bovelder semen. The best 11 produced embryos were transferred into oestrous synchronized Bovelder recipients in the same herd. Results showed that seven calves were born without calving difficulties from four of the original donors resulting in a 64% calving rate. The calves had a normal birth weight apart from the mean of the gestation length, which was significantly longer in males than the herd average (291.6 vs. 285.2 days, respectively).

22.6 Application of Information Systems and Phenomics Technologies in Large Ruminant Improvement in African Input Systems

For many livestock stakeholders, information technologies remain largely unknown or blurry. Nevertheless, examples in several countries show interesting paths that can used to inspire future progress in Africa in the context of the steep growth of animal protein demand. Considering the advantages offered by information systems, the development of animal farming in Africa will increasingly depend on the ability of public bodies to implement multi-partner information systems.

22.6.1 Case Study 1: Information System for Livestock Management in Burundi and Madagascar

In 2012, in the context of the re-population of cattle in Burundi, the International Fund for Agricultural Development (IFAD) supported the creation of a digital system to register the identity of imported animals and the insemination and production recording in Burundi. Adventiel (https://www.adventiel.com/) developed a web application called IBIS (Fig. 22.1) and later a tablet application connected to the same database.

This IBIS system (still in operation today), allows agricultural technicians to record field data and to manage the efficiency of their programmes. It allows the central management and distribution of semen in participating districts, and to plan individual inseminations according to the pedigree of each animal, and thus prevent consanguinity.

The planned extension of the system to all livestock species is yet to be realized due to difficulties accessing farms in remote locations and organizational and regulatory impediments. Nevertheless, it is the first experience for the Ministry of Livestock and Fisheries of Burundi to manage livestock herds in a digital system.

In 2019, the Ministry of Agriculture, Livestock and Fisheries of Madagascar decided to improve the traceability of cattle, fight against the theft of animals, and foster exportations of animals to high-value markets such as Saudi Arabia. For this reason, Adventiel developed ZebuScan (Fig. 22.2), a mobile traceability application designed for this purpose. Today, this system is operational in the field, and the Ministry is able to build on this first system, to add other modules, such as performance recording and genetic improvement, which are so important to foster food security in the country. Indeed, building livestock identification and management systems is a progressive effort.

The chart in Fig. 22.3 gives an example of the structure of a complete system for a developing country. According to the objectives of the genetic organizations and the public bodies in charge, the system can take different physiognomies and offer various functionalities. The most important is to start simple, with animal traceability on a solid regulatory base, and then, with experience, to build on, and offer a connection progressively to the public bodies and various stakeholders of the livestock value chains.

The benefits are huge, as one can see in developed countries. For example, in France today, the Ministry of Agriculture and Food is organizing the renovation of the whole information system for all species. The French system is much more sophisticated than the chart shown in Fig. 22.3 because it comprises several sub-systems. It automatizes many tasks and data flows and considers the numerous structures involved with its

Fig. 22.1 IBIS in Burundi: identification, insemination, and consanguinity management. IFAD, Ministry of Livestock, Burundi and Adventiel

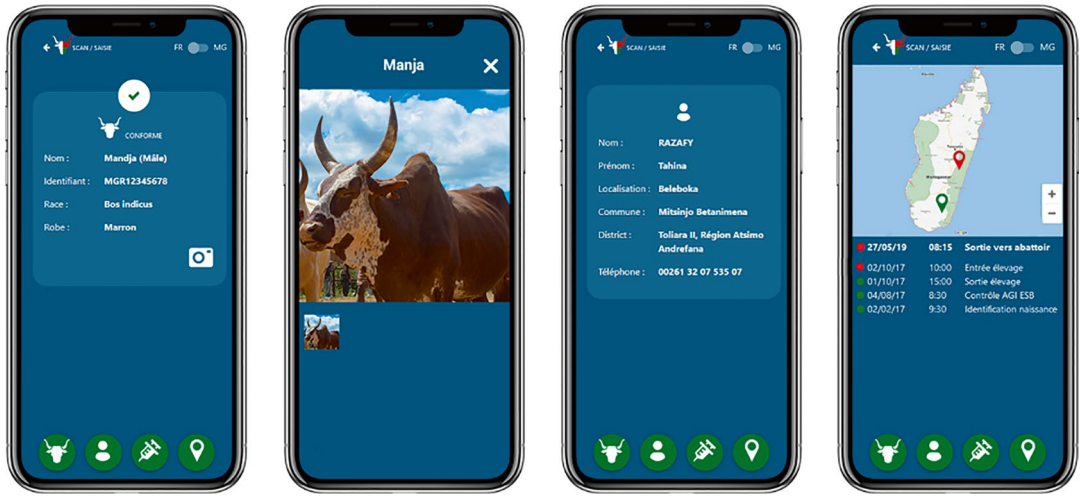

Fig. 22.2 Zebuscan, a mobile application for animal traceability in Madagascar 2019, World Bank, Ministry of Agriculture, Livestock and Fisheries, Adventiel

own information systems. The goal of the Ministry is to reduce costs, foster traceability, animal health, genetic improvement, and market access, and allow the private sector to connect to the system daily to improve the efficiency of the whole value chain.

Today, the digital management of the meat and dairy value chains is a fundamental criterion of economic performance. It has become indispensable for genetic companies and farmers, dairies, slaughterhouses, and all economic stakeholders.

Today, most African countries do not benefit from such systems. However, this is probably one of the most valuable investments they can perform for the genetic improvement of their herds, the profitability of their livestock value chains, and food sovereignty.

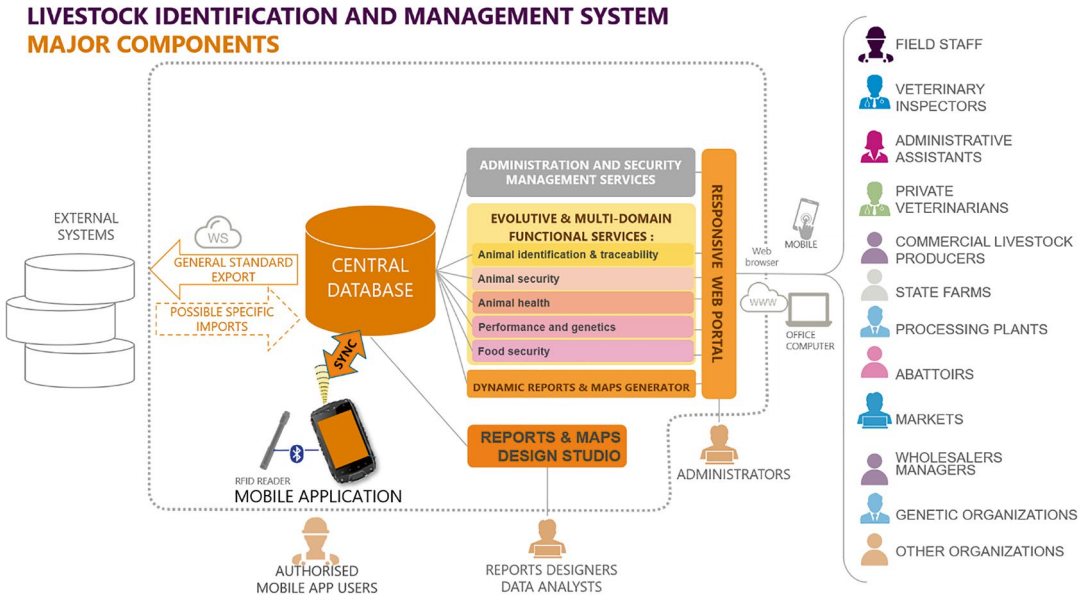

Fig. 22.3 Example of the modular structure of a Livestock Identification and Management System

22.7 Application of Modern Technologies to Improve the Health of Cattle

Local farmers and African governments recognize that the health of cattle is an important aspect of livestock growth, development and productivity, and farm profitability. In an effort to improve the health of livestock, many African governments have dedicated departments of livestock health to support livestock management through access to veterinarians and livestock vaccination programmes, training, and in some cases drugs. However, poor health care management is one of the factors affecting livestock improvement in Africa. In the past and recent times, African governments with funding support from international partners have implemented programmes to enhance livestock health.

22.7.1 Case Study: The Use of a Smartphone App (AfyaData) in Disease Surveillance (One Health Approach) in Africa

An information technology-based system was developed to enhance the detection of human and animal community-based disease outbreaks in Eastern and Southern Africa. The system aims to aid in the training and dissemination of information by health reporters to improve disease surveillance at the national, regional, and global scales.

The system was developed by an EpiHack team comprising human and animal health experts and ICT programmers following a meeting in Tanzania (2014) that identified the major challenges confronting early detection, timely

reporting, and prompt response to disease outbreaks or events. The software and ICT tools were developed and packaged as the *AfyaData* app to support One Health disease surveillance (Karimuribo et al. 2017). The software supports close-to-real-time data collection and submission at the community and healthcare facility and provides reporters with feedback. The software proved effective following the reports of 1915 and 1816 cases in livestock and humans following deployment in and usage in Morogoro and Ngorongoro communities of Tanzania over 5 months (August to December 2016). Hence indicating an opportunity for one health engagement of people in their local communities to detect infectious human and animal diseases (Karimuribo et al. 2017).

22.7.2 Case Study: Livestock Vaccination Programmes in Africa

In September 2015, the FAO and the government of Uganda launched a livestock vaccination campaign (https://www.fao.org/africa/news/detail-news/en/c/327820/) with the goal of controlling transboundary animal diseases (TBAD). The 3-month programme funded by the United Kingdom's Department of International Development (DFID) vaccinated about 500,000 cattle against Contagious Bovine Pleuropneumonia (CBPP), 240,000 cattle against Foot and Mouth Disease (FMD), 1000,000 goats and sheep against Sheep/Goat Pox and Peste des Petits Ruminants (PPR) and 400,000 goats against Contagious Caprine Pleuropneumonia (CCPP). The livestock production system of the Karamoja Region of Uganda is predominantly pastoral characterized by frequent movement of livestock and frequent outbreaks of TBADs such as FMD and PPR. The programme's main goal was to control and prevent future disease outbreaks in the area and disease spread to other regions of the country.

Through a recent programme termed 'The SheVax Story in East Africa' (https://afrohun.org/shevax/), livestock vaccines are being made available to marginalized and women livestock farmers in East Africa.

A Livestock Vaccine Innovation Fund (LVIF) funded by the Canada International Development Research Centre (IDRC), Global Affairs Canada (GAC), and Bill and Melinda Gates Foundation (BMGF) is supporting the development of affordable livestock vaccines as well as diseases that affect women and men livestock keepers. The project is implemented through a set of research action-based accomplishments including the SHeVax+ research (AFROHUN 2023). *SHeVax+ means hearing Their Voices and action Research to Support Women's Agency and Empowerment in Livestock Vaccine Distribution, delivery, and Use. The SHeVax+ research is a partnership* between the Cumming School of Veterinary Medicine at Tufts University, the Africa One Health University Network (AFROHUN), Makerere University, the University of Nairobi and the University of Rwanda. In a bid to improve livestock production and livelihoods in Uganda, Kenya, and Rwanda, the project aimed to understand the state of women's empowerment and gender parity on the vaccine value chain and identify key entry points among women smallholder farmers and entrepreneurs to contribute to and benefit from livestock vaccines.

The project's successes since its implementation include (1) training of 24 animal health service providers and well equipped to serve 140,000 households; (2) animal health training provided to over 1500 persons; and (3) dissemination of over 1200 Vaxxer calendars (a calendar with information on vaccination, animal health, and gender issues). Thus, the SheVax+ research is looking for new ways to improve women's participation, and how women can better benefit from livestock vaccine value chains in Kenya, Rwanda, and Uganda.

In order to transform livestock health services and make veterinary extension services more gender aware, responsive and inclusive, and accessible, the SheVAx programme recommends as follows (AFROHUN 2023): (1) put in place gender-inclusive livestock policies into practice through actual procedures or processes to improve vaccination programmes; (2) reach vari-

ous stakeholders by fostering collaborations between animal health technical providers and community development service providers; (3) make gender responsiveness of service provision an integral part of animal health technical training; (4) improve access by smallholder farmers to efficient vaccination programmes by including women in animal and poultry vaccine value chain; (5) private animal health service providers and governments should recognize and solve the socio-cultural issues at household and community levels that prevent women and other marginalized small holders from using and engaging as providers of livestock vaccine services; (6) committed leaders from government agencies and relevant departments are necessary for public-private collaborations within livestock vaccine value chains; (7) invest in the integration of gender knowledge and communication skills into curriculum and training of animal service providers and veterinarians; (8) encourage women and marginalized groups to become animal health service providers; (9) enrich training of community animal health workers with competence-based learning frameworks and gender and soft skills modules; (10) make animal health welfare services (e.g. veterinary care, drugs and information and technologies) accessible to women, the elderly, the poor and disable livestock keepers; (11) invest in gender transformative approaches in veterinary medicine and extension training; and (12) sensitize community animal health workers, community leaders, and other key community stakeholders on the importance of adequate livestock health management.

22.8 Challenges and Constraints in the Implementation of Modern Technologies in Cattle and Buffalo Production in Africa

Modern technologies have the potential to revolutionize cattle and buffalo production in Africa by increasing productivity, improving animal health, and reducing labour costs. However, there are several challenges and constraints that need to be addressed to effectively implement these technologies in the region. Some of these obvious challenges and constraints are:

1. Limited access to technology: One of the main challenges in implementing modern technologies in cattle and buffalo production in Africa is limited access to technology. Many small-scale farmers in Africa do not have the financial resources to invest in modern equipment and tools, such as automated feeding systems, digital health monitoring devices, and genetic testing technologies. This limits their ability to improve the efficiency and productivity of their operations.
2. Lack of infrastructure: Another major constraint in implementing modern technologies for cattle and buffalo production in Africa is the lack of adequate infrastructure. Many rural areas in the region lack reliable electricity, internet connectivity, and transportation networks, which are essential for the adoption of modern technologies. Without these basic infrastructure elements, farmers are unable to access and utilize the latest innovations in the industry.
3. Limited technical knowledge: In addition to limited access to technology and infrastructure, many cattle farmers and producers in Africa also lack the technical knowledge and skills needed to effectively implement and maintain modern technologies in their operations. Training programmes and extension services are often not adequate in the region, making it difficult for farmers to learn how to use new technologies and troubleshoot problems that may arise.
4. High cost of technology: The high cost of modern technologies is another significant constraint in the implementation of these technologies for cattle and buffalo production in Africa. Many farmers simply cannot afford to purchase expensive equipment and software, which limits their ability to improve the efficiency and productivity of their operations. In addition, the ongoing costs of main-

taining and upgrading technology can be prohibitive for small-scale farmers with limited financial resources.
5. Regulatory challenges: Regulatory challenges, such as import restrictions and licensing requirements, can also hinder the implementation of modern technologies in cattle and buffalo production in Africa. In some cases, government policies and regulations may be outdated or overly restrictive, making it difficult for farmers to access and utilize new technologies that could benefit their operations.

22.9 Conclusion and Future Perspectives

Advances in technology introduced into the cattle industry are more pronounced in countries with advanced economies. Africa has the potential to adopt and tweak these technologies to suit local production. Yet, the absence of such technology in most African farms is a testimony to how much there is to be accomplished on the African soil if African farmers will ever run in the production league with the more technologically advanced countries.

While modern technologies have the potential to transform cattle and buffalo production in Africa, there are several challenges and constraints that need to be addressed in order to effectively implement innovative tools in the region. Limited access to technology, lack of infrastructure, limited technical knowledge, high cost of technology, and regulatory challenges are some of the key issues that must be overcome to realize the full potential of modern technologies in the large ruminant industry.

The adoption and implementation of finished/imported technology are expensive. Investment in animal agriculture in Africa still needs improvement, and government presence and support from financial houses are equally poor. In addition, adopting and modifying advanced technology to suit local production requires capacity development in technological know-how, funding, and sound ethics backed by policy. For this to happen, a united front and government presence are undeniably very important, and a strong public-private partnership (Okpeku et al. 2019) investment into livestock production cannot be compromised. By addressing these challenges and constraints, policymakers, researchers, and industry stakeholders can help to ensure that African cattle and buffalo farmers have the tools, resources, and range of technologies they need to improve the efficiency, productivity, and sustainability of their cattle and buffalo operations.

22.9.1 Potential Solutions and Way Forward

1. Promoting access to technology: To address the limited access to technology, governments, non-governmental organizations, and private sector stakeholders can work together to provide financial assistance, subsidies, or low-interest loans to small-scale cattle and buffalo farmers to help them invest in modern equipment and tools. Additionally, technology companies can develop more affordable and scalable solutions tailored to the needs and budgets of African farmers.
2. Improving infrastructure: Improving infrastructure, such as electricity, internet connectivity, and transportation networks, is essential for the successful implementation of modern technologies in cattle and buffalo production. Governments and international organizations can invest in infrastructure development projects in rural areas to ensure that farmers have the necessary resources to access and utilize new technologies.
3. Enhancing technical knowledge: Training programmes, workshops, and extension services can help farmers improve their technical knowledge and skills in using modern technologies in cattle and buffalo production. Collaboration between research institutions, universities, and agricultural extension services can provide cattle and buffalo farmers with the necessary information and support to effectively implement and maintain new technologies on their farms.

4. Reducing the cost of technology: Governments and industry stakeholders can work together to reduce the cost of modern technologies for cattle and buffalo through subsidies, incentives, and partnerships with technology providers. By making technology more affordable and accessible to small-scale farmers, the adoption rate of modern tools in cattle and buffalo production can be increased, leading to improved efficiency and productivity in the industry.
5. Addressing regulatory challenges: Governments in African Countries can review and update regulatory policies to facilitate the importation and licensing of modern technologies in cattle and buffalo production. By streamlining regulatory processes and reducing bureaucratic hurdles, cattle farmers can more easily access and utilize new technologies that can benefit their operations.

On a final note, while there are significant challenges and constraints in implementing modern technologies in cattle and buffalo production in Africa, there are also potential solutions and a clear way forward to overcome these obstacles as discussed above. By promoting access to technology, improving infrastructure, enhancing technical knowledge, reducing the cost of technology, and addressing regulatory challenges, stakeholders can help African cattle and buffalo farmers harness the full potential of modern technologies that were extensively discussed in Chap. 21. By working together and taking proactive measures, policymakers, researchers, and industry stakeholders can pave the way for a more sustainable, efficient, and productive cattle and buffalo production sector in Africa.

Prospect of Modern Technologies for Poultry Improvement in Africa

23

Victor E. Olori, Sunday O. Peters, and Matthew A. Adeleke

Abstract

Poultry production is the most extensive commercial livestock production sector in Africa. It has the highest potential to meet the projected increase in demand for animal protein in the continent in the next decade. This chapter focuses on technologies used in different areas of poultry production. The emphasis is on the prospect of using these technologies to improve poultry production. Section 23.1 gives a brief introduction of the topic indicating that technology has a key role to play in all aspects of poultry production. Its deployment holds the key to the ability of the poultry sector to fulfil the expectation of being the main source of animal protein in Africa. Genetic improvement and the supply of high-quality day-old chicks, which is the bedrock of commercial poultry production, rely on the deployment of various technologies. Section 23.2 gives a detailed insight into this. Other technologies are essential in maintaining the good health and wellbeing of birds which is critical in the enhancement of productivity. This is the focus of Sect. 23.3. It includes a subsection on the success of vaccination programmes and other animal health initiatives in Africa. Section 23.4 describes technologies useful in the improvement of nutrition, feed, and feeding of poultry, including a subsection on technology used in feed manufacturing and preservation as well as the biological interaction between feed and bird performance. Section 23.5 describes various technologies that can be deployed to create a good and safe production environment. These include the housing of birds, their nutrition, and health monitoring. These technologies support human skill and knowledge to create and maintain a good production environment. Concluding remarks and perspectives for the future are presented in Sect. 23.6, pointing out that the utilization of technology has the potential to facilitate a sustainable increase in poultry production capacity, and the productivity of farms and individual birds.

23.1 Introduction

There is increasing interest in the contribution of the livestock sector in various national economies of African countries. This has come with the need to diversify these economies in order to generate revenue. The interest in the sector is gradually shifting focus from improving livestock performance and their production environment to achieving a sustainable increase in productivity as well as the development of the overall value chain. Sustainable increase in productivity requires improvement in the biological efficiency of individual animals, improvement in productive efficiency of individual livestock farms, and increase in capacity, and diversity of the livestock sector. To this end, the role of proven and emerging technologies cannot be over-emphasized.

The objective of this chapter is to illustrate the role technology can play and the prospect for its utilization in improving the capacity of poultry production in Africa. Although technology has played and will continue to play a key role in the improvement of poultry production, its impact has not been felt in Africa as it has in Western and some Middle Eastern countries. The use of technology in different aspects of poultry production in the aforementioned countries will therefore serve as a case study in the discussion of its prospect in African countries. A more detailed over-

view of modern technologies relevant to livestock production in general is presented in Chap. 21.

The most common poultry species farmed in Africa are chickens, turkeys, ducks, and guinea fowls. Both indigenous and imported breeds of these species are reared in different production systems ranging from small-scale extensive family production systems to large-scale intensive commercial systems. Chapter 2 gives a more detailed discussion of livestock production systems in Africa. The most common factor distinguishing these systems is the level of input use, particularly the quality and availability of day-old chicks that are the primary seed stock in the case of poultry farms. These inputs include the breeds, feed resources, and provision of housing, health care, and biosecurity. To a great extent, it also includes human capacity in terms of knowledge and skill level of the management staff. All of these aspects involve the use of some aspects of technology.

The biggest challenge to poultry production in Africa is the high cost of inputs such as the seedstock which are generally imported and feed. Increased efficiency with technology can create a suitable production environment while the use of genetically improved feed-efficient birds will minimize feed requirement and hence, cost. Another major challenge is disease burden and associated health challenges on the birds. The tropical environment in most of Africa supports the prevalence and persistence of disease-causing pathogens. Genetic improvement of bird resilience and the use of innovative health care and biosecurity approaches are tools that have helped poultry production in other climes. These will be needed in Africa to bring about sustainable improvement. Finally, production capacity in Africa is low mostly due to poor investment in technology that can help in the management of farms with large numbers of birds. To improve production capacity in Africa, technology uptake must increase. Prospective technologies for poultry farm management, health, nutrition, and genetic improvement are discussed in the following sections of this chapter.

23.2 Improvement of the Birds' Biological Efficiency

23.2.1 The Use of Technology in the Genetic Improvement of Birds

Chapter 21 above gives a vivid picture of the low productivity of indigenous livestock resources used in African production systems described in Chap. 2. Chapter 7 highlights the abundant indigenous poultry resources with potential for improvement. Improved productivity however required purposeful genetic improvement efforts. The process of genetic improvement, which brings about a cumulative permanent change in performance or other features of livestock, relies on the application of several technologies. The adoption of a closed nucleus breeding programme is very common in poultry breeding. This requires that birds in the nucleus are housed, fed, and managed with all the skills and tools deployed in commercial poultry production. In addition to this, data required for genetic evaluation in the breeding programme has to be collected from various stages of the bird's life; from hatching through breeding stages. Data is collected on individual animal's performance, pedigree, and genomic information. Available data on the phenotype (observed performance) and the genotype (derived genomic composition) needs to be stored, maintained, and analysed to derive the required information for selection and breeding. In this regard, the process of data collection, transfer, storage, analysis, and dissemination of information all require technologies. In order to ensure a high rate of genetic gain, selection intensity is high and necessarily unequal between males and females. A few numbers of males are usually bred to a large number of females. This requires the use of reproductive technologies that, not only aid successful breeding but also sex and pedigree determination in chicks soon after hatch.

Because technology applies to innovative methodologies as well as tools and equipment, it

is pertinent that the methodologies used to bring about genetic improvement in poultry breeding should be discussed herein. This includes methods and tools used for data collection, transfer, storage, and maintenance as well as the quantitative, biometric, and statistical tools used to analyse both phenotypic and molecular data in poultry breeding. While it is well understood from basic genetic principles that genes control traits, the identification of the specific genes or chromosome sections (haplotypes) responsible for many traits was largely unknown until recently. Despite this, many traits or features are known to be controlled by numerous genes all having small effects, which together determine the quantitative variation observed in the population. It was and still is impossible to precisely identify all the gene variants that affect a given trait and the physiological pathways underlying their effect. Over the years, available technology at the time has facilitated the development of methodologies, quantitative and molecular, to facilitate the elucidation of the underlying genetic composition or genotype of individual birds.

23.2.2 Quantitative Versus Molecular Evaluation

In Chap. 15, an overview of the strategies used in bringing about genetic improvement including the definition of breeding goals was discussed. Subsequent chapters discussed these in relation to cattle (Chap. 16), small ruminants (Chap. 17), and poultry (Chap. 18). In this chapter we give detailed emphasis on genetic evaluation, the process which allows us to bring about improvement through selection in line with the breeding objective. Genetic improvement is achieved through the concentration of the alleles that impact superiority with regard to certain traits, in the next generation. This can be done in two or more ways each adopting various technologies. These include the following:

- Quantitative analysis of variation in phenotypic data based on pedigree relationships and derived population parameters. This is referred to as polygenic evaluation.
- Quantitative analysis of molecular variation based on identified gene markers, reference population, marker associations, and genomic relationship parameters. This is referred to as genomic evaluation.

Genetic enhancement of animal features, traits, or weaknesses, such as susceptibility to a particular disease is also possible through the modification of the genotype and hence the gene variants controlling specific features of the animal. This is generally referred to as gene editing where the individual's genotype is modified through specific gene deletion, silencing, or activation. It is generally referred to as genetic modification where a gene or genetic material from a different breed or species is introduced to the individual's genome through gene insertion by different methods. Individuals whose features have been significantly modified through the introduction of foreign genes from other species or organisms are referred to as transgenic animals.

23.2.2.1 Polygenic Evaluation

The Best Linear Unbiased Prediction Method

The selection of animals to produce the next generation is at the core of the genetic improvement of livestock. The ranking of selection candidates is based on the use of quantitative statistical and mathematical methodologies to decipher the genetic merit of individual animals from observed performance (phenotype). The underlying genotype or genetic merit of an individual with respect to a given trait is measured in terms of the breeding value. It is estimated using information on the observed performance of the individual and its relatives, information on the relationship between animals in the population captured in the pedigree, and population parameters which provide an indication of the total variation of the trait in the given population and components of this variation attributable to genetic and non-genetic factors. The key technological breakthroughs and the evolution of the methodologies for genetic

evaluation of farm animals have been extensively reviewed (Grosu et al. 2013).

Of note are the breakthroughs and people that led to the development of the Best Linear Unbiased Prediction (BLUP) methodology which has become the standard for poultry genetic evaluation. These include J. Lush and C.R. Henderson who developed and with others expanded methodologies for predicting breeding values using the BLUP procedure (Grosu et al. 2013). Although the principles of BLUP and the derivation of its equations were known by 1949, it required improvement in computing capacity brought about by technological breakthroughs in the early 1970s before it could be implemented. Since then, BLUP has been implemented in several models (Grosu et al. 2013; Mrode 2014), whenever phenotypic data from a large population of birds are available to estimate population parameters, and together with relationship information, used to predict breeding values (Simm et al. 2020). The steps in the computation of breeding values with different models and for different sets of data have been well described (Mrode 2014). These include single trait models, multivariate animal models, which allow simultaneous estimation of breeding values for group traits, repeatability, and random regression models which are particularly suitable for traits measured repeatedly over time or space, also called longitudinal traits. Examples of these include body weight at different ages, repeated measures of egg weight, or monthly fertility values as the flock ages.

23.2.2.2 Genomic Evaluation

Genomic evaluation refers to methodologies that allow us to predict the genetic merit of individual animals, quantitatively, with information on the phenotype combined with information on genetic markers. A genetic marker refers to a heritable piece of DNA that can be mapped to a specific location on the chromosome of an organism. Advances in molecular technology have allowed repeated sequences of DNA bases, so-called microsatellites, or simple sequence repeats (SSR), which can be found all over the chromosome, to be mapped. Advances in technology have permitted full sequencing of the genome of many organisms and this has led to the identification of variation arising from changes at the single nucleotide level. These single nucleotide polymorphisms (SNPs) have become the standard genetic markers used in the genomic evaluation of animals.

The derivation of genomic breeding values using genetic markers is based on the principle that these markers are non-randomly associated with, or as we say, in linkage disequilibrium (LD), with loci that affect variation in quantitative traits. SNPs are more numerous than other markers known to date and distributed more widely over the entire genome. They are thus more likely to be in LD with all quantitative trait loci (QTLs). This association between SNP and QTL in the same chromosome segments allows us to track all QTLs and make the evaluation of different traits of the animal possible with the same set of SNPs captured in a 'SNP chip'. Such chip should be of reasonable density, i.e. have a large number of SNPs, to capture QTLs that may be spread across the entire genome. Figure 23.1 shows a picture of a typical commercial SNP chip. Similar chips exist for humans and different livestock species (see Chap. 21).

Advantages of Genomic Evaluation

- The same tissue sample and derived genotype can be used to evaluate several traits or features of the animal, i.e. one sample is sufficient to evaluate several phenotypes because the SNPs captured in a dense chip include some that can explain variation between individuals in a range of traits.
- It can be used to evaluate animals much earlier in life, i.e. as soon as a tissue sample can be obtained and used to genotype the animal. This saves cost of rearing animals to later ages. This is particularly important in traits that can only be measure late in an animal's life such as reproductive traits observed only after sexual maturity. These include egg

Fig. 23.1 A representative SNP Chip

production, fertility and hatchability in poultry, carcass traits in beef and poultry.

- It allows all animals to be evaluated for traits that can only be measure on some animals, e.g. sex limited traits, such as egg production and milk yield.
- Genomic breeding values can distinguish between full sibs with no data where in traditional evaluation, they will both get the same breeding value based on the parent average (PA)
- It allows faster genetic progress in age limited traits due to the reduction of generation interval, and increase in accuracy of predicted BVs.
- It is an alternative selection tool that can be used, in combination with the traditional method, to increase the accuracy of selection.

The above indicates that once an animal is sampled (i.e. a tissue sample is taken) and genotyped using a reasonably dense SNP chip, the genotype, described in terms of the total number of SNPs on the chip, can be used to evaluate several traits or features of the animals. These include sex-limited traits, such as egg production and milk yield that are recorded only in females and in males based on the performance of their sisters and daughters in future generations. With genomic evaluation, the genetic merit of males for such traits can be determined much earlier in life with significant savings in cost. By evaluating animals much earlier in life, genomics offers us the opportunity to reduce the generation interval resulting in a faster rate of gain. In broiler and beef breeding, meat yield and other processing traits are very important traits of economic importance and can be measured directly only on individuals at slaughter. Evaluation of such traits amongst live selection candidates relies on SIB information or the availability of predictors. Genomics offers a chance to evaluate the direct genetic potential of all selection candidates for such traits with a higher level of accuracy. Similarly, genomic evaluation can be applied to complex traits such as disease resistance, robustness, animal welfare, and behavioural traits which are difficult or impossible to phenotype.

For genomic evaluation, once phenotypic information on relatives is available to form a reference population, individuals to be evaluated or selected do not need to have the phenotype before a genomic breeding value can be predicted on them. All that is required is that selection candidates have a genotype derived from a tissue sample, which can be taken very early in life and from all individuals.

The accuracy of genetic evaluation, based on a combination of genetic markers and phenotypes, tends to be higher than the accuracy obtained from polygenic evaluation without the genetic markers' information. This may, however, depend on the genetic architecture of the trait and the model/prediction method (Daetwyler et al. 2010; Wimmer et al. 2013). In addition, genetic markers can be used in genome-wide association studies (GWAS). This has facilitated the mapping of

genetic pathways underlying many biological processes thus increasing our understanding of the genetic control of traits and especially, complex diseases (Wang et al. 2010a; Tam et al. 2019). GWAS can also be used to detect genes with major effects.

23.2.3 Genetic Evaluation Software and Models

The Best Linear Unbiased Prediction (BLUP) methodology has been deployed with a wide range of models in custom software that are widely available and hence transferable for genetic evaluation. These use different mathematical algorithms to solve the linear equations that characterize the BLUP methodology (Mrode 2014). The models to fit depend on the traits, source and structure of available data. Examples of such custom software used in poultry breeding include VCE® for variance component estimation (Groeneveld et al. 2008), PEST® for breeding value prediction (Groeneveld 2006), DMU® (Madsen and Jensen 2013), ASReml® available from VSN® International (Gilmour et al. 2021) which can estimate variance components and also predict BVs, Mix99 (Tam et al. 2019) and MixBLUP (ten Napel et al. 2020). Others include WOMBAT® (http://didgeridoo.une.edu.au/km/wombat.php), which has replaced the old DF-REML (Meyer 2018). Other software such as R® (Team, R. D. C. R 2010), which is freely available, Python® (Van Rossum and Drake 2009), SAS® (Delwiche and Slaughter 2019), and Fortran® (Lahey and Ellis 1994) are used in programming. They are thus useful in developing genetic evaluation pipelines as well as data manipulation and set-up for the various evaluation models. All these software vary in the models they can fit and the volume of data they can handle at a given time. While some can be deployed for genomic evaluation, others cannot. There are yet other software used specifically for genomic evaluation especially those required to fit the available array of Bayesian models for genomic evaluation using various regression models.

The array of models used in farm animal evaluation has been described in detail by Mrode (2014) and Simm et al. (2020). The ability of the custom software to fit these models has evolved with time and in particular with improvements in computing capacity, information communication technology, and data recording. As computing capacity increases in terms of processor speed, ready access memory (RAM), and storage capacity, more complex models can be fitted. For example, more computing capacity is required to fit a multivariate animal model compared to a single trait model. As data and pedigree size increases, more memory is required and more processing speed will facilitate a quick turnaround time in solving the equations for the same number of traits. While multivariate evaluations with the animal model are generally suitable for evaluating most traits in poultry and pig production, the availability of longitudinal data on traits recorded repeatedly over time or space has led to the introduction of random regression models (RRM). Threshold models are particularly useful in evaluating binomial traits which has been included in the F90 Suite of programmes (Misztal 1999). The deployment of different software for routine genetic evaluation depends on human capacity and knowledge, the availability, and the cost of licensing. However, these technologies are highly portable.

Genomic Evaluation Models

Prediction of BLUP breeding values in a polygenic evaluation is based on data on the observed performance of the animals and their relatives. Relationships are based on a detailed pedigree which enables us to derive a numeral value of the predicted relationship between animals based on the assumption that a parent transmits half of his/her alleles to each of its progeny and that each progeny may not inherit exactly the same set of alleles from its parents. The deviation of the average allelic effects a progeny receives from both parents from the average allelic effects from the parents common to all progeny is referred to as the Mendelian sampling. This pedigree relationship matrix is generally referred to as the '**A**' matrix (Mrode 2014). When animals are geno-

typed, the true observed relationship between genotyped animals can be derived based on the common SNPs they carry. This relationship matrix, based on genetic markers, is referred to as the 'G' matrix. Increased reliabilities from genomic selection could in part, be attributed to better estimates of the Mendelian sampling (Hayes et al. 2009).

A common genomic evaluation model or method, which simply uses the G matrix to replace the A matrix in a linear model is referred to as GBLUP. Equations are set up for each animal resulting in the estimation of a direct genomic value (DGV) calculated for each animal which can be used to rank animals for selection. The drawback however is that only genotyped animals can be included in a GBLUP run and hence non-genotyped animals, which may include older relatives of the selection candidates cannot contribute information and cannot get a DGV. This limits the use of GBLUP in a situation where cost and other factors prevent the genotyping of all available animals. In an animal model context, the mixed linear model equation for GBLUP can be written as;

$$y = Xb + Wa + e \tag{23.1}$$

Where y is a vector of observed data, X and W are design matrices relating data to fixed effects and random animals respectively. e represents the random error term and a is a vector of DGV with mean zero and variance; $\mathrm{Var}(a) = G\sigma_a^2$

The mixed model equations for obtaining the solution for Eq. 23.1 are presented in Mrode (2014). A method of genomic evaluation whereby the linear mixed model equations are set up for each SNP rather than each animal is referred to as 'SNP-BLUP'. In this case, solutions are computed for each SNP. To get the DGV for each animal, The SNP genotype at each marker locus, (coded as 2, 1, or 0 depending on the number of the dominant alleles in that locus) is multiplied by the SNP solution for that SNP and summed over all SNPs for the animals. Again, DGVs derived this way are only available for genotyped animals (Mrode 2014).

A two-step genomic evaluation approach can be used to derive Genomic Breeding values (GEBV) for genotyped animals by combining the DGV for each genotyped animal with the estimated (BLUP) breeding values (EBV) based on the data and numerator relations ship matrix or a traditional BLUP run which combines all animals with and without data. The GEBVs for the genotyped animals benefit from the data and pedigree relationship information from related non-genotyped animals as well as the genomic relationship (if derived from GBLUP) or both genomic relationship and SNP solutions if derived from SNP-BLUP.

Misztal et al. (2009) developed the single-step G-BLUP by combining the A matrix of both genotyped and non-genotyped animals and the G-matrix of the genotyped animals into a hybrid matrix, H. This approach allows for the estimation of GEBV for both genotyped and non-genotyped animals. For a detailed understanding of genomic breeding value predictions, see Simm et al. (2020).

23.2.4 Selection

For many generations, the superiority of the next generation was achieved by ensuring that only a few individuals who perform above the population average, are selected and allowed to mate on a pre-determined scheme, i.e. none randomly, to breed the next generation. Selection of the breeding population is based on the ranking of all individuals (males and females) on a genetic merit scale determined by genetic and genomic evaluation described above. Selective breeding is the vehicle through which genetic progress is achieved in traits of economic importance. The efficiency of this process depends on the accuracy of the breeding values in identifying the true genetic merit and hence the ranking of animals for selection. A key aspect of selective breeding is the ability to restrict breeding to only the selected individuals by preventing all non-selected individuals from contributing offspring to the next generation. This requires technologies supporting efficient culling, restriction of movement, and separate housing of different categories of animals. In this regard, building materials

which allow fencing, and flexible partitioning of pens are essential. These include technologies for feeding and supplying water to birds in different sections of a building shed.

23.2.5 Data Recording

The traits of interest in farm animal breeding are mostly quantitative in nature. This means they vary minutely between individuals on a continuum from a physiological minimum to a physiological maximum. For example, in meat-type animals (broilers, beef, pigs, etc.), live weight at a specified age; for dairy, milk yield, milk components, etc. Other traits are binomial in nature, e.g. mortality. (An animal is either alive or dead at a certain age). There are also traits that are categorical in nature, i.e. can be split into a few classes that may be categorical (discrete) or continuous in nature, e.g. carcass grade, feather coverage, walking ability, and lesion score. The description of the observed state, feature, or performance of an individual relative to one or more traits is generally described as phenotyping. The measurement and recording of data relative to the observed, allows these phenotypes and endophenotypes to be captured in a form that can be stored, reviewed, and analysed to provide further information about an individual or group of animals.

In farm animal breeding, data recording is critical as it facilitates the derivation of genetic information useful for bird selection and breeding. Recorded data includes phenotype as well as the genetic composition of the animal (genotype) described in terms of a set of genetic markers. Some phenotypes can be recorded directly by measuring the observed with recording equipment, e.g. recording body weight on a scale. Other phenotypes are derived from one or more recorded traits, e.g. percentage carcass yield can be derived from the eviscerated carcass weight and the body weight. Also, egg weight loss during incubation is derived from the weights of the egg at a set and transfer to the hatcher after 18 days. Male and or female fertility is derived from the total number of eggs set and the total found to be fertile following candling after 7–8 days of incubation. Thus sometimes, useful traits including survivability can be derived from simple counts.

Obtaining a record of the genetic makeup of an individual, or its genotype, is a little more involved than a simple measurement as is possible for many phenotypes. The true genotype of an individual animal is based on its genetic constitution which involves potentially thousands of genes located in a varying number of chromosomes depending on the species. In chickens, the genetic makeup comprises genes located across 39 chromosome pairs. Cattle on the other hand has 30 pairs of chromosomes. The process of determining the genetic makeup of an individual is referred to as genotyping. It is currently impossible to identify the full set of genes a particular farm animal carries. However, the genotype can be expressed in terms of hundreds of thousands of known genetic markers that have been identified and distributed across all chromosomes. The most common of these markers now used to genotype animals are SNPs described in Chap. 21. Hence genotyping is presently done relative to a fixed number of SNP genetic markers previously identified and constituted or described in a SNP Chip. The available chips vary by species and in terms of density, i.e. the number of different markers known across all chromosomes and by the proprietor or group that developed the chipset. Examples include the Affimetrix® medium density 55K SNP Chip (Liu et al. 2019), the Affymetrix High density 600K SNP Chip (Kranis et al. 2013), and the Illumina medium density 60K SNP Chip (Groenen et al. 2011). Further information on DNA genotyping chips can be seen in other chapters. One key feature of genomic data is that it is quite large. Technically speaking, you have as many data points as the number of SNPs used for genotyping per animal hence storage of this data requires a large computing/database infrastructure. Also deriving the data per animal is expensive because it involves a lot of stages with an array of technologies from tissue sampling, and DNA extraction to genotyping.

23.2.5.1 Evolution of Recording Equipment and Breeding

Technological advancement in the development of recording equipment has made data capture in farm animal breeding easier, less tasking, and faster. These attributes are important because breeding involves the recording of data in a very large population over a period of time. For example, measuring the weight of an animal requires a scale. However, scales that can accurately capture the weight of a 7-day-old chick need to be more sensitive than one required to weigh a 7-day-old calf. The sensitivity of scales has improved with technology from balanced weight-based scales to digital scales of different ranges. This has made it possible for the low weight of an egg to be captured as accurately as the high weight of a mature beef cattle.

Another technological development relevant to data recording is the possibility of integrating measuring instruments with other instruments or equipment, which allows the capture of animal identity or the transfer of captured data to a storage system. Such integration saves time and stress by allowing the automatic capture of multiple pieces of information seamlessly. For example, the integration of a barcode scanner (Fig. 23.2) with a scale and a laptop allows bird identification and body weight to be recorded efficiently within a short time and the obtained data safely transferred to a database. Such integration eliminates the need for writing down or typing in records hence avoiding human error or mistakes. It facilitates the recording of phenotypes on hundreds of birds by one individual in the shortest possible time, thus maximizing the efficiency of available labour. This is critical in pig and poultry breeding which requires the recording of numerous individuals within a short time.

Developments in information communication technology (ICT) have enhanced the capture, but more importantly the seamless transfer of data between recording equipment or location and storage database. Compared to wired connectivity, the ability for equipment to communicate wirelessly with each other through a router (Fig. 23.3) via wireless radio signal (WiFi) or directly through Bluetooth connectivity has revolutionized data capture and transfer. It provides data recorders more freedom and mobility in data capture while still allowing the safe transfer of recorded data to a centralized storage device. This is particularly useful in extensive production systems or in obtaining data from highly dispersed small-scale producers. Wireless communication technology has allowed an increase in the variation of equipment that can be used to capture data. For example, the increase in processing and storage capability of mobile phones (Fig. 23.4) makes them now suitable for a whole range of data capture and together with their WiFi and Bluetooth capability, makes them particularly powerful tools for capturing data in remote locations.

Fig. 23.2 A Barcode Scanner

23.2.5.2 Equipment Miniaturization

Over the years, advances in various technologies especially in metallurgy, mechanical and electrical engineering as well as computer technology have facilitated the miniaturization of animal recording equipment. The size of the recording

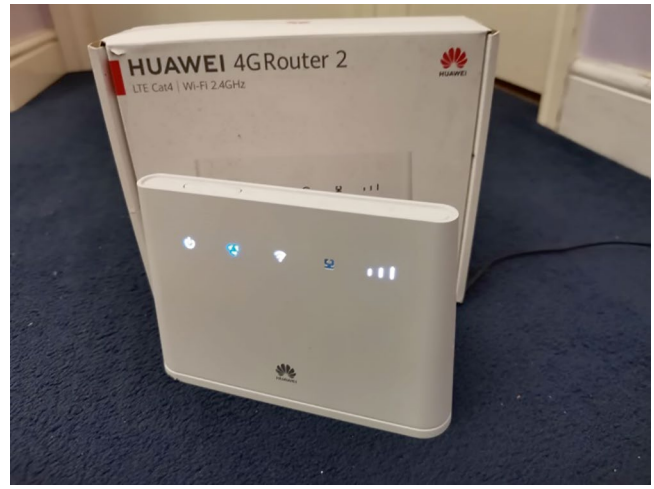

Fig. 23.3 A 4G mobile data sim wireless router useful for digital telephony and data transfer

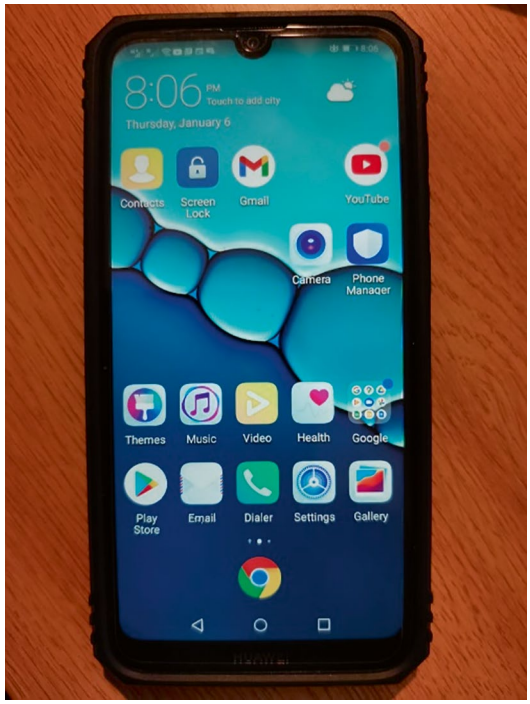

Fig. 23.4 A typical smartphone suitable for communication, data capture, and transfer

equipment affects where and how data is recorded. For example, measuring the body weight of a full-grown cow requires a big and heavy scale hence, this is often placed in one location on the farm and the animals are driven to the scale. Similarly, recording individual animals' feed intake or Methane emission may require the animals to be taken to a dedicated performance-testing pen. Miniaturization of the recording equipment allows the equipment to be taken to the field where the animals are, to record performance rather than moving the animals to the equipment. It facilitates the attachment of recording equipment to individual animals for automatic monitoring, data capture, and direct transfer of information to a central receiving database.

In poultry breeding, a large number of birds are recorded in the shed where they are housed or in the field in a free-range production system. Taking the recording equipment into the shed or field is thus the norm. So, the development of hand-held terminals (HHTs) which are miniature programmable computers with sufficient processing and storage capacity to hold recorded data temporarily makes data recording feasible. Such dedicated recording equipment is often made to be robust to the environment and sturdy enough to cope with knocks should they be dropped. Figure 23.5 shows some HHTs that can be programmed to record data. Figure 23.6 shows a mini printer that can be carried on the person and used to print information captured instantly while Fig. 23.7 shows a USB storage device with the capacity to hold one terabyte (TB) of data and allow such huge data to be transferred easily or even by post.

Fig. 23.5 Programmable hand-held terminals that can be used for data recording

Fig. 23.6 A miniature mobile printer that can be used to print instant labels during recording

Animal Identification

Individual animal identification is critical in the capture and storage of individual animal data. Hence innovations in animal identification systems make data recording on individual animals more feasible. Unique animal identification can be assigned to each animal on paper but for it to be effective, it needs to be associated with or attached to the live animal. For meat-type birds, this means from the day of hatch or birth until slaughter or death. So the form or means by which each bird is identified needs to meet a few conditions.

- It must be light enough to be carried around by the animal without impeding its natural behaviour and welfare.
- It must be rugged enough to survive the wear and tear of the production environment.
- The identification number must remain legible to the data recorder at all times.

Technological advances contributed significantly towards the development of tags that meet these conditions thereby facilitating animal identification and recording. In the simplest cases, animals can be marked simply by colour code (e.g. spraying the tail or wing feathers with different colour paint). Further miniaturization plus advances in electronic engineering have led to the development of electronic tags such as radio-frequency identification (RFID) tags. These are programmable tags that contain a radio transponder, receiver, and transmitter hence capable of transmitting data wirelessly to a designated RFID reader or antennae when triggered. Passive RFIDs do not need batteries but get their power from radio waves from the reader. Active RFIDs on the other hand have embedded batteries to power them. Electronic tags like these allow data to be captured even when the recorder cannot visualize the tag and unlike wing bands, do not need the physical immobilization of the animal either to read it manually or scan the barcode.

Fig. 23.7 A large-capacity portable data storage device (1 TB)

23.3 Improvement of Poultry Health and Welfare

Poultry health and welfare are the main pillars of poultry production where a lot of advancement has been made and they are essential to the sustainability of commercial poultry production (Ben Sassi et al. 2016). The World Organization for Animal Health states that 'An animal is in a good state of welfare if it is healthy, comfortable, well nourished, safe, able to express innate behavior and if it is not suffering from unpleasant states such as pain, fear and distress' (Terrestrial Animal Health Code). This applies also to all farm animals. Health is interconnected with welfare and it is critical to the strategy of sustainability because it directly affects human and animal welfare, economic viability, and environmental impact (Buller et al. 2018). A disease can be defined as any condition that interferes with the normal functioning of the cells, tissues, organs, and whole body systems of the animal. Prevention of disease is therefore one of the most effective ways to keep the birds healthy.

23.3.1 The Use of Technology in Various Aspects of Farm Animal Health and Welfare

There are many factors that affect animal health and welfare. These include stocking, density, carrying capacity, thermal stress, difficulties in accessing essential resources, environmental deterioration, and unsuitable social environments (Applegate et al. 2003; Muiruri and Harrison 1991; Tactacan et al. 2009). While many of these factors can be controlled by good management practices, recent advancements in technology have made the reduction in health and welfare problems in animal production achievable through the adoption of technologies in Precision Livestock Farming (PLF). This involves the use of process engineering that is based on automatic data acquisition, access, and processing (Mollo et al. 2009; Wathes et al. 2008). Data from diverse sources can be collected through smart sensors and compiled into a database where they will be later analysed to create an automatic management system based on real-time monitoring to control animal performance, health, and welfare (Aydin and Berckmans 2016).

23.3.1.1 Monitoring Sensors

Sensors are a good example of new technologies used in precision livestock farming. Great advances have been made in sensing technology in terms of diversity, accuracy, and affordability (Ben Sassi et al. 2016). Wireless sensors have a wide range of applications in engineering and agriculture. They were initially adopted to reduce livestock production costs while improving the health of the animals (Ruiz-Garcia et al. 2009). Environment monitoring sensors alert managers

to deterioration in pen condition, such as temperature changes or air quality, allowing timely corrective measures to be taken before they cause harm to animals. Movement and health sensors indicate the condition of individual animals so that sick or incapacitated individuals can be promptly identify and isolated for treatment or special care. Such prompt action help improve overall flock performance, health, and welfare. Some sensors can be used to predict broiler body weight while others can help in monitoring hatching windows during egg incubation to maximize chick quality at the hatch. Sound sensors can be used to measure feed intake, predict growth, and estimate thermal comfort within farms in broiler production (Aydin et al. 2014; Bright 2008; Moura et al. 2008). Sound sensors have been used in laying pens to detect stress induced by environmental temperature variation and fear. They also help monitor conditions that encourage or induce feather pecking (Zimmerman et al. 2000; Pereira et al. 2014).

Locomotion sensors help assess movement deficiency in broilers while Geographic Information Systems (GIS) allow us to evaluate space use as well as different behaviours in laying hens (Nääs et al. 2010; Daigle et al. 2014). Locomotion sensors have also been used to study the jumping of hens between perches and its impact on the occurrence of bone breakage. They are useful in studying hens' use of pop holes and their effects on keel fracture incidence in hens tagged with radio frequency identification (RFID) transponders (Richards et al. 2012; Banerjee et al. 2014).

The environmental conditions, with specific reference to temperature, relative humidity, and length of exposure to these factors, influence the welfare, performance, and health of broiler chickens (Stamp Dawkins et al. 2004; Jones et al. 2005). For example, growth, feed conversion, and immunological response of birds exposed to elevated levels of carbon dioxide ($CO_{2)}$ and Ammonia (NH_3) is impaired (Wang et al. 2010b; Ben Sassi et al. 2016). The adverse effect of these factors can be ameliorated with the use of sensors which can detect these factors early before their negative outcome manifests. Wireless technology armed with temperature sensors and accelerators has been used to detect highly pathogenic avian influenza (HPAI) infected chickens (Okada et al. 2009). A more sensitive technology based on signals from wireless 3-axis accelerometers and a radial lead thermistor has been used (Okada et al. 2014), to detect unusual responses caused by HPAI using data on the temperature and activities of birds transmitted to the wireless nodes. Sensors can therefore assist in detecting diseases prior to the manifestation of an outbreak which will subsequently prevent or limit economic losses. However, the cost of using sensors makes it difficult for general adoption (Ben Sassi et al. 2016), but recent developments in sensor techniques may help overcome this barrier.

23.3.1.2 In Ovo Technologies

Lack of access to feed for several hours (up to 72 hours) during transportation from the hatchery to the production farm can affect the health of poultry birds. This has adverse effects on the microbiome, immune system, nutrient intake, and utilization. To combat this, *in ovo* technology has been deployed which supplies the developing embryo with nutrients early to stimulate functional gut microflora. This provides necessary nutrients for the growth and development of the gastrointestinal tracts in poultry, thereby enhancing nutrient utilization and growth of the animal (Das et al. 2021). *In ovo* technology generally involves the administration of bioactive compounds, such as vaccines, nutrients, prebiotics, probiotics, creatine, follistatin, growth hormone, polyclonal antimyostatin antibody, and insulin-like growth factor-1, into the embryo. They can be applied during the late stages of incubation to enhance hatchability, performance, immune responses, gut morphology and microbiome, and overall health of birds (Das et al. 2021). The route, dosage, method, time of *in ovo* injection, and the host affect the outcome of this technology. Using this technology in vaccination is time and labour-efficient. It also increases the accuracy of vaccination and the development of immunity, without adversely affecting the hatchability of eggs in large-scale hatcheries.

23.3.1.3 Thermal Imaging

Preventing heat stress is crucial to farm animal welfare as it impacts behaviour, immunity, and physiological processes that can increase the mortality rate. Infrared thermal imaging (IRTI) technology has been used in this area for optimum performance. IRTI creates infrared images that reveal the distribution of the body's superficial temperature from the infrared radiation emitted by objects, which is then converted into electrical signals (Ben Sassi et al. 2016). In a study where optimum temperature and relative humidity were maintained, the optimal air velocity for the thermoregulation of broiler chickens was determined to be 2 m/s using the IRTI technique (Yahav et al. 2004). The body heat loss was calculated by radiation and convection using the IRTI methodology. It was reported (Giloh et al. 2012) that surface temperature detected by IRTI was more useful than ambient temperature in assessing the bird's status under experimental conditions. The IRTI technology has been utilized (Shinder et al. 2009) to influence the body temperature during the final phase of incubation and showed that chicks exposed to short periods of cold stress during incubation (days 18 and 19) had 13% to 18% lower incidence of ascites when compared to the control birds.

23.3.2 The Role of Technology in Handling Drug Resistance in Poultry

Poultry production has been used as a means to alleviate poverty and enhance economic development in Africa. With a rising population and increasing demand for animal protein, there is likely going to be a gradual shift from subsidence to intensive poultry production in Africa with a consequent increase in the usage of drugs and antibiotics (Hedman et al. 2020). Antimicrobial use increased between 2000 and 2015 by 65% (Klein et al. 2018). It is estimated to increase by another 67% by 2030 (Van Boeckel et al. 2019) due to an increase in intensive agriculture with low to medium-income countries leading the charge. This could increase antimicrobial resistance, especially in areas without effective biosafety and biosecurity measures (Hedman et al. 2020; Van Boeckel et al. 2019). It is therefore expedient to study the emergence of drug/antimicrobial resistance in poultry production (Ben Sassi et al. 2016; Van Boeckel et al. 2019; Food and Agriculture Organization (FAO) 2014) and evaluate the role of technology associated with it.

Drug/antimicrobial resistance is a growing global concern for human and animal health. It makes it difficult to treat bacterial infections while increasing morbidity and mortality risk caused by resistant bacteria (Hedman et al. 2020; Tang et al. 2017). The emergence of agricultural antimicrobial resistance in clinical settings has been reported by several authors (Van Boeckel et al. 2019; Allen 2014; Bengtsson-Palme et al. 2018; Robinson et al. 2016). More than 70% of antimicrobials produced globally are used in food-animal production (Van Boeckel et al. 2019; Food and Agriculture Organization (FAO) 2014) and poultry production represents a significant part of that. Although the use of antibiotics as a growth promoter has been banned by some organizations like the European Union, regulating this globally remains an issue (Allen 2014), because antibiotics are used to aid growth, prevent disease and treat infections (Laxminarayan et al. 2013). This makes the emergence of drug resistance a growing challenge. Several methods used in combating this include the use of probiotics, prebiotics, synbiotics, and phytobiotics. Advances in biotechnology have helped to improve the efficacy of these alternatives to antibiotic growth promoters.

23.3.2.1 Vaccines and Vaccination

The use of vaccines can offer protection against certain infections in farm animals. Because of this, the use of antibiotics in farm animals can be reduced without adversely affecting productivity. Vaccines cause a reduction in the symptoms that normally make producers use antibiotics. This results in an indirect reduction of antibiotic usage. When properly used, vaccines inhibit bacteria proliferation, keeping their population to the barest minimum and preventing them from causing havoc in farm animals. (Rappuoli et al. 2017).

Existing vaccines can prevent infections caused by antimicrobial pathogens (*Streptococcus pneumoniae* and *Haemophilus influenza)* (Rappuoli et al. 2017). Just as in humans, farm animal producers should be encouraged to adopt mass vaccination to ensure animal health. The risk of infection reduces as the use of vaccines increases (Woolhouse et al. 2015).

23.3.2.2 Bacteriophages

The use of bacteriophages to control pathogens is a promising aspect of handling drug resistance. Bacteriophages are bacteria-specific and possess the ability to infect only their target species or strain. Because of this specificity, bacteriophages do not destroy the intestinal microflora, hence they are safe and highly efficient. Bacteriophages cannot replicate in eukaryotic cells thereby resulting in a reduction of pathogenic bacteria (Wernicki et al. 2017). The population of pathogenic bacteria in the digestive tract of one-day-old broiler chickens was reduced when a high titre single dose of bacteriophage suspension was used (Fiorentin et al. 2005) while Salmonella concentration and mortality rate decreased (Lim et al. 2012) when 6-week-old broiler chickens received bacteriophages as a feed additive after having contact with salmonella. S. *enteritidis* strains were totally eliminated from the tonsils, 6 hours after application of bacteriophage suspension (Ahmadi et al. 2016). All these show that the use of drugs or antimicrobials can effectively be reduced with the use of phage therapy.

23.3.2.3 Biosecurity

Activities occurring on farms have a direct impact on the level of medications required. Observing adequate biosecurity measures on farms will significantly reduce the risk of infectious diseases. It is a way to minimize the usage of antimicrobials in animals and to prevent infections. Good husbandry and hygiene practices in conjunction with immunization can prevent the emergence and transmission of infectious diseases (Founou et al. 2021). Prevention of these diseases will have a direct impact on medication and the use of antimicrobials on farm animals.

23.3.2.4 Genomics

The use of genomics to solve the problem of drug resistance in poultry and other livestock species has been reported (Hu et al. 2020; Duggett et al. 2020; Delgado-Suárez et al. 2021). This includes the deployment of a genomic surveillance programme and One Health Initiative to tackle the problem of antimicrobial resistance (AMR), in humans, animals, and the environment (Duggett et al. 2020). The utility of whole genome data from both short and long-read sequences in bacteria collected from national surveillance activities has been demonstrated (Duggett et al. 2020). Such surveillance activities provide a wealth of data to assist in the monitoring of long-term national AMR trends more accurately including rapid retrospective analysis of a particular gene or AMR profile.

Whole genome sequencing (WGS) has been used to identify Multi-Drug Resistance (MDR) Non-Typhoidal Salmonella (NTS) from isolates in Mexico (Delgado-Suárez et al. 2021). They further reported that those from poultry and cattle had the highest population of MDR genotypes. The authors suggested that attaining significant improvement in AMR meat safety requires the identification and removal (or treatment) of products harbouring MDR NTS instead of screening for *Salmonella spp* or for isolates showing resistance to individual antibiotics. Further more, they (Delgado-Suárez et al. 2021) concluded that massive interrogation of WGS technologies in AMR surveillance provides the shortest path to accomplish these goals. Having genomic information provides enormous value for rapid retrospective molecular characterization to determine prevalence and transmission and facilitate comparison with new or current datasets in the event of an outbreak (Duggett et al. 2020).

23.3.3 Examples and Success Stories of Poultry Vaccination Programmes, Biosecurity, and Other Health Initiatives in Africa

A myriad of factors affect the health and welfare of animals in livestock production including

intensive poultry production. While environmental factors and the effect of stocking density can be controlled through well-established management practices, temperature, and relative humidity control require improved technology for optimum performance. Technology has aided the evolution of intensive poultry production systems and the resultant improvement in the performance of poultry. It is equally vital in transforming subsistence and commercial poultry production systems, especially in developing countries (Terfa et al. 2018). However, disease outbreak is a big obstacle that could alter the gains of improved management. Vaccination programmes, tight biosecurity, and several health initiatives are deployed to prevent disease outbreaks. Prominent among the diseases is the Newcastle disease (ND). It is endemic in subsistence production systems relative to the intensive system (Terfa et al. 2018). While the use of vaccines has proven effective in intensive production systems, its application has not been equally successful at the subsistence level due to high costs and poor development of the required cold chain storage facility for vaccines (Terfa et al. 2018; Ideris et al. 1990).

Attempts to improve the control of Newcastle disease include the development of vaccines with thermo-tolerant strains of ND virus, artificial selection for enhanced thermo-tolerance, delivery of vaccines in food, and the use of additives to suppress the effect of heat on vaccines. Low-resource areas have recorded success in vaccination against Newcastle disease via the use of avirulent, thermo-tolerant Newcastle disease vaccines, administered to chickens of all ages via eye-drops every 4 months. If freeze-dried, some thermo-tolerant variants (NDV4-HR and I-2 vaccines) can remain potent between 9 and 29 °C for about 2 months, or for about 2 weeks between 30 and 37 °C (Alders et al. 2002). A low-dose, fast-dissolving tablet vaccine that could retain its activity for over 6 months at 4 °C was reported by Lal et al. (2014). This makes the utilization of this vaccine less effective in developing countries where storage might be a problem.

Africa has experienced some progress in the area of vaccine developments in poultry. This has aided the improvement of the performance and health of farm animals. Some examples are as follows;

The Newcastle Disease and Avian Flu Control Project implemented Newcastle disease virus vaccination and general poultry health and management programme in three districts of Tanzania. The scheme utilized the I_2 variant of the Newcastle disease virus using a multi-level community approach. Vaccinators, household leaders, and data recorders were trained and the vaccination regime was followed. The project was successful as the survey on the outbreak of Newcastle disease from household respondents decreased from 53.1% in 2006 (prior to vaccine training and administration) to 15.7% in 2007 (after training and the first round of vaccine administration). By December 2007, all farmers contacted had no reported cases of Newcastle disease outbreak in their flock (Msoffe et al. 2010).

1. In September 2011, Farm Input Promotions Africa (FIPS-Africa), a Nairobi-based non-profit organization, employed a model of ND vaccine delivery that relied on district coordinators and village-based advisors (VBAs) purchasing the '*La Sota*' vaccine from local Agro-vets to vaccinate the birds in the villages.
2. Between 2003 and 2005, the Southern African ND Control Project (SANDCP) was active in four villages in Tanzania's *Chamwino* District, promoting ND vaccination in conjunction with the Tanzanian government.

Based on the positive outcome of intervention provided by these bodies, it was concluded (Lindahl et al. 2019) that interventions in which households are given assistance for vaccination of their birds, even for a short time, could drastically change their perspective, knowledge, and attitudes toward vaccines, resulting in a large decrease in bird mortality.

The absence of adequate ventilation (windows/openings) in the farm, the number of birds per production cycle, and the existence of duck farms in the village were used as measures for the biosecurity levels in an investigation of biosecu-

rity and High Pathogenic Avian Influenza (HPAI) vaccination programme in Egypt (Artois et al. 2018). They concluded that the presence of the HPAI A (*H5N1*) virus on poultry farms depended on the type of production system, vaccination status, and the biosecurity level on such farms. The HPAI vaccination study revealed a decline in the probability of detecting the HPAI A (*H5N1*) virus in ducks with vaccination. The virus was only detected in about 22.08% of the duck farms that were vaccinated while 91.71% of unvaccinated farms reported an outbreak of the virus. The authors reported a few cases in which vaccines appeared not to prevent the virus from infecting the ducks. Statistical analysis found a significant effect of poor ventilation (window opening) in increasing the risk of HPAI A (*H5N1*) infection.

In a study conducted among local hatcheries in Ghana (Agbehadzi et al. 2019) following proper vaccination and biosecurity measures, maternal immunity against a virus was found to enhance the efficacy of vaccines against such virus in the offspring. Birds were vaccinated against Newcastle and Infectious Bursal Disease virus and the authors reported that vaccines, in addition to proper management practices, are efficient in preventing disease outbreaks and ensuring profitability in poultry farming.

In another study (Aliyu et al. 2016), *La Sota* and *Komarov* strains were given as secondary vaccinations at 3 and 6 weeks of age respectively to ISA brown pullets that had been given Newcastle disease vaccine at day-old. They observed a better immune response in the birds vaccinated with the *Hitchner B1* strain of Newcastle disease virus in Nigeria. All these indicate that vaccine development is advancing and Africa is gradually adopting the use of vaccines on a large scale.

Samples collected during an investigation into the high poultry mortalities recorded on the 10th of August 2021 in Mondoukou, Ivory Coast (Lo et al. 2022), were positive for *H5N1* HPAI as confirmed by the national Central Veterinary Laboratory of Bingerville and the reference laboratory in Padova, Italy. Additional samples taken from live poultry markets in various locations, and from migratory birds in water flyways in the initial outbreak areas following preliminary examination of the H5N1 virus's incomplete HA gene sequence, reveal that the virus was highly pathogenic and belonged to the clade 2.3.4.4.b. More than 300,000 fowl were slaughtered on impacted poultry farms by veterinary services as part of ongoing sanitary measures to restrict the virus's spread. Veterinary services further undertook cleaning and disinfection operations in live poultry markets in the Abidjan District. They also conducted countrywide sensitization of Poultry Sanitary Defence Groups and poultry breeders to strengthen biosecurity measures, disease surveillance, and real-time reporting in poultry farms and markets from November 29 to December 18, 2021 (Food and Agriculture Organization (FAO) 2021),with the support of FAO, USAID, and active participation of the Ivorian Poultry Inter-Professional Association (IPRAVI).

23.4 Improvement of Poultry Nutrition, Feed and Feeding

The anatomy and physiology of the poultry bird digestive system is such that formulation of feed for captive birds is complex requiring the supply and balancing of all essential nutrients. This is further complicated by the need for high genetic merit birds which are high in order for them to produce to their genetic potential. While free-roaming birds traverse far to feed on various feed sources to balance their needs, birds housed in poultry sheds require the nutrients to be supplied in their feed. Various technologies have been deployed to facilitate the understanding of nutritional requirements as well as the processing and compounding of feed ingredients, feed storage, and delivery to the birds.

23.4.1 Technology and Poultry Nutrition

Nutritional research revolves around detailed knowledge of ingredients to promote performance, and nutritional requirements of various

poultry types at different stages of development. In general, poultry nutrition aims at feed utilization efficiency, protein efficiency, gut health management, feed enrichment, enzyme and mineral management, and mycotoxins under both conventional and antibiotic-free production systems. Nutritional science is an integration of biology, chemistry, physics, engineering, management, disease control, microbiology, toxicology, and in recent times, molecular biology. Determination of components of ingredients relies on analytical chemistry established in the Official Methods of Analysis published by the Association of Analytical Chemists (AOAC) (2019). Various types of ovens are employed to determine the moisture content of feed ingredients and feed. The traditional chemistry of the Kjeldahl analyser for determining protein content is expensive, laborious, and time-consuming. Technological development using the Dumas technology (LECO®) makes it easier to determine the amino acid and protein content of feed ingredients and feed. Traditional methods for determining ingredient composition have been replaced with near-infra-red (NIR) spectrophotometry, high-performance liquid chromatography (HPLC), plasma optical emission spectrometry, and ELISA methods. Innovations in chemical methods and instrumentations can directly and indirectly affect the diet. Accurate determination of feed utilization and performance are needed parameters for efficient poultry breeding. Therefore, to understand the nutritional needs of the various chicken types at different stages of development, multidimensional modelling and statistical tools are employed to model both biological and economic outcomes especially as nutrition can affect fat-free body composition (Eits et al. 2002). The use of computerized tomography (CT), dual-energy X-ray absorptiometry (DEXA), and nuclear magnetic resonance (NMR) technologies are employed to measure body composition. The use of these technologies and mathematical models can aid in precision nutrition.

23.4.2 Technology Used in Feed Manufacturing, Processing and Preservation

Feed manufacturing is an integral part of the farm value chain which traditionally has comprised grinding, batching, mixing, and pelleting. With innovations in information technology, emphasis is being placed on efficiency and precision in the manufacturing process. A major component of feed manufacturing is centred around ingredients. Ingredient composition has been the basis for diet formulation for years, however, advanced technologies for determining digestible components of nutrients have created a shift from the traditional ingredient compositionally-based formulations. By-product and rendered ingredients are usually not consistent in their components and quality thereby creating challenges in diet formulation. The NIR technology is already readily used in feed mills to analyse ingredient composition (moisture, protein, fat, fibre, starch, and amino acids) in real time. Additional biological information can be extracted by using in-vitro digestion modelling systems that can further improve the nutritional value of feed mill raw materials. Precision feed manufacturing is a quintessential part of feeding to meet the actual requirements of animals to optimize performance. Significant advancements in roller mills and hammer mills have improved the efficiency of grinding ingredients. Automation and adjustments in feed mill machinery have allowed for consistent particle size. Traceability of lot ingredients and usage of barcode readers for incorporating ingredients have benefited from programmable logic computers and variable frequency drive (VFD) controllers (Stark 2014). Enzymes, synthetic amino acids, pre-and probiotics, and other feed additives have significantly increased the number of ingredients used in feed manufacturing. The wide variability of inclusion rate among ingredients from macro ingredients like corn and soybean to micro-ingredients like enzymes requires more bins for micro-ingredients

and VFD controllers to increase the accuracy of ingredient incorporation. Automatic systems allow feed mill operators to perform statistical process control (SPC) analysis to ensure consistency in feed quality from batch to batch. The data from SPC also assists in the decisions on equipment updates to improve precision and accuracy of operation.

The demand for high-quality animal feed requires the conversion of ground mash feed into dense pellets. Pelleting allows for the agglomeration of ingredients of different sizes, densities, and flow characteristics. The process involves steam injection and mechanical pressure. Pellet quality is expressed as the pellet durability index which measures the ratio of intact pellet before and after tumbling. Pellet quality is affected by the type of raw ingredients and additives, diet formulation, ingredient particle size and grinding, pressure steam and duration of the conditioning, roll pressing of the hot mash against metal die, and cooling. Changes in ingredients and formulation can complicate the pelleting process. Technological innovations in the conditioning, roll/die, and cooling process have contributed to the adjustments needed to accommodate changes in ingredients, particle size, and formulation. There are several studies that have demonstrated that feeding broiler chickens pelleted rather than mashed feed improved feed intake, weight gain, and feed efficiency (Jafarnejad et al. 2010; Chewning et al. 2012; Abdollahi et al. 2013; Massuquetto et al. 2019). Technological improvements in the pelleting process can directly affect the determination of feed efficiency values used in genetic improvement programmes.

Differences in feed quality between the time of manufacture and feeding can affect productivity. It is therefore imperative that the quality of feed is preserved in order to attain the expected performance of animals. The spoilage process can negatively affect the nutrient value of feed. Microbes can degrade feed and the degradation products are often unpalatable (Frey-Klett et al. 2011; Amit et al. 2017). Improper preservation of feed can affect feed intake and microbial by-products can be toxic to the animal. Mycotoxins (aflatoxins) produced by moulds can react with lipids and cause peroxidation. Prevention of nutrient degradation also means a more efficient use of resources. Feed contaminated with *Salmonella* or *E. coli* causes significant risk to both animals and humans (Crump et al. 2002; Heredia and García 2018). Feed preservation requires (1) the proper storage of feed ingredients to prevent spoilage, (2) protection of feed ingredients during the processing steps, (3) proper storage of feed to prevent spoilage, and (4) appropriate use of mould inhibitors and antioxidants to extend the shelf life of feed. Feed ingredients should be stored at the required temperature and moisture, under hygienic conditions, and applying preservatives at the required levels. Technological innovations in feed ingredient and feed storage equipment and computer-based sensor monitoring can maintain feed quality.

23.4.3 Interaction Between Feed and Bird Performance/ Genetics Targeted Feeding

Even with all the advances in high throughput omics technologies, estimation of genetic parameters and genetic evaluation of breeding programmes cannot occur without phenomics. Precise and accurate measurement of phenotypes is essential for genetic improvement. Within a defined population, minimizing both environmental and genotype by nutrition interactions is essential in determining the genetic potential of an animal without these confounding effects. Computer-based controls can minimize fluctuations in the ambient environment under which poultry is raised, however, to minimize genotype by nutrition interactions within a population, precision feeding is required. Precision feeding aligns nutrient supply with the nutrient requirement of individual animals without unnecessary ingredient waste, based on a real-time sensor-based feedback system (Zuidhof 2020). Nutrient requirements are complex and depend on the genotype (genome) and the stage of development, assuming uniformity in the production environment (temperature, humidity, air quality, litter quality, disease control, etc.). Thus, in poul-

try, for a breeding population of the same age, nutrient requirements have to be tailored to the sex of the bird, growth, composition of gain, carcass composition, plumage coverage, and growth potential and efficiency of growth for meat-type birds (broilers), and the level and stage of egg production and egg quality for egg-type birds (layers). Emerging technologies (artificial intelligence, sensors, etc.) will have to bridge the gap between assessing the individual chicken's nutrient requirement and delivering the required diet in real time.

Precision feeding should include evaluating the nutri-physiological potential of feed ingredients, precise determination of nutrient requirement, and formulating balanced diets that limit the amount of excess nutrients with concomitant adjustment of nutrient supply to match the requirement of the animal fed (Pomar et al. 2011). Precision feed, therefore, requires extensive data collection, and large data analytics including artificial intelligence and mathematical modelling, which can be empirical, mechanistic, deterministic, or stochastic, and should be dynamic in real-time (Thornley and France 2007).

Nitrogen (protein) retention averaged 60.2% in broilers, 56.8% in turkeys, and 45.6% in laying hens (Applegate et al. 2003). Advances in nutrition by the usage of synthetic amino acids and dietary additives (enzymes, antioxidants, prebiotics, and probiotics) together with precision feeding can improve nutrient retention and reduce nitrogen and phosphorus in farm animal waste. This also requires concurrent technological innovations in the feed formulation system. Feed formulation has to be dynamic to respond to an individual animal's nutritional requirement in real time. The next-generation feed-formulation software should allow for the formulation of multi-blends, allocating ingredients according to cost and nutrient requirements and providing precision ingredient blends.

It has been shown that feeding pigs to meet their daily requirements significantly reduced their protein and phosphorus excretion by 25% and 29% respectively, and nutrient excretion was decreased by more than 38%. Furthermore, feed cost was reduced by about 11% (Pomar et al. 2011) and precision feeding on broiler breeders improved uniformity (Kutlu and Şahin 2017). This clearly demonstrates that precision feeding can lead to improved production efficiency and sustainability.

23.4.4 Advances in Farm Animal Nutrition Science and the Role of Technology

In order to support life in the form of maintenance and performance, farm animals utilize feed. The utilization of feed is a complex process including ingestion, mastication, digestion, absorption, assimilation, and biosynthesis. The dietary need of farm animals unlike other life forms is optimized according to the expected performance above maintenance requirements. Unlike classical nutrition which focuses on the diet or components of the diet and performance, molecular nutrition seeks to provide linkages between the diet through a stagnant genome and its dynamic genome expressions and performance. Thus, the conversion of the diet to animal protein is rather a complex process involving multi-organ interactions which are regulated by the genome and genome expressions. The study of the interaction between variations in the host genome (SNPs, gene variants, copy number variation, etc.) and the entire diet, components of the diet, bioactives, or nutriceuticals is often referred to as nutrigenetics. On the other hand, the effect of diet, components of the diet, bioactives, or nutriceuticals on genome expression (regulation of mRNA, protein, and blood or organ metabolites) is referred to as nutrigenomics. The use of omics to interrogate nutrition offers a huge potential to feed animals based on their individualized genomic signature to optimize sustainable (performance, health, and welfare) outcomes.

Nutrients regulate metabolic and other biological processes by altering genome expressions (Agyare et al. 2018). The technological platforms for determining genotype or sequencing the entire genome are similar regardless of the biological discipline or species. Next-generation

sequencing of either short or long reads has become the standard technological platform for sequencing (Blankenburg et al. 2009; Judes et al. 2016; Karahalil 2016). Similarly, the platforms for metabolomics, targeted or global gene expression, and their associated databases and bioinformatics tools are the same for the different disciplines or species.

The use of the Internet of Things (IoT), which are physical objects that are embedded with sensors, processors, software, artificial intelligence, and data exchange in real-time over the internet, cloud, or other localized communication systems, together with the use of nutri-physical properties of a feed ingredient, smart feed formulation, and precision feeding will allow for accurate measure of phenotypes for genetic improvement.

23.5 The Technology Used to Support Human Capacity in Farm Management

In Chaps. 27 and 28, the human capacity needs for livestock improvement and production in Africa, the state of play and efforts, and human capacity development were discussed. This section focuses on the technologies that can be deployed to support and enhance the efforts, skills, and knowledge of those working in the poultry sector to improve production efficiency. Intensively managed farm animals require a lot of inputs to be efficiently utilized and managed for optimal production and profitability of the animal industry. Besides, human activities are required at different production and processing stages. These production and processing stages are labour-intensive and quite repetitive. For efficient management of staff and these processes, precision animal production becomes imperative. Technology is currently being employed to reduce the amount of labour in relation to output, improve the management of birds, and increase product uniformity and quality. Technology is also being used to capture, transmit, store, and analyse data as well as derive useful information for human and farm management. Most production chains are automated. For example, feeds and water are supplied to birds through automatic feeders and drinkers. As technology advances, sound technology, sensors, and cameras are employed to automatically collect and process data for efficient farm management and optimal production.

23.5.1 The Use of Information and Communication Technology in Poultry Production

The deployment of new technologies in poultry housing and equipment is critical in curbing increasing utility bills and labour costs. It also helps with animal welfare as well as facilitates automation of operations which helps to mitigate the effects of climate change. Information and communication, ventilation, heating, and cooling systems are very important factors for consideration in a modern poultry house. The extent to which a poultry house is information-based will determine the efficiency of production and management (Zheng et al. 2021). The information and communication system should connect all sections of the farm to allow easy management of staff, equipment, environment, inputs, and animals. For example, ventilation and air inlet systems including roofing technologies had the greatest influence on the mechanization coefficient (Samadpour et al. 2018) and thereby improved production efficiency and economic performance of poultry farms. An efficient ventilation system alters air composition by letting in fresh air and getting rid of carbon dioxide, ammonia, particulate matter, and moisture. These would aid the survival and productivity, especially in pig and poultry houses as well as keeping airborne diseases to a level that can be tolerated by the animals (Samadpour et al. 2018). The ventilation system is critical in densely populated and in intensively managed poultry and pig units. The prevailing environmental conditions in the geographical location of farms and the intensity of production will determine the type of ventilation systems to install. In modern

commercial pig and poultry houses, a mechanical ventilation system is used because of its efficiency.

Given the increasing cost of energy and fuel globally, an efficient and cost-effective heating system needs to be in place in pig and poultry houses. Transmission and ventilation are two means of heat loss in pig and poultry houses that should be balanced to ensure that there is moderate heat for cost-effectiveness and the animal's optimal performance (Hulzebosch 2006). In a review of renewable and sustainable heating systems for poultry production towards energy saving and reduction in carbon dioxide emission (Cui et al. 2020), It was concluded that about 85% energy saving is achievable by applying technologically advanced ventilation and heating systems. As already indicated, ventilation helps with the circulation of fresh air, it is also a means of heat loss. Different technologies are being used to ensure a temperature that is tolerable by birds (Cui et al. 2020).

Automatic feeders and drinkers are used to supply feeds and water to birds in an efficient manner. This automation system reduces labour intensity, minimizes feeds and water wastage, reduces litter wetness, and thereby makes the litter less comfortable for microorganisms to thrive and cause diseases in poultry houses, especially from the floor of the pens.

23.5.2 Technology Used in Data Recording, Storage, Management, Analysis and Derivation of Information

Due to the large amount of data needed to be collected for efficient farm management; sound, sensors, and camera technologies are now playing critical roles in recording, storage, management, and analysis to derive useful information. A sound-based monitoring system can allow accurate detection of short-term feeding behaviours (Aydin and Berckmans 2016) at the group level and feed intake in broilers (Aydin et al. 2014, 2015) Individual meal size, meal duration, number of meals per day and feeding rate in broiler chickens can thus be determined in real-time with such sound processing technology. There has also been an attempt to use sound analysis to model the weight of broiler chickens (Fontana et al. 2017).

Sensor technology is important in data collection. These are devices that are positioned to collect data of different sorts that define animal or house stage (Jackman et al. 2020). There exist chemical and physical-based sensors that could be used in data collection from poultry houses and chickens for transmission and analysis. Relatively, camera-based weighing of broilers is potentially able to be used to determine the weight of broilers where contact is to be avoided (such as overweight and sick birds) and traditional automatic weighing machines are not suitable (Mortensen et al. 2016).

Computer vision systems are being deployed in poultry production for data capturing, transmission, and storage. Data can be collected from poultry houses on environmental variables as well as on birds (reproduction, production, health, and animal behaviour parameters). Components of computer vision systems include camera sensor, lighting, image processing board, software, and hardware (Nyalala et al. 2021)

In the fourth industrial revolution, there was huge interest in the application of robotics with the example of Gohbot®, ChickenBoy®, and ALIS chirpy sensor (Poultry Farming 2023). These technologies use machine learning, artificial intelligence, and sensors. With these, huge amounts of data can be generated in a very efficient and automated manner using powerful algorithms. Therefore, artificial intelligence is now available to the poultry industry to process and analyse large datasets being generated with these technologies.

The introduction of these technologies particularly in data analysis and analytics is not without challenges, particularly human capacity development. Hence there is a need for training and retraining for personnel in the poultry industry to be able to acquire and apply these technologies, especially in the area of data analysis involving programming and cloud computing since the majority of these large datasets are

stored in the cloud. This can be in the form of workshops. Besides, curriculum review of Animal Science departments at Universities will be critical to training students with current skills that will be of immediate relevance to the poultry industry.

23.6 Conclusion and Future Perspectives

23.6.1 Conclusion

Africa as a continent is well endowed with a big variation in poultry genetic resources. This includes a wide variety of Indigenous, localized, and exotic poultry species like Chickens, Ducks, Geese, Turkeys, Guinea fowls, Ostriches Emus, and breeds/strains within species. There is thus a high prospect for developing breeds and strains of these species adapted to the widely different ecological and geographical regions of Africa given the will and the right technology. Africa also has a very large pool of human capacity, at home and in the diaspora, with the knowledge and skill to utilize the most appropriate technologies applied to poultry improvements and livestock development in general. Where such knowledge and skill are unavailable, it can be acquired because technology can be bought and skill is transferable given the means.

The prospect for adopting and adapting technology and technical innovation to develop poultry production in Africa therefore depends on having access to the technologies that have been used worldwide, to successfully develop the poultry industry, including the genetic improvement of productivity, housing, health, and welfare of its poultry population. There is also a requirement for development and or access to the human resources needed to deploy these technologies. Success will depend on the creation of the appropriate enabling environment (Olori 2022) to facilitate the application of technological innovations in poultry improvement and production. Deployment of these technologies will aid sustainability, encourage youth involvement in poultry production and minimize the environmental footprint of poultry production. This is critical if poultry production in Africa is to meet its share of the projected increase in poultry meat demand (Food and Agriculture Organization (FAO) 2021) in Africa.

23.6.2 Future Perspectives

Technologies change rapidly. It is envisaged that new methods and tools will become available for livestock production in the future. These may or may not totally replace what is available today. So skills in adapting to changes in technology will be essential. Sometimes new technologies still depend on old and basic things. For example, the application of genomic selection still requires traditional data collection and it can be enhanced with full pedigree knowledge. So whatever technologies are adopted today will not necessarily become obsolete in the future. New discoveries may lead to new ways of feeding animals just as the introduction of nipple drinkers revolutionized the way birds are given water to drink.

With climate change and the stress on agricultural resources, it is envisaged that new housing technologies may become available to allow more intensive control of the livestock housing environment. For example, the menace of Avian Influenza and other diseases has led to the development and deployment of air filtration systems in poultry houses to improve biosecurity. Rising temperatures and increasing use of solar power technologies may see the deployment of cooling systems in managing poultry stock in African countries where open-sided houses currently suffice.

Automation in many operations can be envisaged as labour shortages increase in the future. In big operations, the increase in the use of robotics cannot be ruled out. These have been deployed in milking cows so it is possible that as costs go down in the future, similar robotics could be deployed in egg collection grading and packaging, feeding, water dispensing, and waste management in livestock farms. The use of modern technologies may require new or different skill sets, so further training and re-training of farm managers and staff can be envisaged.

This chapter has described technologies that are currently available and being deployed for efficient poultry production in many Western countries. These technologies if adopted will enhance the efficiency of poultry production in Africa. Globally, genetic improvement of poultry birds has been mastered by commercial breeding companies and they have a good distribution network that makes highly improved poultry day-old chicks available in every locality. Deploying technologies described above for poultry feed and nutrition, health and biosecurity as well as housing and management will lead to massive improvement in poultry production capacity in Africa.

24 Prospect for Utilization of Modern Technologies for Small Ruminant and Pig Improvement in African Input Systems: Case Studies

Jean M. Feugang, Othman E. -M. Othman, Wilson Nandolo, Donald R. Kugonza, and Richard Osei-Amponsah

Abstract

Small ruminants and pig production are crucial elements of the agricultural value chain. Several innovative technologies have been developed globally since the 1980s to improve the animal resources sector's efficiency, productivity, and profitability. However, the diverse mixed farming systems and their limitations in Africa are very poignant, and the continent has yet to tap into its animal agriculture technology use, including digitization to reach optimal production and satisfy its markets. Modern biotechnologies are used to very limited extent, especially in sheep and goat systems that are dominated by local breeds reared in extensive or semi-intensive production systems. On the other hand, the high prolificacy of pigs and the relatively higher profitability of pig farming create more interest in intensive commercial production systems. Furthermore, the current reliance on pig production, mostly on imported or exotic breeds, motivates the introduction of various innovative technologies to enhance animal welfare and sustainable productivity. There is significant oppotunity for African smallholder farmers to harness available modern technologies to improve reproduction, production, farm management, or environmental monitoring. These technologies have great potential to transform livestock operations to become more profitable and improve livelihood and social conditions of the people. This chapter explores the prospects of utilizing these technologies in African small ruminants and pig farms for sustainable production, including genetic resource conservation.

24.1 Introduction

Small ruminants (sheep and goats) and pigs are essential animal genetic resources (AnGR) in Africa and significant contributors to rural livelihoods (Nantoumé 2020). With their hardiness and adaptability, goats and pigs, efficient feed converters with low initial investment requirements, are ideal candidates for helping farmers graduate from poverty. Both are profitable for small-scale rural farmers and well suited to Africa's harsh environmental conditions (e.g., climate, food availability, extensive farming systems, infectious diseases). Due to their higher prolificacy and fertility rates and little related capital investment, goats and pigs are likely to be dominant players in the livestock sector in Africa, at least until 2050 (Herrero et al. 2014), providing clear advantages for income generation to smallholder rural farmers. The pork business, which provides food and income to about 70% of rural farmers, could see further improvements in production efficiency with the introduction of modern biotechnologies.

Biotechnological advances have improved production efficiencies in livestock, including sheep, goats, and pigs. However, their adoption in African countries needs improvement despite their potential to address specific challenges (Simpkin et al. 2020). Livestock biotechnologies can be categorized as (1) monitoring production conditions for effective use of resources; (2) monitoring environments for effective animal health management; (3) identifying superior animals efficiently; and (4) quickly multiplying animals to increase the pool for selection and/or reproduction of superior animals. The first two categories fall under precision livestock farming (PLF) (Berckmans 2017), which is still limited in Africa (Banhazi et al. 2012; Andonovic et al. 2018). However, their combination with other technologies, such as genomics tools and assisted reproductive technologies (ART), can enhance livestock production in Africa, especially small

ruminants and pigs having higher prolificacy. The combined use of these technologies is gaining popularity in countries like Ethiopia, Kenya, and Senegal, for improved breeding programs, breed selection in East African dairy cattle farms, and the creation of new breeds like Trypanosome-resistant cattle (Marshall et al. 2019).

24.2 Challenges Related to Small Ruminant and Pig Farming in Africa

Challenges such as the lack of sustained conservation programs (e.g., infrastructures, human capacity, regulations), genetic resource characterization, cultural issues, persisting climate change, and regulatory frameworks hinder the productivity of small ruminants and pigs in Africa (Visser 2019; Van Eenennaam et al. 2021; Havlík et al. 2015; Batlang et al. 2014; Adeyemo and Silas 2020). Continuous crossbreeding with imported breeds (e.g., Large White and Landrace pigs) increases productivity but leads to offspring less adapted to local conditions (Oluwole and Omitogun 2015). These offspring face issues like low-quality feed (e.g., reduced crop yields and access to water) and susceptibility to diseases such as African Swine Fever, which impacts global food security (Costard et al. 2009).

In Africa, the genetic diversity of small ruminants and pigs comes from controlled and unintended breeding with European and local breeds, allowing adaptability to the harsh environment and improved productivity (Amills et al. 2013; Mrode et al. 2018). Most African smallholder farmers practice in low-input settings (e.g., insufficient resources and poor feed and quality breeds) without any straightforward breeding program favoring genetic improvement (e.g., disease resistance, efficient growth rate, high meat quality, and reproductive performance), underscoring the urgent need for structured breeding programs. Some African governments (e.g., Algeria, Ethiopia, Morocco, and South Africa) and research institutes are working on genetic resistance to tropical diseases. These programs have been undertaken mostly through *in situ* or *ex situ* conservations (See Chap. 25). Sheep and goats are the preferred choice for smallholder farmers in Africa due to their economic benefits and resilience to environmental challenges. Community-based livestock breeding programs (CBBPs) have successfully preserved indigenous small ruminants and pigs in Malawi and Uganda, potentially revolutionizing future livestock breeding practices (Kaumbata et al. 2021; Demir et al. 2022). Initiatives to enhance the productivity of Indigenous goats through selective breeding and improved animal care have been introduced in Malawi and Uganda under the Feed the Future Initiative led by the United States Agency for International Development (USAID) and the African Goat Improvement Network (AGIN). These collaborative efforts among government agencies, stakeholders, smallholder farmers, and research institutions aim to leverage indigenous breeds and modern technologies to improve livestock productivity and uplift the livelihoods of farmers and stakeholders in Africa (Herrero et al. 2014; Latino et al. 2020). Therefore, smallholder pig, goat, and sheep producers in Africa must consider technological changes to leave the vicious cycle of poverty (Batlang et al. 2014). Despite the availability of various technologies (see Chaps. 20 and 21) to improve animal breeding, feeding, health care, traceability, record-keeping, and environmental monitoring in Africa, their adoption and use by stakeholders in the region are relatively low compared to other parts of the world. This chapter highlights successful cases of technology implementation and explores strategies to ensure their sustainable use, paving the way for a brighter future in African livestock farming.

24.3 Modern Technologies for Small Ruminants and Pigs Farming in Africa

Numerous technological approaches are available, and several have been applied to African livestock. For example, precision livestock farming (PLF) utilizes artificial intelligence and machine vision to automatically monitor individ-

Table 24.1 Examples of precision livestock farming technologies

Application	Technologies	Main objective/Function
Animal behavior	GPS sensors	Tracking location
	A neck collar with a series of sensors	Detection of estrus events through analysis of rumination rate, and the feeding and resting behavior
	Cameras and microphones Sound tool based on an algorithm	Find a correlation between vocalization and behavior
	A noninvasive imaging system such as VGG-face model, Fisherfaces, and convolutional neural networks	Pig-face recognition
Animal Health and welfare	A machine learning method	Pig cough detection-processing all incoming sounds and automatically identifying the number of coughs
	Air sensors	Prediction of the onset of Coccidiosis by monitoring the concentration of volatile organic compounds in the air
Feed management	An automated feeding system	Control the amount of feed provided, and the ambient temperature to optimize animal growth and reduce ammonia emission.
	A feed sensor	Measure and control the amount of feed delivered to individual feeders
	A next-generation feeding system	Provide feed with a variety of nutrient specifications to tailor both the amount and composition of the feed.
	A computer vision-based system CNN models using a low-cost RGB-D camera	Measures individual feed intake
	NIRS technology	Evaluation of physio-chemical composition of TMR and manure in dairy farms
Weight management	Weighing system based on image analysis	Determine the weight of an individual or group of animals (specifically pigs)

Adapted from Monteiro et al. (2021)

ual animals, boost production, and improve well-being (Monteiro et al. 2021; Berckmans 2017; Vranken and Berckmans 2017). The PLF relies on digital technologies (e.g., chips, wearable sensors, microphones, internet connections, smartphones, and video imaging) to track behavior, optimize feed, and evaluate animal well-being (Table 24.1). PLF's potential to significantly enhance livestock production (Monteiro et al. 2021; Racewicz et al. 2021), is particularly relevant in regions facing rapid population growth, including African countries such as Ethiopia, Kenya, Nigeria, and South Africa. Additionally, integrating genomic regions related to environmental adaptation into genomic selection practices holds promise for enhancing the sustainability of animal husbandry, mainly sheep and goats. Combining assisted reproductive technologies with genomic findings ensures further dissemination of highly genetic-merit animals with better commercial indexes and environmental adaptability.

24.3.1 Technologies for Environmental Mitigation and Precision Feeding

24.3.1.1 Animal Environment and Housing Monitoring

In Africa, persistent hot ambient temperatures require critical environmental modifications to animal housing to improve convection, conduction, radiation, and evaporative heat loss in animals. Additional cooling systems such as fogging, misting, showers, and evaporative pads have been

developed to mitigate the negative effects of high temperatures on Africa's already insufficient livestock production systems. The use of these engineered systems would be beneficial for both small ruminants and pigs.

Small ruminants have the advantage of being highly versatile and tolerant to rising temperatures. Approximately 50% of the total populations of both goats and sheep are found in the world's arid regions (Gowane et al. 2017). About 80% of the total dairy goat population is distributed in the tropical areas of Africa and Asia, meeting the demands of low-income communities (Silanikove et al. 2010) and supporting their livelihoods. In most African countries, small ruminants are reared in rangelands, requiring less human input. However, Precision Livestock Farming (PLF) technologies such as Global Navigation Satellite Systems (GNSS) reflectometry may help characterize grazing sheep behavior for data-based decisions in pasture management.

Additionally, the Global Positioning System (GPS) collar sensors allow the location of animals on pasture to help better understand their habits and spatial distribution. These tools, along with the widespread use of cell or mobile phones, are bridging the rural-urban and rich-poor divides, creating a sense of community among African smallholder farmers. Moreover, mobile phones have greatly benefited African smallholder farmers, allowing them to communicate on flocks' movements and theft protection or livestock market activities (Aker and Mbiti 2010).

In the hot tropical climate of Africa, the potential of PLF technologies to revolutionize pig farming is immense. Most animal buildings have undergone structural changes and flooring types to help decrease indoor air temperatures, such as tunnel ventilation and evaporative pads, reducing heat stress impact on animals. During periods of heat, some animal houses are equipped with sprinkling nozzles and high-velocity air streams or conductive cooling pads to alleviate the effects of indoor heat (Godyń et al. 2020). However, most African small ruminants and hog operations are open barns often built with cheaper local materials (e.g., wood, straws, and bricks), allowing full ventilation and preventing direct exposure to sunlight. Upgrading these facilities to modern environmentally regulated buildings with advanced technologies such as PLF is unaffordable to most African smallholder farmers despite the foreseeable positive impacts on animal growth and well-being. Indeed, pigs in such improved housing conditions show higher feed efficiency than their counterparts in older (Godyń et al. 2020). Renaudeau et al. reported that feed intake and average daily weight gain of growing-finishing pigs decrease with increasing temperature starting from 20 °C (Renaudeau et al. 2011). A later report indicated the beneficial influence of precision feeding in improving feed intake. However, in Africa, the widespread small and medium-scale extensive farming systems and the more conservative behavior of farmholders and consumers do not favor adopting new technologies.

24.3.1.2 Animal Feeding Performance

The demand for livestock feed has led to the development of technologies to increase the production of high-quality feed with limited resources. These technologies fall into five main groups: feed productivity improvement, feed quality enhancement, feed quality maintenance or preservation, enhancing the nutritional status of animals, and analytical and operational technologies (Balehegn et al. 2020). Small ruminants have shown higher efficiency in converting feed into weight gain (FCR or Feed Conversion Rate) and high-capacity conversion of low-quality feed into quality products, which is critical for low-income smallholder farmers in Africa. In these countries, sheep and goats are farmed on grazing land in variable numbers, without any or no feed supplements, and relying on low feed, water, and labor inputs. Many smallholder farmers rely on naturally selected breeds (e.g., Anglo-Nubian goat breed and Malabari, Malpura, Salem Black, and Damara sheep breeds), showing more tolerance to arid conditions while maintaining good productivity (e.g., meat and milk) and greater adaptability and survival to extreme environmental conditions (e.g., high temperature, feed, and

water scarcity). These conditions make introducing modern technologies in extensively reared flocks potentially less challenging for optimal nutrition and production achievements. Indeed, the existing technologies to monitor farm animals have the potential to ensure improved production and protection from thieves in conflict zones. In addition, these technologies may enable the characterization of grazing sheep behavior (i.e., GNSS) for database decisions in pasture management and animal location on pasture (i.e., GPS collar sensors) better to understand the habits and causes of the spatial distribution. Collar sensors are more accurate than human visual observations for tracking animal behavior to feeders, resting behavior, and frequency (Monteiro et al. 2021; Gaillard et al. 2021). In addition, noninvasive images and sound recording systems have a promising future, given the perfect correlation between animal sound and behavior (Berckmans 2017; Banhazi et al. 2012; Gaillard et al. 2021). Furthermore, technologies based on automatic identification have used approaches such as ear tags containing an RFID chip allowing recognition of individual animals (e.g., sheep, goats, and pigs) at electronic feeding stations (Banhazi et al. 2012; Andonovic et al. 2018; Vranken and Berckmans 2017).

Pigs lack natural adaptation mechanisms to environmental changes, requiring more human intervention in intensive production systems. The PLF in pig farming improves sustainability by minimizing losses, enhancing genetic identification, and reducing waste. Precision feeding improves nutrient utilization and reduces environmental impacts such as high altitude, climate change, environmental adaptation, and disease resistance (Rauw et al. 2020).

In Africa, the underutilization of feed improvement technologies is due to systemic constraints. Successful technology adoption is driven by financial incentives and the ability to address multiple problems. Engaging stakeholders in technology development is crucial. Diversifying suitable technologies for specific agroecologies and production systems is essential (Balehegn et al. 2020).

24.3.2 Machine Learning Systems and Growth Technologies

Feed efficiency (FE) is the ratio of daily weight gain to daily feed consumption over a specific period. Improving FE is a primary goal in livestock production to reduce costs and environmental waste. Precision feeding considers individual nutrient requirements within a group to adjust the quantity, quality, and timing of feed supplied, aiming to improve efficiency and reduce farm costs (Hendriks et al. 2019).

24.3.2.1 Feed Quality Improvement and Higher Feed Efficiency

The current meat production in Africa has relied on extensive traditional systems in challenging socio-economical environments that lead to insufficient supplies to meet market demands in Africa (Enahoro et al. 2019; Osei-Amponsah et al. 2019; Abdalla et al. 2021). Embracing technological advancements and innovative solutions to intensify livestock production offers a promising strategy to boost meat production rapidly. Critical factors such as genetic potential, environmental conditions, complete nutrition, and practical farm management practices influence the growth performance of livestock. In the Sahelian region of West Africa, 135 million people raise 173 million ruminant livestock, primarily sheep and goats. These animals rely on pastures and crop residues for food, while commercially formulated feeds are used for poultry and pig production. The availability and quality of feed resources vary across different agricultural areas and seasons. To meet the increasing demand for animal-source food, enhancing the nutritional value of crop residues, preserving fodder, and promoting feed markets is crucial (Amole et al. 2022). Smallholder farmers worldwide are encouraged to consider affordable alternatives such as growth promoters, improved breeds, housing, feed additives, hormones, and antibiotics to enhance the growth performance of farm animals (Gadde et al. 2017).

Various feed additives, such as nutrients (like hormones, pro/pre-biotics) and non-nutrients (such as antibiotics and exogenous enzymes),

have been found to have positive effects on feed efficiency, growth performance, and meat quality improvement (Valenzuela-Grijalva et al. 2017; Suryadi et al. 2019). However, the continuous use of hormones and antibiotics in feed has raised serious concerns. This has led to the One Health concept, which emphasizes the connection between environmental, animal, and human health in managing antimicrobial-resistant and food safety concerns (Andrew Selaledi et al. 2020). The increasing use of antibiotics as growth promoters for prophylaxis and metaphylaxis has been blamed for cross-resistance, multiple antibiotic resistance of pathogenic bacteria in humans and livestock, increased foodborne allergies, and negative environmental impacts (Rai 2013; Popova et al. 2017; Al-Shawi et al. 2020; Selaledi et al. 2020). As a result, the use of antibiotics in feed is being re-evaluated worldwide. Meanwhile, their increased "unsupervised" uses in Africa pose a threat to food safety and security, prompting stakeholders to consider alternative solutions for healthy meat production. Among various alternatives (such as enzymes and organic acids), probiotics and prebiotics have emerged as safe and viable options for increasing performance in livestock (Alayande et al. 2020).

24.3.2.2 Case of Pro- and Prebiotics, and Plant Extracts

Several reports indicated growth performance, carcass yield, and meat quality improvements following the application of growth technologies in meat production, particularly with probiotics and prebiotics (Valenzuela-Grijalva et al. 2017), which are amongst livestock's most used growth promoters (i.e., feed additives and hormones). Probiotics are live microorganisms conferring health benefits when consumed in adequate amounts. Upon ingestion, probiotics help to balance the intestinal microflora and impact the local and systemic immune systems by producing beneficial enzymes, organic acids, vitamins, and nontoxic antibacterial substances (Popova et al. 2017). Common probiotics include Lactobacillus, Bifidobacterium, *Saccharomyces boulardii* yeast, *Clostridium butyricum,* and some *E. coli* and Bacillus species. The most commonly used are *Lactobacillus acidophilus, Lactobacillus lactis, Lactobacillus plantarum, Lactobacillus bulgaricus, Lactobacillus casei, Lactobacillus helveticus, Lactobacillus salivarius, Bifido bacterium spp., Enterococcus faecium, Enterococcus faecalis, Streptococcus thermophilus, Escherichia coli* bacteria, and other probiotic fungi such as *Saccharomyces cerevisiae* and *Saccharomyces boulardii* (Al-Shawi et al. 2020). Probiotics are widely used in livestock animals (e.g., ruminants, poultry, pigs, and horses) to enhance growth rate, increase milk yield, meat, and egg production, and improve reproduction (Jin and Speers 1998; Denli et al. 2003; Higgins et al. 2008; Timmerman et al. 2006; Markowiak and Śliżewska 2018).

Prebiotics are non-digestible but fermentable food ingredients. They affect the host by selectively stimulating the growth and/or activity of specific bacteria in the colon (Davani-Davari et al. 2019). Prebiotics are dietary substances consisting mainly of non-starch polysaccharides and oligosaccharides, commonly used as oligosaccharides (e.g., fructans, oligofructose, fructooligosaccharides, galactan, galactooligosaccharides), resistant starch, pectin, fiber components, insulin, and breast milk oligosaccharides. Additionally, prebiotics help prevent the colonization of the digestive system by pathogens by creating unfavorable conditions, such as altering the pH of intestinal content.

Plant extracts are alternatives to antibiotics, known as phytobiotics, which could be affordable for African smallholder farmers. These plants possess antimicrobial, anti-inflammatory, antioxidant, and antiparasitic activities and have been used in poultry production for many years (Andrew Selaledi et al. 2020). Other plant extracts found in Africa include aromatic spices (cinnamon, clove, etc.), pungent spices (pepper, garlic, and ginger), and herbs spices (rosemary, thyme, mint, etc.). They have received increased attention due to their low costs and availability. Therefore, they are viable alternatives to meet the WHO antimicrobial usage recommendations in Africa. This is necessary to avoid the growing deterioration of livestock health and mortality rates, jeopardizing food security attainment.

Probiotics, prebiotics, and plant extracts are essential in animal production and health, contributing tremendously to the meat industry. Feed additive technologies have had positive impacts on feeding efficiency and growth performance. More studies are needed to evaluate their efficacy in small ruminants and pigs in Africa's tropical climate, and stakeholders should support such initiatives. National governments and other key stakeholders should encourage smallholder farmers to implement their plans to boost meat production in Africa.

24.3.3 Technologies for Animal Health, Welfare, and Disease Prevention Monitoring

Animal health is crucial to the One Health concept, impacting human health and livestock productivity through the misuse of antibiotics. Therefore, advanced biotechniques are being developed to monitor animal physiological and genetic changes for proactive health management. Modern livestock systems use noninvasive monitoring devices (e.g., cameras, microphones, and detectors) and information technology to support farmers and improve animal welfare. Precision farming technologies also help address production challenges and meet consumer demands (Racewicz et al. 2021).

24.3.3.1 Wireless and Wearable Sensors

Precision livestock farming uses advanced technology to monitor individual animals' health and welfare in real time. It involves analyzing images, sounds, tracking data, weight, and biological metrics for early illness detection and continual monitoring of physiological status (Benjamin and Yik 2019). This approach is particularly beneficial in pig production, where imaging technology helps with weight estimation, behavior monitoring (e.g., aggressivity, walking patterns, and posture), and lactation observation. Simple microphones and infrared cameras further enable the detection of specific acoustic events and physiological changes (e.g., stressful situations, coughs, and respiratory diseases), ultimately enhancing animal welfare and agricultural efficiency (Benjamin and Yik 2019).

Available devices can be classified into three categories based on the methodology and range of technology applications. *The first category of devices* detects specific animal behavior using special sensors like automatically measuring the frequency of pig visits to the feeder and the time taken to feed through radio frequency identification (RFID) technology. This category uses real-time video visualization using conventional monochromatic, color, or 3D cameras to depict activity level, area occupancy, aggression, gait scores, resource use, and posture. *The second category of devices* detects and records specific behaviors, such as drinking, feeding, and spatial distribution. The data collected is then processed into numeric form and presented graphically. This allows for the identification of changes in animal behavior, with the interpretation of data being a crucial step in understanding the implications of these changes. *The third category of devices* involves intelligent production systems that automatically analyze recorded physiological and behavioral changes. Based on the optimal settings of the farm environment, these systems can extract deviations from these settings and automatically make decisions to adapt the production environment to optimal production conditions (Racewicz et al. 2021). Using audio recordings, voice analysis, and machine learning algorithms, this category can detect animal heat stress, illness, or discomfort. Such a combination could benefit the detection of respiratory diseases or discomfort due to poor air quality, signaled by changes in vocal characteristics and acoustic signs such as coughing and sneezing. Specialized microphones' capability to differentiate between infectious coughs and those caused by environmental factors, such as accumulated ammonia or dust, underscores their incredible potential for health assessment (Racewicz et al. 2021).

24.3.3.2 Imaging Technologies

Extensive studies have investigated the behaviors and welfare of small ruminants and pigs, focusing on early disease detection using 2D/3D cam-

eras. Video monitoring and imaging are the most suitable technologies to enhance livestock production efficiency within PLF methods. These technologies offer noninvasive and effective tools for recording both individual and group animal behaviors. For instance, imaging can successfully assess body weight, detect lameness, and aggressive behavior, and identify heat in pigs (Racewicz et al. 2021). Digital infra-red imaging (DITI) is one of the latest imaging technologies adopted in veterinary medicine (Stelletta et al. 2012). It is an effortless, pain-free, and remote tool that can detect symmetric and asymmetric temperature gradients on the surface of the skin. This noninvasive nature of DITI reassures the audience about its animal-friendly application. This enables an accurate measurement of temperature gradients through thermal imaging. DITI is used in livestock production and reproduction systems to evaluate animal health and welfare (Soerensen and Pedersen 2015; Rekant et al. 2016; Nääs et al. 2020), with the ability to identify thermal abnormalities of the body and diagnose injuries and diseases in pigs and small ruminants. Recent studies have demonstrated the relevance of DITI in detecting temperature changes of animal bodies in tropical regions (Popoola et al. 2022; Leles et al. 2017), indicating its potential use in veterinary medicine for conditions such as heat stress, inflammations, and sickness.

Ultrasonography, an integral part of contemporary veterinary medicine, plays a crucial role in disease diagnosis. It involves using different transducers to examine structures close to the body surface (e.g., 5.0, 7.5, or 10.0 MHz transducers) or over 20 cm depth (e.g., 2.5 and 3.5 MHz). This inverse relationship between the depth of sound waves' penetration (frequency) and the image resolution means that low frequencies, permitting more significant penetrations, are associated with lower image resolution. Ultrasonography is widely applied in veterinary clinics to examine various areas and abdominal organs such as the thorax, spleen, digestive and urinary tracts, and reproductive organs for pathology detection (Cartee et al. 1993). Most organs can be imaged using the 3.5 MHz transducer (Braun 2004). Compared to routine histopathological analyses, it is an efficient and fast method for diagnosing diseases (e.g., endometritis) (Meira et al. 2012).

Digital Infrared Thermal Imaging and ultrasonography have revolutionized healthcare since their introduction over 40 years ago. Their implementation in Africa can enhance epidemic surveillance, improve animal welfare, and elevate reproductive management. For example, Precision Livestock Farming methods like electronic identification devices (i.e., RFID) are gaining popularity for identifying pigs and detecting diseases early (Arulmozhi et al. 2021).

24.3.4 Genomics Tools for Genetic Improvement

Molecular biology is driven by the transfer of genetic information from DNA to RNA and proteins, influenced by environmental factors. Gene transcription into RNA molecules is crucial for decoding the genome and regulating cell activities.

24.3.4.1 Natural Breeding and Genetics

Insemination by sexual intercourse, natural insemination, or mating is the common practice of animal breeding in most African countries, which lack sufficient infrastructure for assisted reproduction, such as artificial insemination (AI). In small ruminant and pig production systems, natural mating is cheaper and noninvasive. Still, it has less genetic input in livestock production. Furthermore, the lack of knowledge and absence of proactive government policies and legal frameworks to favor selective breeding hamper the generation of improved genetic animals for better adaptation to local conditions.

Nonetheless, genetics to improve livestock breeds and productivity is the focal point for scientific research and innovation. Most of the world's livestock breeding improvements rely on artificial insemination (AI), a powerful breeding tool in Africa, especially in small ruminants and pigs. Unlike natural mating, AI of synchronized females has higher pregnancy rates (Sh et al.

2020). Still, the existing constraints limit the widespread of AI in Africa. For example, a crucial need is for well-trained operators, accurate estrus detection, high-quality and good semen, an unbroken chain of liquid nitrogen storage, and appropriate equipment for enhanced precision breeding. Therefore, the recent progress in genetics and genomics opens exciting possibilities for creating new breeds that exhibit potential resistance to local factors (e.g., environment and disease). These innovations hold the promise of providing new approaches for African smallholder farmers to better manage animals in harsh environmental conditions. Genetic advances, stemming from increased knowledge in epigenetics (Zsidó and Hetényi 2020), DNA Methylation (Jang et al. 2017), histone modification (Alaskhar Alhamwe et al. 2018), RNA sequencing (Thorstensen et al. 2021), noncoding RNA (Mercer and Mattick 2013), and gene editing (Li et al. 2020a), are paving the way for a brighter future in livestock breeding in Africa.

24.3.4.2 Genetic Tools for Precision Breeding

Genomics, a crucial component of the African Strategy for biodiversity preservation, is a field that offers numerous biological techniques, particularly in genetics. The use of DNA, which serves as the stable fingerprint of an individual among cellular components, is of particular interest in the context of genomics conservation.

Restriction Fragment Length Polymorphism (RFLP), also known as DNA Fingerprinting, is a technique that involves the digestion of genomic DNA with restriction enzymes, followed by gel electrophoresis to visualize different DNA sequence lengths (Powell et al. 1996). This method, which exploits homologous DNA sequences, is widely used in forensic investigations and the mapping of hereditary diseases (Allen et al. 2000; Van Marle-Koster and Nel 2003).

Microsatellites are simple sequence tandem repeats (SSTRs) or short tandem repeats (STRs) corresponding to short (1–9 bp) and repetitive (5–50 times) segments of DNA scattered throughout the genome in noncoding regions between or within genes (introns) (Li et al. 2004). This technique locates mutations and identifies gene(s) responsible for a given trait or disease. It can be helpful for phylogeographic studies (Wright and Bentzen 1995). The literature lecture indicates that the genetic characterization of local tropical breeds is mainly achieved through microsatellites, especially with small ruminants such as the indigenous Moroccan sheep (Gaouar et al. 2016) and the goats in Southern Nigeria (Okpeku et al. 2011). Microsatellites and SNPs have been crucial in using and conserving animal genetic resources. Now, with the affordability of these new sequencing technologies, whole-genome sequencing (WGS) and genome editing have the potential to revolutionize livestock population studies, making advanced genomic techniques more accessible to African research institutions (Cortes et al. 2022).

Mitochondrial DNA (mtDNA) is an extranuclear double-stranded and small DNA with 2–10 copies in each mitochondrion. This technique detects population changes along with their maternal origin and migration routes (Moritz 1994; Wong and Boles 2005). It is less common in tropical breeds than the microsatellite technique.

Whole-genome sequencing (WGS) allows the determination of the order of the bases in an organism's genome in one process. As a result, data can potentially discover all genetic variants, showing the power of genome-wide associated studies (GWAS). Despite its costs for a large number of sample analyses, GWAS permits the identification of trait loci and nucleotides related to a particular trait or disease (Molotsi et al. 2017; Ramos-Onsins et al. 2014).

Microarrays are microchips containing short-sequence DNA (cDNA, oligo DNA, BAC, and SNP) or RNA to simultaneously detect polymorphisms or expression profiles of thousands of genes within a population (Heller 2002). The single nucleotide polymorphism (SNP) arrays are variants of DNA microarrays used in WGS for DNA genotyping to help predict individual responses to stimuli in GWAS (e.g., disease, drugs, and environmental factors) (Gunderson et al. 2006). Millions of equally dis-

persed biallelic SNPs within the animal genome (i.e., 335 million SNPs in humans) make this technical approach far better than microsatellites for gene expression studies (Cánovas et al. 2013). Still, many SNP markers are required to achieve valuable and comparable information to microsatellites.

RNA-Sequencing is based on labeling fragmented RNA (50–500 bp) with adapter sequences, sequence reads counts, and full-length transcripts assembly (Mantione et al. 2014). It offers improved specificity for detecting transcripts and isoforms better than microarrays while offering high sensibility detection of differential expression. As a result, RNA-Seq is more likely to be used routinely than microarray for gene expression profiling and has a bright future in bioinformatics data collection (Griffith et al. 2010; Cui et al. 2014; Toms et al. 2021).

Gene editing, the ability to make specific changes in the DNA sequence of a living organism, is a complex process that uses engineered nuclease enzymes to target a particular DNA sequence by removing, adding, or replacing a specific DNA segment spot. CRISPR (clustered regularly interspaced short palindromic repeats) technology, known for simplicity, is the top choice for genome editing. The gene editing technology is CRISPR-Cas9, a sophisticated genetic tool that plays a crucial role in gene inactivation (Li et al. 2020b). Inactivating genes (e.g., slick, NANOS2) may create novel farm animals with a modified genetic pool. These newly engineered animals may better adapt to tropical conditions, such as heat stress and high resistance exposure (Park et al. 2017; Ciccarelli et al. 2020; Karavolias et al. 2021). Unfortunately, few African countries (e.g., Nigeria and Kenya) have legislative interpretations of new genome editing techniques.

Bioinformatics or computational biology is an interdisciplinary science that models biological systems combining mathematics/physics, computer science, medicine, and biology85. According to animal species, the availability of various software, algorithms, and bioinformatics permits the interpretation of generated biological datasets (e.g., genomics, transcriptomics, proteomics, and metabolomics).

The abovementioned technical tools have been utilized for genomic selection in various African livestock animals. Unfortunately, only a few African countries have functional research laboratories or centers capable of completing genomics analyses to improve livestock. However, these techniques are gaining popularity across the continent. For instance, in Ghana (Osei-Amponsah et al. 2017), livestock genomic technologies have revealed the origin and phylogenetic status of the Ashanti black forest Dwarf Pig, which has several advantages over exotic European breeds, such as better survival under poor input environments, less susceptibility to local diseases and parasites, and better meat quality. In Ethiopia, these technologies were used to estimate breed proportions in the local sheep population (Marshall et al. 2019). Various research centers collaborate to share expertise and reduce costs. Genomic tools assess genetic diversity, improve animal genetics, trace phylogenetic relationships, and study geographical distribution and origins (Ibeagha-Awemu et al. 2019). The significant role of national governments (e.g., Algeria, Ethiopia, Kenya, Morocco, Rwanda, Senegal, and South Africa), international organizations or foundations (e.g., USAID, FAO, AU-IBAR, and Bill & Melinda Gates), and research organizations (e.g., ILRI and CTLGH) cannot be overstated. Their efforts have been instrumental in genetically improving small ruminants and pigs for increased milk or meat production through specific genetic improvement programs, such as Nucleus-based breeding schemes (Kosgey et al. 2006). As a result, more animals on the continent are genotyped and sequenced to enable precision farming (e.g., breeds and geographic matches, enhanced breeding programs) or to create new breeds (e.g., heat resilient or trypanotolerant breeds).

Genomic selection has transformed breeding in advanced economies and holds promise for African countries. Despite challenges, collaborative efforts are overcoming barriers for smallholder farmers. These hurdles, which make

traditional genetic programs impractical for smallholder farmers, are being overcome by the collective efforts of stakeholder-led initiatives (e.g., ILRI) and projects like ADGG and iCow (http://www.icow.co.ke/). The lack of infrastructure and human capacity are significant limitations, but the establishment of the African Animal Breeders' Network (AABN—http://animalbreeding-africa.org/) is a crucial step toward building the necessary human capacity to drive genetic improvement programs across the continent (Burrow et al. 2021). Various chapters of this book discuss further applications of genomic tools with benefits in Africa and reviewed elsewhere (Marshall et al. 2019; Amills et al. 2013; Mrode et al. 2018; Muchadeyi et al. 2020).

24.3.5 For Reproductive Performance Improvement

The increasing worldwide demand for animal-source food for the human population drives the widespread use of ARTs for massive livestock production. These technologies, such as artificial insemination (AI), estrus synchronization (ES), pregnancy detection, *in vitro* embryo production (IVP), multiple ovulations coupled with AI, embryo collection and transfer to recipients (MOET), and IVP—embryo transfer (IVP–ET) hold the key to revolutionizing genetic improvement and reproductive processes in various livestock species90. In addition, imaging technologies such as Digital Infrared Thermal Imaging (DITI) and ultrasonography have been adapted for further reproductive improvement in various livestock species, including small ruminants and pigs. While developed nations have embraced ARTs to drive productivity and reduce production costs, the potential of these technologies in developing countries, particularly in Africa, remains largely untapped. Countries like Ethiopia, Kenya, Nigeria, and South Africa have seen varying degrees of success, primarily focusing on cattle. However, these technologies have immense potential to drive significant advancements in livestock production on the continent (Balehegn et al. 2020; Yadeta 2020; Niyiragira and Rugira 2018; Celestin et al. 2019).

24.3.5.1 Assisted Reproductive Technologies.

Artificial Insemination (AI) and Estrus Synchronization (ES) These are the popular technologies to disseminate improved genetics in livestock species in a broader reach to farmers in communities, facilitating access to genetic gain while reducing infectious reproductive diseases' transmission. Intensive pig production systems apply AI to introduce superior genes into sow herds. The AI is primarily used in various African countries in crossbreeding programs with freshly collected (indigenous breeds) or imported (exotic breeds such as Landrace and Large White). Boar semen is relatively easy to harvest by hand-gloved technique, initiating semen release (King and Macpherson 1973; Ko et al. 1989). Single ejaculates contain enough sperm to inseminate 15–25 sows through conventional cervical AI (Maes et al. 2011). Semen is used to inseminate females (gilts or sows) following naturally occurring estrus or hormonal synchronization. The combination of equine (eCG) and human (hCG) chorionic gonadotropin for synchronization induces better results than the boar exposure (e.g., sound, smell, and physical presence), inducing GnRH secretion, estrus, and ovulation. The success rate of pig AI (~90%) with fresh extended semen is comparable to natural mating (Roca et al. 2006; Knox 2016). The AI technology in pigs is adaptable and has been successful in many countries (Waberski et al. 2019; Vishwanath 2003). Estrus synchronization is the second most important technology for improving animal productivity. It brings females together for parturition, reducing labor and financial resources, shortening the calving period, and ensuring more consistent weaning weights. Additionally, it eliminates the need for estrus detection in AI, making the process more efficient and cost-effective. Both AI and ES techniques are sustainably adopted in many African countries for intensive and extensive (smallholder backyard) pig production systems, with a practice in cattle that goes back to 1938 in Ethiopia

(Bamundaga et al. 2018; Oke-Egbodo et al. 2018; Niyiragira et al. 2018).

For sheep and goats, AI is mainly practiced on a commercial level. Fresh or frozen semen is collected using an artificial vagina or electrical stimulation that gives a 10 to 15-volt output (Steyn 2003). Inseminations using estrus-induced ewes are done through cervical and intrauterine (or laparoscopic) routes. Sheep farming is of great economic, social, and environmental interest in the southern Mediterranean countries, such as Morocco, Algeria, and Tunisia. Artificial insemination (AI) of sheep has been studied since the 1980s, with AI centers established by public authorities in Morocco. Nonetheless, the main challenge in using AI in sheep selection programs is preserving ram semen, and the successful cryopreservation of semen for non-surgical AI is seen as the golden way to enhance fertility outcomes for rapid genetic progress (Atigui and Chniter 2022). In Ethiopia, the development of low-cost, low-infrastructure AI protocols supported sheep and goat breeding programs involving various stakeholders (i.e., research centers, universities, national AI centers, and veterinarians). Due to better management, this innovation improved conception rates (50–60%), overall fertility, and the number of offspring produced in the Community-Based Breeding Programs' flocks. The program has low infrastructure needs and applies to both sheep and goats. Stakeholders should ensure that any AI system put in place is reliable and easily accessible by farmers. Meanwhile, in Rwanda, the use of drone technology to deliver semen straws should be encouraged.

Several ES protocols are available to stimulate follicular development and regulate ovulation. Protocols use intramuscular prostaglandins F2α (PGF2α) administrations alone or combined with eGC, progesterone, or analogs through controlled intravaginal drug release device (CIDR and sponge), ensuring over 72% estrus induction (Ramukhithi et al. 2012; Gore et al. 2020a; Fierro et al. 2013; Bukar et al. 2012). Nonetheless, progestogen devices induce vaginitis in females, reducing fertilization rates and making the PGF2α administration a safe alternative to progestogens. Estrus synchronized ewes are frequently inseminated with fresh semen using the intrauterine route (Gore et al. 2020a), reaching the highest pregnancy rates (60–80%). Both ES and AI have been practiced in African breeds of sheep and goats but remain experimental or low-scale in various countries (Omontese et al. 2016; Mekuriaw et al. 2016; Abu et al. 2008; Gore et al. 2020b; Godfrey et al. 1999; Habeeb and Kutzler 2021). The most common estrus synchronization procedure in the Maghreb region involves using vaginal devices (sponges) impregnated with 30–40 mg of fluorogestone acetate progesterone implants for 14 days, along with an equine Chorionic Gonadotropin (eCG) intra-muscular injection on the removal day. Two synchronization treatments were tested for Moroccan sheep breeds using progesterone implants combined with either eCG or prostaglandin analog injection. The lambing rate of D'man ewes was 34.9% and 21.7% for ewes treated with PGF2α and progesterone, respectively. For the Timahdite breed, the rate was 39.1% and 13% for ewes treated with PGF2α and progesterone, respectively (Atigui and Chniter 2022).

Pregnancy Detection Pregnancy detection and monitoring are essential diagnostic procedures undertaken in livestock as part of fertility management. However, routine pregnancy diagnostic methods in small ruminants and pigs are more indirect. These methods include endocrine hormone detection (e.g., progesterone, estrogens, PGF2α, and estrone sulfate concentrations) (Goel et al. 2009; Williams et al. 2008) and visual systems, the most used approach in farms (Goel et al. 2009; Bharti and Jacob 2019; Kauffold et al. 2019). Hence, the non-return rates to estrus and teaser males are routine visual methods applied in smallholder farms to detect non-pregnant females within the herds. The transabdominal visualization of the reproductive tract through ultrasonography is another visual method (A-mode, Doppler, and B-mode ultrasound). Furthermore, the direct method of pregnancy diagnosis consists of rectal palpation of sheep and goats by placing fingers in the rectum and lifting the abdomen (Kutty 1999). Although pregnancies can be detected as early as

25–30 days in small ruminants and pigs, the most accurate detection appears to be around and above 45 days of gestation (Williams et al. 2008; Gonzalez-Bulnes et al. 2010).

Multiple Ovulation (MO), In Vitro Embryo Production (IVP), and Embryo Transfer (ET) Hormonal induction of multi-ovulation (e.g., PMS, FSH) may follow synchronization for in vivo embryo production. Pigs (gilts/sows) and small and small ruminants (does and ewe) are naturally multi-ovulating animals. Hormonal treatments (e.g., hCG and LH) allow more eggs to ovulate from the donor females during natural heat. The insemination of donors will permit egg fertilization and embryo development until collection through oviductal flushing. Contrarily to large animals (e.g., cows and mares), embryo flushing is a surgical procedure in small ruminants and pigs. This procedure limits the MOET application in most African countries, needing more resources and trained personnel. Despite the recent progress in non-surgical procedures such as intracervical catheter insertion in pigs (Martinez et al. 2001; Yoshioka et al. 2012), embryo recovery rates remain low.

Hence, the MOET using fresh or frozen-thawed embryos can help increase genetically superior females or breed restocking in Africa. Furthermore, IVP's potential for additional embryo production is generally low and more costly than AI, limiting its application in the continent (Graff et al. 1999; Cognie et al. 2003). Indeed, various limitations affect the successful application of IVP in Africa due to its reliance on immature oocytes harvested from living (e.g., laparoscopy and ultrasound-guided ovum pick-up) or post-mortem (e.g., slaughtered females at abattoirs) females (Fowler et al. 2018; Cognié et al. 2004; Ikoma et al. 2014).

24.3.5.2 Imaging Detection Techniques

Researchers have used DITI and ultrasonography to diagnose the reproductive status of livestock animals (Rekant et al. 2016). For example, the DITI has been used to detect estrus in gilts (Sykes et al. 2012), ovulation, and decreased vulvar temperature of sows during the periovulatory period (Clark 2011). In a recent study, we found the effectiveness of DITI in examining scrotal and udder temperatures of Red Sokoto goats and Uda sheep under semi-intensive systems during the hottest climate in Nigeria (Popoola et al. 2022). In this later study, bucks and rams exposed to high ambient temperature showed higher scrotal temperatures, which may negatively influence male fertility due to reduced semen outputs and compromised sperm quality.

Since 1983, transcutaneous B-mode ultrasonography has successfully diagnosed pregnancy in pigs (Inaba et al. 1983) and small ruminants (Tainturier et al. 1983; Baronet and Vaillancourt 1989). Its introduction in pig facilities has shown to be helpful in various applications, such as monitoring ovarian activity and estimation time of ovulation, detection of puberty onset, accurate pregnancy diagnosis around 30 days post-insemination, or end of estrus (Kauffold and Althouse 2007). Although transrectal examinations provided the most accurate diagnoses, the transcutaneous B-mode US at 5.0 MHz transducer also provides correct diagnoses. Studies show that successful pregnancy diagnosis in early gestation depends upon transducer frequency, application route, technical expertise, experience, and other factors inherent to the animal. Therefore, B-mode ultrasonography is the most valuable tool for scanning small ruminants and pigs. It is a relatively simple, fast, and safe procedure that does not cause additional distress to animals.

24.4 Capacity Development for Technology Adoption

The training programs for small ruminants and pigs in Africa can bring economic, environmental, and social benefits. Educating farmers about sustainable practices like biosecurity and water consumption is essential. It is crucial to increase awareness, training, and skills programs for farmers and stakeholders to promote the adoption of modern technology. Governments should

focus on building local capacity in innovative water and agricultural solutions. Indigenous breeds can be crucial in adapting to climate change, and capacity development is essential to improve husbandry. Engaging pastoral communities through gender-inclusive groups is crucial for accelerating the adoption of new practices. Uncontrolled animal mating can lead to inbreeding, so improving animal husbandry practices and implementing biosecurity measures is essential. Omics technologies offer the potential for understanding how resilient breeds adapt to environmental changes, but their use in tropical animal production is limited. Advanced technologies such as PLF, omics, remote temperature monitoring, and GPS animal tracking have revolutionized sheep and goat farming. Further research is needed to gauge African farmers' awareness and willingness to adopt these technologies.

24.5 Conclusion

Small ruminant and pig genetic resources are crucial for African agriculture, but traditional methods must be revised to meet rising demands. Biotechnology and other innovations, including digital technologies, offer hope for achieving the "UN Sustainable Development Goals related to food security, poverty reduction, improved livelihoods, and the One Health Concept." These goals are achievable, and action is required. Governments must invest in capacity building, enact supportive policies, and leverage indigenous livestock diversity in production systems.

Conservation of African Livestock Genetic Resources

25

Conservation and Management of Animal Genetic Resources in the Context of African Livestock Production Systems: The Case for In Situ and Ex Situ Conservation

Jean M. Feugang, Richard Osei-Amponsah, John E. O. Rege, Khaled Fantazi, Christian K. Tiambo, Felicien Shumbusho, Isidore Houaga, Derradji Harek, Notsile H. Dlamini, and Semir B. S. Gaouar

Abstract

Conserving and managing African animal genetic resources requires understanding how these resources evolve (political, environmental, cultural, and social). Factors associated with this context are unfavorable for sound conservation and management in most African countries. This chapter presents the major threats to indigenous animal genetic resources (Sect. 25.2) in Africa; the in situ and ex situ conservation methods practiced (Sects. 25.3 and 25.4), operational guidelines (Sect. 25.5), and the opportunities presented by modern technologies (Sect. 25.6). More research structures and skills in reproductive biotechnology and genetics are needed in the continent to ensure the sustainability of animal resources, in particular those with low numbers or less economic interest. Some African countries with constituted herds for conservation (ex situ in vivo) have also taken the initiative to generate gametes, embryos, tissue, and DNA banks.

25.1 Introduction

Livestock production faces significant challenges associated with critical drivers of change in the global livestock sector today. These trends include changing market demands, more specifically the *livestock revolution*—the unprecedented global shift in demand for livestock products such as meat, milk, and eggs; economic development and globalization; significant changes in the demographic as well as the regional distribution of these demands; the need to reduce poverty in rural communities by supporting sustainable livelihoods; a growing awareness of the need to reduce the environmental impact of livestock production; the uncertainties of climate change;

and science and technology innovations. The need for legislation on livestock breeding and the equitable distribution of grazing lands and water resources is a major challenge for development in Africa. The continent remains home to significant genetic diversity, which trends affect livestock's ability to improve livelihoods and reduce poverty and the use of natural resources. In the developed world, the narrowing animal genetic resources (AnGR) base in industrial livestock production systems also raises the need to maintain a broader range of AnGR to deal with future uncertainties, such as climate change and zoonotic diseases. The implications are that breeds cannot adapt in time to meet new circumstances. Therefore, strategic interventions are necessary to improve the management of animal genetic resources in situations where these genetic resources are most at risk (Seré et al. 2008).

The worldwide growing industrial livestock production systems have a limited demand for biodiversity. In contrast, crop-livestock and pastoral systems, the primary livestock systems in Africa, will continue to rely on biodiversity in diverse genotypes of improved productivity under different and constantly changing environmental and socio-economic conditions. However, all systems will require genetic diversity, albeit to varying degrees, to cope with expected climate change and other insecurities (Osei-Amponsah et al. 2019). Thus, threats to livestock genetic diversity, wherever it is occurring, should be a global concern. Furthermore, the multiple values, functions, and consequences of the different livestock production systems and their rapid rate of change imply diverse interests within and among countries.

Conversely, uncertainties about the implications of rapid, multifaceted global change for each livestock production system, the livestock species and breeds within it, and the resulting future changes in the required genetic make-up of AnGR make collective action to tackle their conservation a long-term, global public good. In this context and a spirit of complementarity, North-South and South-South win-win relations are to be encouraged and initiated quickly by international organizations (e.g., Food Agricultural Organization or FAO) or research institutes (e.g., International Livestock Research Institute or ILRI). Of course, conserving AnGR will not, by itself, solve these problems. Still, it is an essential first step toward maintaining future options (Seré et al. 2008). The conservation of AnGR refers to all human activities (i.e., strategies, plans, policies, and actions) undertaken to maintain the diversity of AnGR for food and agricultural production and productivity or other present and future values of these resources (e.g., ecological, cultural) (Rischkowsky and Pilling 2007). It consists of both in situ and ex situ conservation methods. The latter is subdivided into ex situ in vivo and ex situ in vitro.

This chapter examines significant threats to African indigenous AnGR. Then, it presents options for conservation interventions, focusing on community-based approaches designed to be owned and driven by local farming communities.

25.2 Major Causes of Threat to AnGR

Considerable literature describes numerous threats to AnGR. For example, in an early study on African cattle genetic resources, 32% (47/145) of total cattle breeds in the continent were at risk of extinction, while about 15% (22/145) were extinct in the last century (Rege 1999). In 2007, the FAO provided the first global assessment and analysis of the status and trends in AnGR that raised worldwide awareness and understanding of the ongoing erosion (Food Organization, A 2007), with existent threats for indigenous livestock breeds in Africa. Several factors, such as the replacement of indigenous breeds by others, crossbreeding practices, local conflicts, animal diseases, neglected or lack of sustained breeding programs, and loss or restriction of habitats, gradually influence the distribution and characteristics of production systems (Alexandratos and Bruinsma 2012). Such is the case of various species, including the Bakosi cattle in Cameroon, the Ouled-Djellal sheep in Algeria, the Kuri cattle of Lake Chad, and the Walia Ibex goat of Ethiopia (Rege 1999; Gaouar 2002; Carson et al. 2009;

Iniguez 2005, 2011; Tawah et al. 1997). In the 2009 FAO global survey report, the economic and market drivers (28.5%), poor livestock sector policies (20.2%), and poor conservation strategies (14.5%) were the three most frequently mentioned threats (Hoffmann 2010a). Later, the FAO alarmed the world about the increased proportion of breeds classified in danger of extinction, from 15 to 17% (249/1,458 total breeds) between 2005 and 2014 (Scherf and Pilling 2015). This increase persisted in 2019, with 26% of the world's livestock breeds being at risk of extinction (Pilling et al. 2020; Bélanger and Pilling 2019).

The causes of threats to AnGR are multifactorial and global due to the following: (1) human and bioclimatic activities of the surrounding environments; (2) visual and highly unpredictable climate change impacts (i.e., high frequency, severity and duration of drought, high temperatures, and soil erosion) in various regions of Africa (Köhler-Rollefson 2004; Famien 2020); (3) resurgence/persistence of diseases affecting animals, while pandemics such as COVID-19 are putting the world in a public health crisis requiring a coordinated and multisectoral response (Baptista et al. 2021; Obese et al. 2021); (4) worldwide fast-growing human populations creates unprecedented demands for animal-source food (ASF); (5) indiscriminate crossbreeding between local breeds, and with exotic breeds; (6) replacement of local breeds by exotic breeds; and (7) the lack of continued efforts for management and conservation of local AnGR.

Since the Convention on Biological Diversity (CBD) in 2002, numerous global, regional, and national efforts have been undertaken to reverse the current trend of biodiversity loss (Hoffmann 2010a). However, the results of these efforts remain challenging to measure, and there is still a belief of an unimaginable loss of the diversity of endemic livestock affecting AnGR. For example, in Africa, the existing animal populations are increasingly losing their purity, and the notion of race no longer has any meaning. Nonetheless, FAO has made significant progress in assessing biodiversity. First, by publishing "The State of the World for Animal Genetic Resources" and second, by maintaining the Domestic Animal Diversity Information System (DAD-IS) as the clearinghouse mechanism for AnGR recognized by the CBD (Rischkowsky and Pilling 2007; Food Organization, A 2007; Hoffmann 2010b).

In a joint study, FAO, ILRI, and AU-IBAR (African Union-InterAfrican Bureau of Animal Resources) have estimated that the meat and milk markets will reach 34.8 and 82.6 million tons by 2050, corresponding to a respective increase of 145% and 155% compared to the levels of 2005/2007 (Ugo et al. 2013). As a result, consumption will surpass production. Africa will become a net importer of ASF if national governments do not make solid decisions for livestock development. For example, many countries use exotic breeds to improve productivity through crossbreeding programs with local breeds. This breeding approach is the preferred continent's tool for carrying out genetic improvement within the framework of controlled programs to preserve local diversity. Unfortunately, progeny from F2 crossbreeding perform poorly in most cases due to the loss of adaptive traits in African production systems, which undermines the sustainability of breeding programs. Nonetheless, various genetic conservation programs are established in response to the existing constraints related to crossbreeding (Table 25.1). Several priorities and complementary interventions are identified to improve the management of AnGR and their maintenance for future uses. The "keep it on the roof," encouraging the continuing sustainable use of traditional breeds (in situ conservation), and the "Put some in the bank," using new technologies for ex situ in vitro conservation of AnGR, are among those strategies.

25.3 In Situ Conservation Methods

This conservation method refers to preserving genetic resources through living animals evolving or rearing in cost-effective and safe natural environments (Rischkowsky and Pilling 2007; Hoffmann 2011). *Most African livestock* genetic resources *are maintained* in situ *in living populations, as this* conservation method provides sev-

Table 25.1 Constraints of animal selection and crossbreeding in Africa

Crossing constraints	Selection constraints
Knowledge of local genetic resources by population size, genetic characteristics, and average performance Low involvement of breeders Supply of genetic resources (exotic and indigenous), food resources, and healthcare Uncontrolled technicality for a more demanding product Satisfaction of the breeder with the product (cost/product ratio) Difficult flow of products Lack of clear and guaranteed programs for elements that may affect the sustainability of the program	Marginalization of local breeds in favor of exotic breeds Lack of information and exhaustive knowledge of local resources and their qualities, characteristics, and precise data on numbers by breed Lack of a selection program for the conservation of biodiversity Insufficient technical expertise Lack of technological equipment (IA, MOET, and molecular tools) Weak monitoring and control Poor collection and dissemination of information

eral advantages (Rege and Gibson 2003; Jiri et al. 2017). A few examples are as follows: (1) management of a wide range of genetic and species-diverse populations in their natural environment, thus a substantial genetic base (e.g., indigenous breeds and wild species co-conservation); (2) maintenance of an integrated system supporting continuous environmental adaptation; (3) preservation of animals selected based upon their adaptive traits (e.g., low feed requirement, ability to utilize poor quality feeds, thermo- and hydric-tolerance, and disease and parasite resistance); (4) introduction of high-performance breeds for genetic improvement of local breeds; and (5) low cost and effective gene conservation method.

In parallel, some drawbacks to the in situ conservation method can severely hamper farm success. Indeed, the same factors that allow for dynamic, holistic agroecosystem conservation may threaten the security of breeds (e.g., natural disasters, pathogen outbreaks, genetic problems, breeding cessation), altering genetic diversity (Gaouar 2002; Tiambo et al. 2019). Also, social and economic changes due to government policy changes (e.g., subsidies or direct interventions) may either foster or hinder on-farm AnGR conservation over time. Numerous examples indicate the reliance of this conservation method on smallholders' encouragement through market-driven incentives supported by appropriate public policies.

25.3.1 Challenges of Applying In Situ Conservations in African Countries

Many challenges are associated with in situ conservation methods in Africa (Gaouar 2002; Rege and Gibson 2003; Tiambo et al. 2019; Rege 2003; Gaouar 2009). The following examples can engender secondary causes of breed extinction, production, and productivity threats. (1) Economic and market drivers are significant threats that act through other more direct causes, such as crossbreeding and breed replacement, considering the spatial and temporal dynamics. (2) Significant gaps in regulatory policies and institutional arrangements directly relate to smallholders, generally rearing indigenous livestock breeds. (3) Insufficient knowledge of local breeds can lead to inappropriate crossbreeding, negatively impacting the hybrid vigor of the offspring. Indeed, most African farmers do not keep detailed records of each animal (e.g., pedigree, performance, and tags) to enable better breeding results. These farmers mostly use a complex set of traits (e.g., egg production, size, shape, color, milk yield and quality, aspects of adaptation, and the source of the breeding material) to name their animals as the basis of selection decisions and management. (4) Policies must address disease management. (5) Lack of risk awareness of climate change impacts and rigorous interventions for long-term mitigations. (6) Social and cultural contexts of breeds are critical for selection, often associated with traditional practices and beliefs having important implications [e.g., *Muturu* cattle considerations in various Nigerian communities (Adebambo 2001)]. (7) Lack of social organizations and institutions that can influence

farmers' access to, and management of, household and community-level resources (e.g., equitability of land tenure and ownership distribution in the community, size, and the number of parcels of household land, intrahousehold access to land), and actions regarding sustainable use and maintenance of farm animal genetic diversity. (8) Economic reasons do not always drive breeding objectives and may take many forms [e.g., the coat color patterns in the Nguni cattle in South Africa (Tada et al. 2013)]. (9) The inconsistency in naming breeds or strains. For example, geographical connotations, tribes, or ethnic communities are associated with breed names (e.g., *Boran* cattle, *Mashona* cattle, *Nguni* cattle, and *Somali* sheep), while some generic names such as the *Djallonke* breed of sheep distributed in the whole coastal West and Central Africa may be overshadowing several sub-populations due to local environment and breeding practices (Wafula et al. 2005; Hoffmann and Scherf 2005).

In addition, western countries' typical industrial livestock systems focus on enhanced control of the production environment, favoring a narrower range of high-producing breeds and increasingly limited within-population diversity. In Africa, farming with imported breeds has largely been a failure in smallholder production systems. Instead, there is more attention to using indigenous breeds and crossbreds while increasing related scientific knowledge. Therefore, livestock development programs in Africa remain driven mainly by imported technological packages (e.g., artificial insemination, exotic germplasm) with minimal involvement of communities in their implementation.

25.3.2 Community-Based Management of Animal Genetic Resources

The "community-based management" emphasizes the involvement of local communities in AnGR conservation. Its contribution to "in situ conservation" can be valuable in an integrated system for maintaining genetic resources. In addition, community-based management is critical for conserving breeds or strains in areas with rich diversity, allowing continued adaptation to changing climate and evolution (Jiri et al. 2017).

In recent decades, the FAO has been working with national and intergovernmental levels to promote international collaborations on AnGR. This effort focuses on institutional and policy frameworks required to improve management worldwide. Strategies are based on currently valuable livestock species in their ecosystems (crops, forages, agroforestry species, and other animal species) to underpin an on-farm conservation program. This strategy helps (1) conserve processes of adaptation, evolution, and diversity, (2) integrate farmers into a national AnGR system, and (3) improve the livelihood of resource-poor farmers through economic and social development.

The "in situ conservation" and "community-based management" of AnGR are conceptually similar. Community-based livestock breeding programs (CBBP) are good examples of community-based management. These programs rely on defined geographical boundaries with farmers of common interests working together to design breeding objectives and execute genetic improvement. Livestock species are generally selected based on community needs and wants, as listed in Sect. 25.3.1. Several African countries have implemented the CBBP as an Open Nucleus Breeding Scheme (ONBS). These strategies comprise nucleus herds established from the best animals selected through screening from the base population of farmers' flocks. Programs started in various African countries in the early 1980s as alternatives to centralized government-controlled breeding schemes with governmental (e.g., research centers) and non-governmental (e.g., farmers) contributions.

The Ivory Coast government established the PNSO (Programme National de Selection Ovine) to improve the growth and live weight of indigenous *Djallonkè* sheep (Yapi-Gnaoré et al. 1997). This program involved approximately 143 farms, of which 88% and 12% were from farmers' flocks and state-owned, respectively. It resulted in the association of the *Djallonke* sheep producers of Ivory Coast (APRODJALCI) and a slightly

increased genetic value during the selection period despite the deteriorating environment.

In Morocco, a similar development program termed "Moutonnier" is an excellent example of promoting AnGR conservation and improving the national genetic heritage (Boujenane 2005). This program involved the Moroccan government and the National Association of Sheep and Goat Breeders (ANOC). Local breeds (e.g., the *Barcha*, *Noire*, and *Chefchaouen* goats) of various stakeholders (e.g., community officials, industries, and farmers) were maintained in their cradle zones of origin to ensure the effectiveness of selection and crossbreeding with parents of high genetic value and replication in other geographical sites (e.g., oases of the southern, middle atlas, and the high plateau of Morocco, and the Wadi Saorua Valley of South Algeria) throughout the country (Boujenane 2005; Boukallouch 2006). This project has enabled the production of high-quality goat's milk, butter, buttermilk, and cheese marketed with the label "Ajbane Chefchaouen," the name of the city of production "Ajbane Chefchaouen," the name of the city of production (Boukallouch 2006).

In Ethiopia, established CBBP with small ruminants achieved a substantial genetic improvement of Bonga, Horro, and Menz breeds of sheep (Haile et al. 2020), with a net gain of one to three sheep per year at slaughter, having significant impacts on the livelihood of farmers. As a result, there has been a demand for improved rams and bucks within (e.g., NGOs and other local communities) and across the neighboring countries (e.g., Iran, Malawi, South Africa, Sudan, Tanzania, and Uganda) http://www.icarda.org/update/ethiopia-community-based-breeding-genetic-improvement-sheep-and-goats.

In Rwanda, two cattle breeds, Inyambo and Inkungu, are under in situ conservation and utilization by the Rwanda Indigenous Cattle Breeds Organization (RICBO) and in partnership with the Ministry of Agriculture and Animal Resources.

Despite the real-life successes, in situ conservation through CBBP requires substantial monitoring to ensure that farmers keep or continue keeping indigenous breeds in favor of new ones. Also, incentives may be necessary to encourage farmers to retain and continue traditional practices and know-how. There is a clear need for integrated conservation approaches that combine a range of available in situ and ex situ options. The current technological advances are making the ex situ conservation methods the viable alternatives for AnGR success through live-animal conservation (in situ option) and in vitro manipulations of various animal samples (ex situ option) in designated localities.

25.4 Ex Situ Conservation Methods

Ex situ conservation involves preserving genetic resources off-site or outside their natural habitats. Ex situ collections of AnGR offer the potential to reduce extinction risks, affording the option to maintain future breeding opportunities for productivity and heritage traits (De Oliveira Silva et al. 2019). Ex situ conservation could be in vivo (i.e., live animals in the form of organized herd/flock maintained in zoos, on-farm, or on station) or in vitro (i.e., cryo–conservation of a wide variety of living cells or tissues) for long periods.

25.4.1 Sample Candidates for Conservation

Nowadays, there is increasing recognition by national governments that livestock diversity has political, social, and economic utility. Existing works throughout many African countries indicate the reliance on AnGR conservation sustainability in manipulating various sample types. The harvest of such samples from living or dead animals facilitates their transportation, long-term diversity conservation, and marketability of genetic materials.

Sample candidates for conservations are gonadal, gametic, embryonic, and somatic tissues, and DNA (Bolaji et al. 2021; Morrell and Mayer 2017). Gonadal samples are both testicular and ovarian tissues that can be frozen for future uses through re-implantation or in vitro

production of mature gametes. Both female (oocytes) and male (spermatozoa) gamete collections permit further in vitro quality improvement for viable embryo production and generation of somatic cells exhibiting adult embryonic stem cells. Samples are harvested from living or postmortem animals to improve understanding of their biological characteristics and quality. Collected samples should possess a detailed case history to ensure clear identification [e.g., owner's name, species, geographic location, sex, age, and sample type] and management [e.g., handling and breeding techniques (Alhajeri et al. 2021)] using software such as the *Epicollect5* (https://five.epicollect.net/). These cells are kept for long-term storage in cryogenic conditions (freezing at −80 °C or deep-freeze at −196 °C in liquid nitrogen), with relative success across species and sample types. This capacity for conserving samples is often called Genetic Resource Banking (GRB). Numerous studies have demonstrated the ability of fresh and frozen-thawed cells to generate new individuals via assisted reproductive technologies (ARTs), having crucial roles during livestock production or the repopulation of endangered animal species. ARTs are helpful in both in vivo and in vitro options of ex situ conservations.

Freezing various sample types offers many possible strategies for countries to address their AnGR conservation needs (Leroy et al. 2019). Each type of sample has its advantages (e.g., long-term freezing storage—from −20 °C, −80 °C, or −196 °C), disadvantages (e.g., different freezing tolerance, different freezing protocols, and ingredients), and outright (e.g., equipped facilities) limitations, depending upon the species, the cryopreservation, and the technical capacity of the country. For many livestock species, semen collection and cryopreservation are common, inexpensive, and represent simple options for preserving animal genetic resources. However, if semen cryopreservation makes it possible to recreate the descent of the breed, the reconstitution from exclusive semen requires many generations of backcrossing. In parallel, oocyte cryopreservation is now commonly performed with many species. However, cryopreservation of exclusive oocytes results in the loss of the breed's Y-chromosome in mammalian species. When cryopreserved embryos are considered, their preservation captures the diploid genome of an animal. It can therefore be immediately utilized to meet a particular need. As with most germplasm samples, the success of using frozen-thawed or vitrified embryos for regenerating live animals depends on many factors, such as the quality of post-thawed samples, qualified personnel for appropriate manipulation of post-thawed samples, and high expenses. Therefore, using germplasms to generate viable offspring requires surgical expertise and high costs associated with producing and preserving samples (e.g., embryos), limiting the widespread use of this option in many African countries.

The use of harvested samples for artificial insemination (AI) and embryo transfer (ET), the most popular breeding tools of ARTs in Africa, have been effective for genetic improvements worldwide. However, these technologies remain luxuries in most African countries due to low human and institutional capacities, lack of infrastructure, high cost, and poorly designed breeding programs (AU-IBAR 2019). Nevertheless, South Africa and Namibia appear as the only African countries reporting cases of in vivo- and in vitro-produced transferrable bovine embryos for breeding in both dairy and beef cattle farms (Viana 2019).

25.4.2 Animal Management and Sample Collections

The conservation of threatened and underutilized AnGR is a top priority. The loss of a typical breed may be crucial for some African communities as it may reflect the local cultural and historical identity or the genetic heritage of farm animals. Therefore, it is strategic to safeguard animal breeds for subsequent needs through ex situ conservation methods, either in vivo (populations of live animals not reared under typical management conditions) or in vitro (artificial manipulations, under cryogenic conditions, providing long-term insurance against future shocks)

(Rischkowsky and Pilling 2007). Regardless of the chosen approach, animal resource managers face many responsibilities and challenges when overseeing animal management programs. These challenges dependent on the type of facilities and species managed, and the kind of research conducted (Stark et al. 2010). All stakeholders should receive proper gene bank management training regarding human and institutional capacity building. Genetics researchers can help and train in developing and utilizing gene bank collections. Animal resource management programs using software appear more effective when they integrate researchers, decision-makers, and smallholder farmers with an active effort to sensibilize the breeders on the extinction risks of the breeds (Gaouar 2002, 2009; Alhajeri et al. 2021). Overall, the need for a statewide identification policy in most African countries is a critical problem in managing and developing domestic animals.

25.4.3 Extended Preservation for Immediate Utilization

Various germplasms (sperm, oocytes, and embryos) of cattle, small ruminants, pigs, and chickens are successfully conserved for AnGR and commercial utilization for ARTs. Since the 1960s, the practice of AI in African countries has boosted the use of livestock semen and the easiness of reproductive biotechnology, such as estrus synchronization, cryopreservation, and embryo production. The dilution of freshly collected semen of small ruminants (sheep and goats) and pigs in commercial extenders containing specific additives (e.g., nutrients, antibiotics, antioxidants, and chelating agents) provides prolonged storage in the cold (4–8 °C, for goats and stallions) and chilled temperatures (16–20 °C for boars) during one to five days post-collection (Johnson et al. 2000; Roca et al. 2016; Falchi et al. 2018). Such semen conditioning is known as liquid semen, which utilization right after collection or refrigerated storage results in satisfactory fertility rates (>65% births) after intra-cervical inseminations. However, these commercial extenders are only affordable to a few African smallholder farmers. Therefore, the large majority of smallholder farmers interested in the AI technique may rely on basic extenders supplemented with cheap compounds, such as indigenous plant extracts (e.g., cactus extracts, plant oils, rooibos, and honeybush) to counteract the progressive decrease of semen quality during storage (Hiemstra et al. 2006; Kameni et al. 2021; Ros-Santaella et al. 2020; Ros-Santaella and Pintus 2017). In addition, the poor conditions of post-collection semen manipulations (e.g., packaging, storage, and handling) contribute to the rapid loss of semen quality, drastically limiting the widespread application of liquid semen in African countries.

In contrast, the use of livestock embryos for transfer to take advantage of the genetic merit of females faces several technological and institutional barriers. Consequently, the application of embryo transfer remains limited in African countries.

25.4.4 Cryopreservation for Biobanking

Cryopreservation for ex situ in vitro conservation is a critical tool for genetic improvement and sustainable protection. Both gametes and embryos are the most vital genetic materials, but their cryopreservation requires the installation of processing, storage, and packaging facilities (Hiemstra et al. 2006; Leibo and Songsasen 2002). Unfortunately, few African countries abide by these rules due to a lack of resources (e.g., material, equipment, and local organization). Increasing government and FAO initiatives are creating more gene banks worldwide (Rischkowsky and Pilling 2007). As a result, more African countries now possess institutional facilities for gene banking (e.g., Botswana, Burkina Faso, Egypt, Rwanda, South Africa, and Tunisia). Meanwhile, the AU-IBAR facilitates regional gene banks storing genetic materials, resulting in universities and governments establishing cooperations and collaborations to develop joint training programs (AU-IBAR

2019). However, these supra-national or regional implementations require a fair and equitable sharing of the benefits of using these resources for research, commercial, or other purposes.

Semen of most livestock species can be frozen adequately using pre-existing or adapted protocols with commercial/homemade extenders and deep-freezing storage in liquid nitrogen (−196 °C). Frozen-thawed semen and embryos have served for AI or ET with relative success in cows, goats, and sheep (Viana 2019). Compared to other livestock species, ruminant spermatozoa are the most resistant to cryopreservation. In most African countries, efforts are made toward freezing local bull semen (e.g., Nguni cattle) for appreciable post-thaw motility (>70%) and fertility (>37%) rates following AI (Nengovhela et al. 2021; Magopa et al. 2021). In contrast, the ET is still limited to a few African countries. Only South Africa has reported cases of successful transfers of frozen in vivo-produced embryos from domestic dairy and beef cows (1107) and in vitro-produced by ovum-pick-up (OPU) from domestic beef cows (1976) (Viana 2019).

In summary, there is still a need to find solutions to overcome the current institutional and personnel challenges to establish successful cryobanking of farm animals' germplasms in Africa. In addition, researchers should consider the cost of specimen cryopreservation and the likelihood of successful outcomes following utilization. Despite the structural conditions in most African countries, other advanced biotechnologies of reproduction, such as cloning and DNA microinjection, having several advantages for ex situ in vitro conservation, are progressively penetrating the continent.

25.4.5 Current Efforts and Challenges in the Conservation of AnGR in Africa

The Convention on Biological Diversity (CBD) recommends the implementation of any ex situ conservation initiatives within the geographical location of the targeted species. In early 2010, ILRI launched the World's first livestock gene bank (Scidev.net 2013a, b), known as Azizi biorepository (http://azizi.ilri.cgiar.org/), ensuring the safety, security, and efficient collection and storage of biological materials and related data. Samples currently held include semen, embryos, blood, serum, pathogens, tissues (lung, brain), arthropod vectors, cultured cells, primers, plasma, milk, DNA, RNA, and swabs. These materials come from a wide range of species and environments. The Azizi biorepository offers African livestock the following services: (1) a platform for long-term storage of materials, (2) a platform for proper labeling of samples from the field, (3) support to livestock projects for proper sample and data collection (4) retrieving of samples and data in the repository, and (5) source of liquid nitrogen to various projects.

The technical office of the African Union Commission (AUC), the African Union InterAfrican Bureau for Animal Resources (AU-IBAR), has established five (5) Regional Multi-Purpose Animal Gene Banks under the project known as "Strengthening the Capacity of African Countries to Conservation and Sustainable Utilization of African Animal Genetic Resources." Infrastructures are located in Eastern Africa (the National Animal Genetic Resource Centre and Data Bank, Entebbe, Uganda); in Northern Africa (National Gene Bank of Tunis or BNG, Tunisia); in Western Africa (Centre International de Recherche-Développement sur l'Elevage en zone Subhumide or CIRDES, Bobo-Dioulasso, Burkina Faso); in Southern Africa (Department of Agricultural Research, Gaborone, Botswana); and in Central Africa (University of Dschang, Cameroon).

Several challenges contribute to the need for multi-country animal gene banks in Africa. Amongst them are the need for more funding, regulations on regional and continental exchange of animal genetic material, and a lack of consensus on procedures for operating gene banks. Coordination between countries is highly required for transboundary animal breed conservation. Although all countries agreed that regional African animal gene banks are a practical approach to conserving animal genetic resources,

negotiations for their operationalization are lengthy and complex, mainly because gene banks should operate under internationally agreed legal protocols (Nagoya Protocol). In contrast, though signatory countries of the Convention on Biological Diversity and Party of the protocol, the various countries have different implementation frameworks. Legal protocols require that the samples in a regional animal gene bank remain in the ownership of the country of origin with provision made for appropriate access by interested parties presenting valid claims for its use. Users will also be expected to replenish the gene bank materials when possible.

For example, at the regional gene bank set-up at CIRDES, the legal and regulatory frameworks to govern the collection, use, and exchange of genetic materials between the Economic Community of West African States (ECOWAS) countries are required but have yet to be available. Hence, the gene bank still needs to be operational to receive genetic materials. At present, semen has been collected from some West African transboundary cattle breeds (N'Dama, Baoulé, Borgou, Somba, and Zébu Peulh Soudanais) available on the experimental farm of CIRDES.

25.5 Operation Procedures and Guidelines—Past and Current Efforts in Africa

The AU-IBAR has created five regional gene banks in Africa. For example, the AU-IBAR inaugurated the North Africa gene bank in Tunis (Tunisia), regrouping six North African countries in 2016, following the 6th General Assembly of the sub-regional focal point for genetic resources. This action is part of the action plan drawn up to establish a network of regional gene banks, issuing smooth running and sustainability, namely:

1. The NAGOYA and APA (Access and Benefit-Sharing) protocols are signed by all countries on a working basis.
2. Any samples and genetic materials transmissions to the BRG (Bank of Genetic Resources) must be done after declaration and authorization by the concerned departments.
3. Workshops on the development of the legal and contractual framework for the gene bank will be scheduled with technical experts and lawyers' participation to develop a draft cooperation convention to be submitted to member countries.
4. Regional value chains should be discussed and amended within the 'Live2Africa' project, established by the European Union and AU-IBAR, to "support the transformation of the African livestock sector for enhanced contribution to environmentally sustainable, climate resilient, socio-economic development and equitable growth." The ANOC (National Association of sheep and goats) of Morocco was cited as an example to promote these value chains.
5. Consider the contexts and realities of livestock farming in each country, the case of Mauritania, where livestock systems are mainly based on livestock mobility, especially transhumance.
6. Transboundary breeds are a priority in the action plans of the regional gene bank and breeds, or populations threatened with extinction, considering aquaculture and beekeeping.
7. Sample characterization and inventory must be done in the countries of origin with two regulatory and technical aspects.
8. The health aspect is important for exchanges between countries and the necessary health certification mechanisms, for example, during the COVID-19 pandemic.

25.6 Further Opportunities via Genomics

25.6.1 Existing and Explorative Genomic Tools

Advances in genetics and genomics tools have permitted remarkable improvements and discoveries in biological sciences. These techniques are based on the three pillars of the dogma of biology, namely DNA, RNA, and proteins.

The corresponding molecular methods could be listed as Restriction Fragment Length Polymorphism or DNA Fingerprinting (RFLP), microsatellites, mitochondrial DNA, whole-genome and RNA sequencing, microarrays, and proteomics, which are described in other chapters of the book. The high heterogeneity of African livestock breeds permits practical adaptations to the extremely changing environmental conditions of the continent. Yet, the benefits of genomics advances applied to livestock species are not widespread and harmonized. Most existing research is performed through foreign collaborations due to various limitations (e.g., nationally equipped facilities, qualified personnel, and high-related costs) within the continent (Kosgey et al. 2005; Rege et al. 2011; Marshall 2014). Only a few countries possess functional research laboratories or centers capable of complete livestock genomics analyses (e.g., Biotechnology Research Center or CRBt in Algeria, BNG in Tunisia; Veterinary Genomics Laboratory in Morocco, several biotechnology laboratories in South Africa—Inqaba Biotech; Agricultural Research Center & Biotechnology Platform or ARC-BTP; Africa Centre for Gene technologies or ACGT—African Biosciences Limited, Nigeria; and ILRI in Kenya). Nevertheless, the usefulness of these genomic tools in livestock has been explored in various programs to characterize and conserve animal genetic resources in Africa (Marshall et al. 2019).

25.6.2 Monitoring and Identification of Resilient Animals and Sampling

Explorative studies using genomics tools have found benefits in various economic and ecological traits by identifying the most adaptable and profitable breeds within several African countries' livestock production systems.

In small ruminants, researchers used various genomic tools to assess the genetic diversity of Nigerian Balami, Yankasa, Ouda, and West African Dwarf breeds of sheep (RFLP (Geka Rukayat et al. 2020)); genetic variability and phylogenetic relationships within and between various Algerian and Moroccan sheep populations (Ouled-Djellal, Hamra, Sidaoun, Taâdmit, D'men, Beni-Ighil, Foro-Foro, Rembi, Sardi, Boujaad, Timadhite, Barbarine, Ifilene, Srandi, Darâa, Berbere, BembiRembi, and Tazegzawt) sheep populations [Microsatellite markers (Ameur et al. 2020; Abdelkader et al. 2018; Gaouar et al. 2005, 2014, 2015, 2016)—mtDNA (Ghernouti et al. 2017)—Sequencing and Genome Wide Association (GWA) analyses (Djaout et al. 2018)—SNP (Belabdi et al. 2019; Gaouar et al. 2017)]. The studies revealed (1) high and alarming genetic dilution of traditional breeds due to uncontrolled crossbreeding (e.g., Barbarine, Berber, Rembi, Ouled-Djellal), (2) genetic origins that would be given priority for conservation programs (e.g., Tazegzawt, Hamra, D'men, Sidaoun), (3) geographical distributions (e.g., Ouled-Djellal in the entire Maghreb region), and (4) robust genetic proximity between Algerian sheep with the Caribbean and Brazilian breeds, indicating the immense influence of the Atlantic slave trade on their genetic make-up. More interestingly, the use of SNP assay in an Ethiopian project, aiming to upgrade local (Menz and Wollo) breeds through repeated backcrossing with the exotic Awassi breed, identified animals of 37.5–50% Awassi genes as the most productive (lamb weight) at 8 months of age (Getachew et al. 2017). Genomic tools have been used on local goat breeds (e.g., Naine de Kabylie, Arbia, Mekatia, M'zabite, West African Dwarf, Red Sokoto, South Africa Kalahari breed) for various purposes, such as the (1) genetic characterization and diversity using microsatellites (Tefiel et al. 2018, 2020) and SNP (Fantazi et al. 2018); (2) polymorphism associations of various genes, i.e., BMP15, BMPR1B, GDF9, and POU1F1, with prolificacy of Cameroon and local Nigerian goats using microsatellites (Wouobeng et al. 2020) and SNP (Olasege et al. 2021); and polymorphism association of the PRNP gene with scrapie resistance in Algerian sheep breeds using SNP (Djaout et al. 2018; Fantazi et al. 2018).

In cattle, genetic studies of genetic diversity and structure were achieved using four indige-

nous Algerian populations [Microsatellites (Rahal et al. 2020)]. At the same time, an analysis of mtDNA markers focusing on the Haplogroup T1 attributed the origin of two taurine breeds of Cameroon (Namchi Poli and Ngaoundere) to South-West Asia. However, the White and Red Fulani zebus gene flows may have contributed to their genetic diversities (Patrick Jolly et al. 2018). Another study used the SNP approach to investigate the population structure and genetic diversity of the Algerian Guelmoise cattle breed (Ourida et al. 2017). Findings indicated that the Guelmoise breed is an admixed population with strong genetic similarity to the Tunisian cattle breed but less permissivity to foreign breed introgression. Finally, regarding dairy cattle production, the use of bovine SNP arrays in programs such as the Kenya "Dairy Genetics East Africa project" and "Senegal Dairy Genetics" revealed the benefits of genomic tools in multi-objective studies (Marshall et al. 2019). The study used African indigenous Zebus, exotic *Bos taurus* breeds (e.g., Montbeliard and Jersey), and crossbreeds with various proportions of indigenous breeds to reveal SNP markers as predictors of high-level milk-producing cows.

Additionally, SNP assays enhance estimated breeding value (EBV) accuracy by assigning parentage that accelerates genetic improvements in African countries lacking reliable pedigree records of livestock animals. Two ongoing CBBP programs in four African countries (Kenya, Uganda, Ethiopia, and Tanzania) are conducted to validate SNP candidates for enhancing breeding programs: the "Dairy Genetics East Africa" and the "African Dairy Genetic Gains" (Strucken et al. 2017). In addition, there are great expectations to use the SNP as EBV predictors to enable the selection and recruitment of young bulls for national artificial insemination programs (Strucken et al. 2017; Mrode et al. 2018; Aliloo et al. 2018).

Various genomic tools have been applied in other domesticated animal breeds such as dromedary/camels (Harek et al. 2015; Cherifi et al. 2017), chickens (Mahammi et al. 2016; Al-Jumaili et al. 2020; Boudali et al. 2020), pigs (Osei-Amponsah et al. 2017), and horses (Benhamadi et al. 2020) for different purposes. In addition, new biotechnologies like gene editing can create new "breed types" of desired phenotypes.

Overall, informative utilization of the abovementioned genomic tools relies on optimal farm management. At the same time, their incorporation into established breeding programs is still limited in most African countries.

25.6.3 Restocking and Improving Farm Populations from Conserved Materials

The sustainable management of local livestock species is a central issue in livestock animal conservation. Furthermore, because of many challenges related to climate change (e.g., poverty, conflict, drought, and disease), the demand for programs for genetic animal conservation is increasing (Olney et al. 1993). The restocking of genetically important (e.g., cultural, economic) livestock animals is achieved through in situ and/or ex situ conservations.

Many public and private initiatives have applied community-based approaches and restocking to rebuild herds and livelihoods as emergency programs to fight poverty in Africa. Initiatives included beneficiary governments and international public partners (e.g., USAID, AU, and EU), research organizations (e.g., ILRI and CTLGH), and non-governmental organizations (e.g., Heifer International). As a result, programs such as Girinka "One-Cow-per-poor family" and "Send-A-Cow" have been adopted in many African countries, such as Rwanda (Argent et al. 2014; Klapwijk et al. 2014), Ethiopia (Flax et al. 2021), and Tanzania (De Vries 2008), while many others received veterinary and extension services. Nevertheless, the distribution of animals maintained in community-based structures remains the most popular method for restocking livestock farms. Restocking has been primarily used as a relief program to assist victims of natural disasters or diseases while considering the beliefs and culture of farmers. For example, the Kenyan government first applied this program to

provide livestock to victims of the devastating droughts of 1983–1984 and 1990–1993 through the Samburu District Development Program (SDDP) between the Kenyan and German governments from 1993 to 2000 (Lesorogol 2009; Hogg 1985). As results (Lesorogol 2004), beneficiary farmer families (~326 from four different communities) received 15–40 small ruminants (sheep or goats) per family per year with little assistance (e.g., food, animal health worker), with significant measures to ensure accountability (e.g., retaking animals from restocked families in case of no appropriate care taken, training restocked families, provide proofs of dead animals), translation into more milk production (>10% increase), poverty alleviation (e.g., substantial rose of animal heads, >10% herd growth rate), restoring social standing in the community (about 80% of restocked families), and empowering beneficiary women (~27% of total beneficiaries, mainly widows).

Nonetheless, the enhancement of livestock populations by restocking, however, remains both controversial and challenging for livestock repopulation. *Firstly*, stocking well-identified animal breeds is crucial to meet and exceed the capital value of the selected livestock chain of value, requiring an accurate genetic characterization and selection of animals with added genetic merit. *Secondly*, using ex situ/in vitro conservation approaches with cryopreserved genetic materials poses several institutional and personnel capacity-building and development challenges. Indeed, the lack of qualified personnel and shortages in materials for cryopreservation are other barriers to successful restocking. As mentioned above, there are continued efforts throughout the continent for intensive cooperations and collaborations to improve the cryopreservation practice. *Thirdly*, cryopreserved germplasm requires a solid grasp of assisted reproductive technologies or ART to ensure successful farm repopulations with improved animal breeds. While reintroducing animals, avoiding the potential risk of density-dependent mortality in some small ruminant breeds is crucial. This phenomenon is commonly observed in fish (Nickelson 2003; Levin et al. 2001). *Lastly*, breeders should consider the characteristics of newly crossbred animals during the stocking and restocking of farm populations to avoid ecological competition between local and crossbred animals (Goodman 2005).

25.7 Policies and Regulations Governing Conservation and Improved Management of AnGR

Most African countries lack appropriate livestock policies, and where they exist, most are embedded in the general agricultural policy. At the same time, regional policies on the management and sustainable use of AnGR, the development of which is being spearheaded by AU-IBAR remain largely unimplemented (see Chap. 30). For example, the lack of policies and legislation directly formulated and designed for farm AnGR is due to the policymakers being unaware of the economic contribution of AnGR in national incomes. Additionally, governments need to have complete control of the benefits of regional gene banks, which are controlled by international agreements on biodiversity following the Nagoya Protocol on Access to Genetic Resources and Fair and Equitable Sharing of Benefits.

Most countries in Africa still need formal policies and legislation on crossbreeding (AU-IBAR 2019). The few with stand-alone AnGR policies have legislation prohibiting imports and exports of farm animal genetic resources for the control of zoonotic diseases. Joint efforts between the EU and AU-IBAR assist several countries in developing National Strategic Action Plans (NSAP) to manage their AnGR. At the same time, creating platforms for governments and institutions with already set policy, legislative, and regulatory frameworks will permit the sharing of lessons learned and best practices with partners. Rwanda is one of the few countries with policies that give direction on crossbreeding and a strategy for genetic improvement (MAAR 2017). In addition, Ghana's National Strategic Action Plan (NSAP) seeks to promote the conservation and sustainable use of its local AnGR

and the development of stabilized crosses, especially for peri-urban (Ahiagbe et al. 2021). Kenya defined its breeding policy in 1980, and the major national objectives targeted (fight against poverty, production of surpluses for export, development of conservation plans, etc.) (Anyango et al. 1989; Kenya, R. o 2013). Tanzania's priority investments through the Tanzanian Livestock Modernization Initiative include various combinations of nutrition, animal health, and animal genetics (e.g., AI and multi-breeding approaches) to improve the quality and performance of Tanzanian livestock populations (MoLFD 2015; Michael et al. 2018).

25.8 Conclusions and Future Opportunities

African smallholder farmers have multifactorial relationships with livestock animals, which, together with the environmental conditions, may jeopardize animal diversity maintenance. Hence, most endangered African AnGR are maintained in situ in living populations, which carries risks of loss due to various factors. The availability of the most advanced technologies of assisted reproduction and genetics tools makes the ex situ conservation method a viable complementary to in situ actions for successfully keeping animal biodiversity in Africa. Nonetheless, the deterioration and loss of valuable genetic material is a continuous and fast process. Therefore, it is urgent to rapidly overcome all existing political, structural, and infrastructural barriers and to develop the needed human and institutional capacity for increased productivity and successful conservation and management of AnGR in Africa. Finally, the best form of conservation of Africa's unique AnGR is to ensure their continued sustainable use in the various agro-ecological zones. Therefore, there will be a need to select breed(s) for development, improve husbandry practices based on innovative technological strategies and value-addition to their products, and consider government-inspired private-sector-led stakeholder collaborations.

Acknowledgment This work was partially supported by the U.S. Department of Agriculture, Agricultural Research Service, project 6066-31000-015-00D, and the International Livestock Research Institute, Nairobi, Kenya.

26 Economic Considerations and Framework of Conservation of African Animal Genetic Resources

Wilson Kaumbata, Maria Wurzinger, and John E. O. Rege

Abstract

This chapter provides an overview of the economic aspects of animal genetic resources (AnGRs) and an economic framework for the sustainable use and conservation of AnGRs in Africa. It begins with a look at the role of economics in the sustainable use and conservation of AnGRs. The methods and tools used to quantify the economic value of AnGRs are discussed both from a theoretical and practical points of view. Drawing from literature and examples of experiences from practical applications, this chapter presents decision-making information on the economic and social benefits and costs of AnGRs conservation. The chapter concludes by discussing the framework that theoretically underpins not only the economic valuation of AnGRs but also other economic aspects of AnGRs' use and conservation.

26.1 Introduction

Africa's indigenous livestock breeds have many unique characteristics and represent the heritage of Africa's diverse rural communities (AU-IBAR 2019). The current manifold functions, genetic attributes, and potential future uses of animal genetic resources (AnGR) described in Chaps. 2 to 14 of this book underpin the significant economic values of Africa's indigenous AnGRs, most of which are not captured in the marketplace (Drucker et al. 2001). These values are usually categorized into use and non-use values. Economic valuation of AnGRs usually considers the total economic value (TEV) of the genetic resource. The TEV is equal to the sum of all direct and indirect use values plus non-use and option values as described in Table 26.1.

A review of past economic assessments (Drucker 2010; FAO 2007; Roosen et al. 2005) showed that conservation decisions regarding native animal genetic resources have been largely based on the first category, that is, direct use values, although the other categories may be of equal or greater importance. For example, it has been estimated that approximately 80 percent of the value of livestock in low-input systems in developing countries can be attributed to non-market roles, while only 20 percent is attributable to direct production outputs (FAO 2007). By focusing exclusively on direct use values, native animal genetic resources have been consistently undervalued, resulting in a bias towards activities that promote the erosion of such resources.

The main economic reason for the erosion of AnGRs is that there is an underlying disparity between private (financial) and social (economic) costs and benefits of genetic resource use and conservation due to the existence of externalities (Drucker et al. 2001). Externalities are the losses to society (social economic costs) due to activities of individuals aimed at maximizing personal profits (private financial benefits). The divergence between private and social costs and benefits exists because the costs to society are not usually taken into account by the individuals as they do not represent a cost of production to the personal enterprises. Hence the existence of externalities, the divergence between private and social costs, and a focus on direct-use values only, contribute to the apparent undervaluation of local AnGRs and thus favour activities that promote the erosion of such resources. The economic valuation of AnGRs is thus important from a policy and management decisions perspective because it reveals the true value of the genetic

Table 26.1 Values of indigenous animal genetic resources

Use value	Direct use value	Refers to the benefits resulting from actual uses, such as for food, direct income, draught power, socio-economic (finance and insurance functions) and socio-cultural, religious, manure, hides, skins, fibre, meat, milk, and eggs
	Indirect use value	Are the benefits deriving from ecosystem functions, such as the maintenance of genetic stock and other important interactions between these breeds and the ecosystem. For example, some animals play a key role in the dispersion of certain plant species
	Option value	Are derived from the value given to safeguarding an asset for the option of using it at a future date. It is a kind of insurance value against unfavourable future events, for example, the occurrence of new animal disease or drought/climate change
Non-use values	Bequest values	Are non-use values that measure the benefit accruing to any individual from the knowledge that others might benefit from a resource in the future
	Existence values	Are non-use values derived simply from the satisfaction of knowing that a particular asset exists (e.g. blue whales, elephants, or N'Dama cattle)

Note that some asset values may overlap between these categories and double counting must be avoided (FAO 2007)

resources and can play a key role in translating such social values into efficient incentives and institutional arrangements (Drucker et al. 2001).

Establishing the total economic value of AnGRs is important (Drucker et al. 2001) because this can:

(i) Guide resource allocation between conservation of various types of AnGRs, research and development, and other socially valuable endeavours. Given that the benefits of genetic resource conservation and utilization are currently undervalued, taking their 'true' value into account in investment decisions would lead to a relative shift in the allocation of resources towards genetic diversity conservation because the marginal benefits to investment in this sector would now be more attractive.
(ii) Assist in the design of economic incentives and institutional arrangements for farmers/genetic resource managers and breeders. For example, landscape maintenance, cultural, existence, and future option values of local cattle breeds have been shown to account for 80% of their total economic value (Zander et al. 2013; Martin-Collado et al. 2014), and this justifies the need for incentive mechanisms that motivate farmers to capture some of these public good values and hence motivate them to undertake conservation-related activities. However, Signorello and Pappalardo (2003) have argued that such payment schemes are often insufficient to cover the true financial opportunity costs faced by the keepers of the local cattle breeds.

Moreover, in the face of strengthening laws for intellectual property protection of germplasm under the Convention on Biological Diversity (CBD), it became apparent that the past collegial system of free exchange of germplasm among stakeholders was going to break down fast, requiring that some mechanism (e.g. through mutually agreed terms) for genetic resources movement across borders would be needed—both for research and for commercial purposes (Roosen et al. 2003). It was recognized that, because markets exist only for finished or nearly finished commercial genetic resources, the value of unimproved materials and the value added that were not 'valued by commercial interests' in the long process of breeding (including through efforts of indigenous communities) could not be directly measured. Yet this was going to be critical under the CBD regime. Hence, it is important that 'parties' (e.g. communities and countries) have a way of determining the values of the animal genetic resources involved in the 'exchange', whether within countries or across borders. Of particular interest is the situation in developing countries where on the one hand, livestock make important contributions to human livelihoods and food security while on the other, genetic erosion continues to place many breeds that are adapted to low-input agriculture and extreme environments, typical of these countries, at risk of loss. Mendelsohn (1999) has provided at least three arguments for the economic valuation of AnGR: (i) to inform the development of effective breeding programmes; (ii) to guide the choice of breeds in conservation programmes; and (iii) to facilitate benefit sharing in the context of the CBD.

26.2 Methods and Tools for Economic Valuation of AnGRs and Examples of Practical Application

How can we measure the value of AnGRs and which valuation methodologies are the most appropriate? A range of valuation methodologies exists. Most of these methods were initially developed for applications in plant genetic resources. Following the project on 'Economic Valuation of Farm Animal Genetic Resources' which was implemented by the International Livestock Research Institute (ILRI) (Mendelsohn 1999), a wide range of studies have been undertaken in the African continent during recent years to establish the true values of local AnGRs to guide conservation and sustainable use. Reviews of available valuation methodologies (Drucker et al. 2001) have concluded that they do provide

good estimates of values which are useful for answering policy-relevant questions and as decision-supporting tools regarding conservation options. Available methods can broadly be categorized into three categories on the basis of the practical purpose for which they may be applied: (i) determining the appropriateness of AnGR conservation programme costs (i.e. consideration of environmental values); (ii) determining the actual economic importance of the breed at risk (i.e. a focus on breed values); and/or (iii) priority setting in AnGR breeding programmes (i.e. a focus on trait values).

The Contingent Valuation Method (CVM) is one of the most commonly cited approaches with the potential for determining the appropriateness of conservation programme costs—purpose category (i) above—although there are hardly any examples of cases where it has been applied in practice. CVM relies on questionnaires about willingness to pay (WTP) or willingness to accept (WTA) payment for conservation. It is considered a promising option for biodiversity valuation in general because: it is the only way to elicit non-use values directly; the potential for information provision and exchange during the survey process offers scope to experiment with respondent knowledge and understanding of biodiversity; and it can be used as a surrogate referendum on determining conservation priorities based on public preferences. Hypothetically, farmers might be asked about their willingness to accept payment for on-farm maintenance of AnGR, and the general public might be queried on WTP for maintenance on-farm or in gene banks. In this way, an upper bound to the costs that society is willing to confront for AnGR conservation could be determined. An alternative approach to defining an upper bound for economically justifiable conservation costs is to identify the minimum that society could economically justify based on a measure of production loss averted (Drucker et al. 2001). This approach attempts to identify the magnitude of potential production losses in the absence of AnGR conservation.

Examples of methods for determining the economic values of breeds at risk—purpose category (ii)—include the following:

- Econometric estimation of aggregate demand and supply curves can provide a measure of consumer and producer surplus based on the fact that changes in the traits or the composition of breeds will produce shifts in the estimated functions, which in turn will bring about a change in consumer and producer surplus (Mendelsohn 1999). Where multiple demand equations (one for each breed) can be estimated, the substitution effects across breeds can be explicitly modelled providing the most comprehensive evaluation of breeds while capturing substitution effects as well.
- Cross-sectional household and farm studies can also be applied to construct demand and supply functions.
- Market share analysis is a simpler but conceptually inferior approach that involves identifying the total share of market value that can be attributed to a given breed as a measure of the value to society of the bundle of traits embedded in the breed. The approach does not provide a consumer/producer surplus measure of value.
- The existing or potential value of Intellectual Property Rights and/or Contracts for AnGR use and conservation could also be used as an indication of the economic importance of given breeds.

Methods for priority setting in AnGR breeding programmes—purpose category (iii)—a focus on trait values are crucial because they speak to conservation through use. Specifically, it is the means by which indigenous breeds are maintained by ensuring that they remain a functioning part of the production system. Examples of approaches include the following:

- *Breeding programme evaluation approaches.* These are used to assess the costs versus benefits of breeding programmes and/or alternative genotypes or breeds. For example, the

benefits of genetic material could be valued assuming that the yield effects of successive breeding stages and the necessary input cost information can be identified using the difference between the benefits of an improved breed (based on yield differential and associated prices) and the costs of all other factors employed in breeding operations such as capital and labour. The value of using alternative inputs/traits could then be compared to see how they affected economic returns.

- *Genetic production function models* are similar to breeding programme evaluation approaches, but their focus is on predicting potential future values rather than using the actual results of breeding programmes.
- *Hedonic valuation of animal characteristics* attempts to decompose the total value (price) of the single animal transacted into its relevant traits. In principle, this technique could also be used to value breeds (Mendelsohn 1999). It relies on having enough variability in the relevant vector of phenotypic (or genetic) traits of the animals involved.
- *Farm-level simulation models* of animal production can also be used by breeding programmes in order to ensure that breed benefits are being maximized by directly modelling the effects of improved animal characteristics on the economics of farms.

Table 26.2 presents a more detailed summary of the economic valuation methods and findings from the application of the methods in some African countries. Major findings include the following:

- AnGRs have economic values beyond those related to direct use (i.e. benefits resulting from actual uses, such as for food, direct income, drought power, socio-economic, finance and insurance functions and socio-cultural, religious, manure, hides and skins, fibre, etc.), The non-use values include those related to ecosystem functions, the option and knowledge that the resource is available for future use, and the satisfaction of knowing that a particular resource exists.
- The economic valuation of AnGR is important from a policy perspective because it can play a key role in translating such social values into efficient incentives and institutional arrangements for farmers/genetic resource managers and breeders.
- AnGRs conservation programmes have costs, and it is most cost-effective to conserve in situ.
- In a low-input farming system, attributes related to the subsistence functions of local AnGRs (reproductive, adaptive, and fitness traits) are more valued than attributes that directly influence marketable products of indigenous animals. These findings suggest the need to invest in the improvement of attributes that enhance the subsistence functions of AnGRs that the keepers accord higher priority to support their livelihoods than they do to tradable products.
- Phenotypic traits of traded indigenous animals (e.g. age, colour, body size, and tail condition in sheep) are major determinants of price and point to the importance of trait preferences in determining the price of AnGRs in local markets. Season and market locations are also very important price determinants.
- Production traits such as milk yield, fertility, and body size rank highly.
- A range of valuation methodologies drawn from the literature on plant genetic resources are available for consideration of potential application to AnGRs. It is concluded that a broad range of these tools needs to be field tested in order to determine which is best or most suitable for differing circumstances.

Data on available valuation methodologies suggests that they have both strengths and weaknesses. The decision on which technique to use for a particular application requires experience and judgement on the part of the analyst (Drucker et al. 2001). Data availability and the potential for acquiring relevant data will clearly be an impor-

Table 26.2 A summary of the main findings of economic valuation studies that have been undertaken in Africa

Method	Country (specie/ breed)	Summary of main findings	References
Choice experiment	Benin (Chickens)	Chickens have values beyond growth and production performance, namely those related to religious beliefs and cultural ceremonies (peace) and the health status of animals.	Faustin et al. (2010)
	Ethiopia, Kenya (Cattle/ Boran)	The costs of a community-based conservation programme split between Ethiopia and Kenya, based on safe minimum herd size, would require €25,400 per year in terms of direct support payments and management and monitoring costs. It is most cost-effective to conserve in situ the Ethiopian Borana subtype in Ethiopia and the Somali Borana subtype in Kenya.	Zander and Drucker (2008), Zander et al. (2009)
	Ethiopia (Cattle)	Attributes related to the subsistence functions of cattle (reproductive and adaptive traits) are more valued than attributes that directly influence the marketable products of the animals. The findings imply the strong need to invest in the improvement of attributes of cattle in the study area that enhance the subsistence functions of cattle that their owners accord higher priority to support their livelihoods than they do to tradable products.	Kassie et al. (2009, 2010)
	Kenya (Cattle/ Zebu)	There are at least three classes of buyers with distinct preferences for cattle traits and most buyers favour exotic rather than indigenous breeds. Such preferences have implications for the conservation of indigenous cattle in Kenya and in other developing countries and suggest that some form of intervention may be required to ensure the preservation of this important animal genetic resource.	Ruto et al. (2008)
	Kenya (Cattle)	There is preference heterogeneity based on cattle production systems. Highly valued cattle traits for the cropping systems include traction fitness and trypanotolerance, while traits associated with herd increase are considered important in pastoral systems.	Ouma et al. (2007)
	Kenya (Goats)	Disease resistance is the most highly valued trait whose resultant augmentation results in a welfare improvement of up to KShs.2899. Drought tolerance and milk traits were found to be implicitly valued at KShs.2620 and 1179, respectively.	Omondi et al. (2008a)
	Kenya (Sheep	Disease resistance is the most highly valued trait whose resultant increment results in a welfare improvement of up to KShs.1537. Drought tolerance and fat deposition traits were found to be implicitly valued at KShs.694 and 738, respectively.	Omondi et al. (2008b)
	South Africa Pigs	Farmers in market-oriented production systems derived more benefits from productive traits such as heavier slaughter weights and large litter sizes than subsistence-oriented farmers. Under the subsistence-oriented production system, farmers in CSF-affected areas placed higher prices on adaptive traits than in the unaffected areas. Subsistence-oriented farmers who were affected by CSF wanted a total compensation price of US$1563.43 for keeping a pig genotype with unfavourable traits when compared to US$605.00 for their CSF-unaffected counterparts.	Madzimure (2011)
	Ethiopia (Sheep/ Afar, Bonga, Horro, and Menz)	Producers' trait preferences were heterogeneous except for body size in rams and mothering ability in ewes where nearly homogeneous preferences were investigated. In the pastoral production system, attention was given to the coat colour of both breeding rams and ewes, favouring brown and white colours over black. Breeders in all areas attempt to combine production and reproduction traits as much as they can in order to maximize benefits from their sheep.	Duguma et al. (2011)

(continued)

Table 26.2 (continued)

Method	Country (specie/ breed)	Summary of main findings	References
Conjoint analysis	Kenya (Chickens)	The study identified traits preferred by the farmers based on their current low-input production circumstances. Using these traits, indigenous chickens can be selected for higher productivity and performance while retaining their diversity and adaptability.	Bett et al. (2011)
	United Republic of Tanzania (Cattle/ Tarime Zebu)	Livestock keepers in the Tarime district prefer Tarime cattle to exotic dairy cattle. The preference for indigenous cattle by most farmers should be viewed as the most favourable starting point for the conservation of Tarime cattle through sustainable utilization.	Ngowi et al. (2008)
Contingent valuation	Ethiopia (cattle)	Season, market location, class of cattle, body size, and age are very important determinants of the cattle price. The relative weight of the phenotypic characteristics of the animals is among the highest of all the factors considered. These preferences at the farmers' and farmer traders' levels are the ones that matter most in shaping the diversity of animals kept at the farm level, and the diversity of cattle genetic resources is quite essential for generating or identifying the best-suited breeds of cattle, given the livelihood objectives of the target community.	Kassie et al. (2011)
Hedonic pricing	Ethiopia (sheep)	Phenotypic traits of traded indigenous sheep (age, colour, body size, and tail condition) are major determinants of price implying the importance of trait preferences in determining the price of sheep in local markets. Season and market locations are also very important price determinants.	Terfa et al. (2013)
	Burundi, Rwanda, Uganda, United Republic of Tanzania (cattle/ Ankole)	In Burundi, Rwanda, and parts of Uganda, livestock keepers are sedentary and herds are small, whereas in the other areas, Ankole cattle are kept in large herds. Productive traits such as milk yield, fertility, and body size were ranked highly. For bulls, the trait 'growth' was ranked highly in all study areas. Phenotypic features (coat colour, horn shape, and size) and ancestral information are more important in bulls than in cows.	Wurzinger et al. (2006)

(continued)

Table 26.2 (continued)

Method	Country (specie/ breed)	Summary of main findings	References
Preference ranking	Ethiopia (poultry)	Farmers' ratings of indigenous chickens with respect to modern breeds showed the highest significance of the adaptive traits in general and the superior merits of indigenous chickens to high-yielding exotic breeds in particular. Adaptation to the production environment was the most important attribute of chickens in all the study areas. The high significance attributed to reproduction traits indicates the need for maintaining broody behaviour and a high level of hatchability while breeding for improved productivity of indigenous chickens for village conditions.	Dana et al. (2010)
	Ethiopia (cattle/ Zebu/ Sheko)	Overall, farmers showed slightly more preference for local Zebus over the Sheko breed. This is due to the voracious feeding behaviour of Sheko cattle, which makes them less preferable in the face of worsening feed shortage, and due to the aggressive temperament of Sheko cattle. This is despite Sheko's outperforming potential over local Zebus in their milk production, draft power, and hardiness.	Desta et al. (2011)
	South Africa (cattle/ Nguni)	Trait preference in breeding bulls and cows is significantly influenced by socio-economic and demographic factors. It is recommended to consider farmer preferences in trait selection and designing communal breeding programmes.	Tada et al. (2013)
	Uganda (cattle/ Ankole)	In the selection of cows, performance and fitness traits are emphasized by the cattle keepers while in the selection of bulls, the phenotypic appearance of the animal plays an important role. Individual fertility followed by milk performance are the main criteria for selecting cows, resistance to East Coast Fever was of the highest importance in bulls. In both sexes, a dark red coat colour was highly rated.	Ndumu et al. (2008)
	Zimbabwe (chickens)	Chicken body size was ranked the major determinant in choosing breeding animals followed by mothering ability, and fertility. More households culled chickens associated with poor reproductive performance, poor growth rates, and those intolerant to disease pathogens.	Muchadeyi et al. (2009)
	Ethiopia (cattle)	Dairy cow owners should be advised to use the optimum levels of inputs and replace their indigenous cows with cross-breed cows. Moreover, the herds should be medium size and feeding mainly depends on concentration.	Dayanandan (2011)
Production function/ gross margin analysis	Kenya (cattle/ Orma and Sahiwal Zebu)	The Orma/zebu and Sahiwal/zebu breeds had comparable economic benefits, hence a pastoralist in the Magadi division is likely to get similar returns from both breeds. This study therefore recommends the adoption of not only the Sahiwal/zebu but also the Orma/zebu breed for cattle improvement in trypanosomosis endemic areas and conservation of indigenous genetic resources.	Maichomo et al. (2009)
	Malawi (Goats/ Small East African)	Local goat enterprises in smallholder farms are profitable and economically viable. The mean annual net profit per flock and per goat was MK54,406 and MK11, 140 (€1 = MK830.00), respectively. The average return on capital invested was 24.6%, exceeding the prevailing average commercial deposit rate (8%) by several folds. The inclusion of intangible benefits of goats significantly increased the mean annual net profit and the return on capital by 60.3%, reflecting the importance of socioeconomic roles goats play in providing current and future economic stability to rural households' economy.	Kaumbata et al. (2020)

Adapted from the second report of the State of the World's Animal Genetic Resources (FAO 2015)

tant determinant, especially given the problems of missing markets for non-marketable values of animal genetic resources and market imperfections commonly encountered in developing country situations. Furthermore, despite the difficulties associated with the complexity of the economic valuation of farm AnGRs, the results of the studies reviewed suggest that the integration of methods based on expressed preferences, such as contingent valuation and choice experiments, can produce valuable information to assess breeding schemes and/or the cost-benefit analysis of conservation programmes for breeds at risk of extinction (Drucker et al. 2001).

26.3 Estimating the Economic and Social Benefits and Costs of AnGR Conservation

The economic, social, cultural, and environmental benefits of AnGRs are their capacity to produce food and other goods and services that can be sold or used at home and are generally the main reason why people choose to raise them. Estimating the value of these benefits and the associated costs of maintaining the diversity of AnGRs is fundamental for supporting decision-making regarding conservation, improvement, and sustainable use. The benefits constitute different components of TEV of AnGRs. As described in Sect. 26.2, several valuation methodologies have been suggested to estimate the different components of the TEV of AnGRs. Unfortunately, there is no single methodology that can be used to estimate all four 'values' (use, non-use, option, and quasi-option value). Moreover, a number of these methodologies have significant conceptual shortcomings and intensive data requirements (Drucker et al. 2001). However, they have been shown to produce useful estimates of the values that are placed on the market, non-market, and potential breed attributes useful for designing breeding and conservation strategies. The integration of methods based on expressed preferences, such as the contingent valuation methods (CVM), with bioeconomic models (Cicia et al. 2003) can produce valuable information to assess the cost-benefit analysis of conservation programmes for breeds at risk of extinction. Even though the CVM cannot account for some types of social values, such as quasi-option value, which in the valuation of AnGRs can play an important role, components such as use, passive-use, and option values, have a relevance that alone may justify a conservation policy. Drawing from a study conducted by Drucker and Anderson (2004) to assess the benefits and costs of conservation of the endangered Box Keken pig breed using three valuation methodologies, FAO (2007) opines that despite the shortcomings of the employed methodologies and the fact that values can only be approximated, benefits of conservation clearly outweigh the costs. In a similar study (Zander et al. 2009), the cost of conserving the Ethiopian Borana cattle breed in Ethiopia and Kenya, based on opportunity cost, was estimated at €25,400 per annum. The benefits of conservation (e.g. maintaining option values) and sustainable use (e.g. poverty alleviation, improved food security, maintenance of Borana cattle for traditional and cultural uses) would need to be weighed up against these costs. Generally, conservation costs have been shown, in a number of case studies (Drucker and Anderson 2004), to be relatively small, both when compared to the size of subsidies currently being provided to the commercial livestock sector, and with regard to the benefits of conservation. These costs are lowest in developing countries which is encouraging given that an estimated 70 percent of the indigenous livestock breeds existing today are in developing countries, and that this is where the risk of loss is highest (Rege and Gibson 2003). Despite this, studies specifically tailored to comparing the benefits and costs of AnGRs conservation in Africa to inform decision-making are lacking. However, several African countries, have initiated actions aimed at conserving some endangered livestock breeds, using either in situ or ex situ methods. The major agencies responsible for AnGRs conservation programmes are governments, breeders' associations, private farms, and research institutes or universities. Major species of focus for in situ conservations include cattle, sheep,

goats, pigs, poultry, and camels as well as emerging or non-conventional species such as duck, rabbit, pigeon, and guinea fowl. These include both locally adapted indigenous and exotic breeds. Traditionally, smallholder farmers have, for millennia, played key roles in conserving and using native breeds to support their livelihoods. They have maintained the rich biodiversity and the associated local knowledge in addition to the crucial role in sustaining livelihoods and other environmental benefits (AU-IBAR 2019). Conservation interventions should, therefore, aim to support these efforts in order to maintain the existing genetic wealth. Currently, ex situ conservation of AnGRs is quite low due to a lack of appropriate technology and expertise. Only 12 African countries reported that they undertake in vitro activities (AU-IBAR 2019), whereas 28 countries are planning to establish similar centres. The lack of prioritization of ex situ conservation programmes results in limited budget allocations.

Virtually, in all studies where breed comparisons have been conducted, indigenous breeds have shown superiority over exotic breeds in adaptive characteristics, such as fertility, survivability, disease resistance, heat and drought tolerance, and the ability to produce under conditions of nutritional inadequacy. Current models used for predicting climate change show that for the arid and semi-arid areas in which a large part of Africa falls, there is likely to be an increase in the frequency, severity, and length of droughts as well as significant increases in ambient temperatures (Drucker 2010). Under these aggravating conditions, the maladapted exotic breeds will be even more challenged. Indigenous AnGRs, therefore, represent a distinct economic resource to the continent, which must be conserved (see Chap. 24 on conservation and management of animal genetic resources). They also represent a valuable contribution to biological diversity at community, national, regional, and global levels. The arguments for the conservation and sustainable use of indigenous and the design of policies to counteract trends towards marginalization of adapted breeds are therefore compelling.

26.4 Economic Framework for Sustainable Use and Conservation of AnGRs

Economic arguments for the conservation and sustainable use of AnGRs can be an effective means of garnering the necessary public and political support, including the development of appropriate policies (Rege and Gibson 2003). As alluded to in Sect. 26.3, a range of methods and analytical approaches are available that could be used to value livestock breeds or traits. However, the practical applications of these tools and methods in contexts that could influence policymaking and livestock keepers' livelihoods remain limited (Drucker 2010). To translate the existing knowledge and recognition of the importance of economics within the Global Plan of Action on AnGRs into mainstream activities, the following should be ensured: (i) awareness creation; (ii) capacity development; (iii) availability and access to appropriate data; (iv) resources and incentives for conservation; and (v) multidisciplinary approach to conservation.

26.4.1 Awareness Creation

In most African countries, one of the main reasons for the lack of policies and legislations directly formulated and designed for the management of AnGRs is that policymakers are usually not fully aware of the economic value and contribution of AnGRs to national economies (AU-IBAR 2019) and the commensurate need to provide policy and budgetary support. Hence there is a need to raise awareness (through effective communication channels) of researchers, breeders, development practitioners, policymakers, and farmers regarding the important role of economic analysis in improving the sustainable use and conservation of AnGRs. Correct and accurate information about the value and economic contribution of AnGRs at household and national levels in Africa can help to design appropriate conservation strategies and action plans. Effective communication and coherence between ministries responsible for AnGRs and other

stakeholders in the sector is essential. The methodologies and tools to undertake such interventions should be readily available to all relevant stakeholders.

26.4.2 Capacity Development

Beyond awareness, and the need for attention to technical capacities covered in Chaps. 26 and 27, there is a need to strengthen national capacities in the area of economic valuation so that relevant methods and decision-support tools can be applied. There is also a need to integrate such tools and methods into wider national livestock development programmes, including designing appropriate incentive mechanisms (FAO 2015). Institutions (teaching and research, extension, trade and marketing, policy and legal entities) that deal with AnGRs and allied sectors need to be strengthened. The idea of developing some selected African institutions at a national and regional level to become effective centres of excellence could be supported by regional economic communities (RECs). Farmers' and breeders' associations and/or organizations should be strengthened as they can potentially play important roles, including representation of important actors involved in the management of AnGRs and various commodity value chains. Capacity of field technical staff responsible for data collection, analysis, and reporting at the breed and household levels should also be strengthened (AU-IBAR 2019).

26.4.3 Availability and Access to Appropriate Data

Closely connected to capacity development is data availability. Data for economic analysis are either not available or perceived as expensive to obtain, perhaps also contributing to a misperception that the tools are too technically complex to apply (Drucker 2010). The absence of data/information regarding local AnGRs shakes the very foundation of the understanding of what the genetic resources are and how best to conserve and sustainably improve and use them (AU-IBAR 2019). Until breed-level data are routinely collected as part of the national statistics, there will continue to be a need to undertake intensive primary data collection for specific purposes. This is likely to require the application of participatory rural appraisal techniques for which, once again, capacity is limited in many countries (Drucker 2010). Research and development in AnGRs are critical for up-to-date evidence-based information and data on the usefulness and importance of African AnGRs. There should be national and regional monitoring mechanisms that will function as early warning systems particularly on breed populations to flag and respond to emerging risk of breed loss. These should be put in place through the collaboration of national governments and RECs to ensure breeds at risk are monitored and populations restored when necessary (AU-IBAR 2019).

26.4.4 Resources and Incentives for Conservation of AnGRs

The need and methods for the conservation of animal genetic resources are covered in Chap. 24. Major funding for AnGRs conservation programmes in Africa is usually provided by the government and international donor agencies. However, funding by governments has generally been both inconsistent and inadequate (AU-IBAR 2019). In most African countries, few nucleus herds of local animals exist in government or research institutional farms. Conservation activities are usually restricted to a few breeds of major livestock species such as cattle, goats, sheep, chickens, and pigs. Currently, ex situ conservation is quite low due to a lack of appropriate technology and expertise. A few countries have national gene banks, others have specialized agricultural research institutes responsible for maintaining genetic resources, and many do not have any specific programmes on the characterization and conservation of AnGRs. Incentive payments aimed at compensating livestock keepers for the financial opportunity costs of continuing to maintain locally adapted AnGRs are hardly found in

African settings. The Global Plan of Action on AnGR however expects governments to demonstrate sustained political will and mobilize adequate resources needed for successful implementation. This will require regional and international cooperation. FAO and other relevant international organizations, countries, the scientific community, donors, civil society organizations, and the private sector, all have important roles to play. Indeed, there are both moral and practical imperatives to provide support to livestock keepers and breeders, who are the custodians of Africa's diverse animal genetic resources. Failure to take these actions will mean continued erosion as Africa's livestock biodiversity remains underutilized and underdeveloped (Kaumbata et al. 2020), and at-risk and endangered breeds will disappear.

26.4.5 Multi-Disciplinary Approach to Conservation

There are multiple deficiencies impeding the uptake of economic tools and methods regarding the valuation of AnGRs and the design and implementation of conservation plans. Biodiversity conservation programmes tend to be deficient in their design as a result of a lack of consideration of a broad range of technical issues, of which economics is just one (Drucker 2010). The national reports and Global Plan of Action tend to confirm this view as characterization and improvement use strategies identify priorities that go well beyond economic valuation, and include molecular analysis, performance evaluation, and monitoring. Given that the economics of AnGRs work is best carried out within a production systems' context and requires informational inputs from a range of disciplines, overcoming other deficiencies influencing the conservation and use of AnGRs will play a contributory role. Such multi-disciplinary approaches may include the following:

(i) *Development of national and regional livestock information systems*. Livestock information systems are vital for data/information collection storage and retrieval. At the global level, the Domestic Animal Diversity Information System (DAD-IS), developed and maintained by FAO, provides access to searchable databases of breed-related information and photos and links to other online resources on livestock diversity. It facilitates analyses of the diversity of livestock breeds at national, regional, and global levels, including the status of breeds regarding their risk of extinction. ILRI has also developed the Domestic Animal Genetic Resources Information System which focuses on technical (characterization) information and focuses on Africa and Asia. The AU-IBAR also hosts the Animal Resources Information System (ARIS) as the main information system specifically on Africa's AnGRs (AU-IBAR 2019). Similarly, some countries and regions have established information networks. In the SADC region, for example, the Livestock Information Management Systems (LIMS) is hosted by the SADC Secretariat. Despite the availability of these information systems, countries generally do not routinely provide data and hence there are significant data gaps in these databases. This is in significant part because most of the countries do not have dedicated in-country organizations, networks, and initiatives for sustainable use, breeding, and conservation of AnGRs (AU-IBAR 2019). Where they exist, they require strengthening.

(ii) *Participation of* stakeholders*, including the private sector.* Stakeholders play important roles in the implementation of the various activities in the management of AnGRs. In most African countries steps have been taken to engage or empower relevant stakeholders in the management of AnGRs (AU-IBAR 2019; Drucker 2010). The establishment and support of permanent and dedicated supporting organizations and other stakeholders provide sustainable institutional support (Wurzinger et al. 2021) instrumental for the establishment and growth of breeding (and conservation) programmes. The private sector participation in the development of

AnGRs institutions and networks is happening in some countries, but there is still much to be done in this regard. A value chain approach to the development of the AnGRs subsector requires that all value chain actors, including those in the private sector, play an active role in the governance as well as identifying opportunities for upgrading the AnGRs value chain, including through the introduction of higher-value products (AU-IBAR 2019). Product processing and trade in livestock products are key areas of business opportunities for the private sector and may have a lasting impact on conservation and breeding programmes, especially through investments in traits unique to indigenous breeds. For example, participation of the private sector through the establishment of small ruminant abattoirs, and engagement of processors and retailers of indigenous small ruminants' products boosted the incomes of smallholders (Kaumbata et al. 2020) contributing to the sustainability of small ruminant breeding programmes in smallholder farms. Public-private partnership arrangements are also possible and viable in some situations and must be pursued in the development of programmes and projects. The private sector stakeholders in the AnGRs sub-sector also have a role in the policy development process by bringing on board their unique perspectives, for example, experiences on the input supply and marketing of products as well as financing.

26.5 Conclusions

The current manifold functions and potential future uses of animal genetic resources, underpin the significant economic values of Africa's indigenous AnGRs. The economic valuation of AnGRs takes into account the total economic value of the genetic resources. A review of past economic assessments showed that conservation decisions have been made based on direct use values alone leading to the undervaluation of Africa's AnGRs, which results in a bias towards activities that promote the erosion of such resources. Establishing the true total economic value of AnGRs is important because it guides resource allocation between the conservation of various types of AnGRs and assists in the design of economic incentives for various stakeholders.

A range of valuation methodologies exist most of which provide good estimates of values that are useful for answering policy-relevant questions and as decision-supporting tools regarding conservation options. Data on the application of the available valuation methodologies in Africa suggests that they have both strengths and weaknesses. The decision on which technique to use for a particular application requires experience and judgement on the part of the analyst. The integration of various valuation methodologies is also recommended since no single methodology has the capacity to estimate all four components of the TEV.

Although a range of methods and analytical approaches that could be used to value livestock breeds are available, the practical applications of these tools and methods in the contexts that could influence policymaking and livestock keepers' livelihoods remain limited. To translate the existing knowledge and recognition of the importance of economics within the Global Plan of Action on AnGRs into mainstream activities, the following should be ensured: awareness creation; capacity development; availability and access to appropriate data; resources and incentives for conservation; and multi-disciplinary approach to conservation.

Institutional Arrangements and Enabling Environment for Enhanced Utilization of African Livestock Genetic Resources

27 Capacity Strengthening of Animal Genetic Improvement Education in Africa

Samuel E. Aggrey, Richard Osei-Amponsah, Donald R. Kugonza, Raphael A. Mrode, Romdhane Rekaya, and John E. O. Rege

Abstract

Africa is home to a rich diversity of farm animal genetic resources which play major roles in poverty alleviation, food, and nutritional security as well as helping meet various socio-cultural needs. These valuable animal resources range from the major species such as pigs, cattle, sheep, goats, donkeys, camelids, poultry, aquatic resources, and bees to micro-livestock such as guinea fowl, grasscutters, and cavies. In line with the Global Plan of Action on Animal Genetic Resources, there is a need for Africa to sustainably manage these resources and help ensure their conservation. Genetic improvement of Africa's animal resources will be key to breeding resilient, productive, and climate-adaptive animals for the current and future generations. Unfortunately, Africa continues to lag behind in both the institutional and human resource capacity for animal genetic resources management, including improvement. This chapter presents a brief overview of human resources capacity challenges, limitations in animal breeding and genetics and subsequently suggests how to turn some of the challenges into opportunities. The basic concepts and misconceptions in animal breeding, lessons learned from past capacity-building initiatives, and the need to improve agricultural education in primary and secondary schools are covered. Additionally, we review post-secondary technical education and graduate education in animal breeding. Finally, we highlight the need to embrace good collaborative partnerships to enable Africa to boost its human and institu-

Animal agriculture · Breeding · Genetics · Human resource development

27.1 Introduction

Animal genetic improvement can be viewed in general terms as the science of increasing the genetic merit of the progeny population through the selection and the appropriate mating of genetically superior parents. Increasing the genetic merit of animals within a population can lead to significant improvements in traits that are directly or indirectly under selection pressure. Mastering this know-how requires the acquisition of a diverse set of skills and knowledge. This is a multi-level education and training process that integrates knowledge from quantitative genetics, population genetics, statistics, and computer science. This chapter reviews the current status of animal genetic improvement education in Africa, identifies gaps and deficiencies, and makes recommendations to strengthen the existing capacity.

As clearly articulated in the next chapter (Chap. 28, Sect. 28.2), the importance of animal genetic resources (AnGR) to the attainment of the United Nation's Sustainable Development Goals (SDGs) and the Livestock Development Strategy of Africa cannot be overemphasized. This calls for concerted stakeholder actions to ensure sustainable use, improvement, and conservation of Africa's AnGR. National animal genetic improvement programmes that have a significant and continuous impact on animal production systems in Africa are, at best, scarce, but generally non-existent. While there are several reasons that explain the lack of successful genetic selection programmes in Africa, this chapter focuses on issues pertaining to animal breeding education. Among other things, the scientific and technical knowledge of locally trained personnel in charge of planning, implementing, and managing farm animal improvement and conservation programmes is abysmal in the whole of Africa. Without adequately trained personnel to develop and implement efficient and sustainable animal improvement programmes, Africa will continue to be a net importer of farm animals and animal products. Continuous importation is not only unsustainable but also provides no path towards long-term animal protein food security and self-sufficiency.

27.2 Concepts and Misconceptions of Animal Genetic Improvement

The definition of 'animal genetic improvement' is implicit within the phraseology. It means positive changes in the productivity of animals within a population resulting from genetic selection. Genetic improvement usually applies to a population; therefore, the change must increase the genetic merit of that particular population. Selection pressure will lead to changes in the phenotype of traits defined within the population, as well as the population's genetic composition and parameters. To effect genetic improvement, a breeding scheme needs to be in place. The breeding scheme may include the following: (i) the breeding goals, (ii) trait measurement and data analysis, (iii) selection and mating, and (iv) genetic evaluation. The purpose of a breeding scheme is to efficiently integrate all components to achieve the optimum genetic gain in the progeny generation of a population. The basic understanding of what genetic improvement is should guide how academic and non-academic education and training are conducted, and how animal genetic improvement programmes are designed, executed, and evaluated. Classically, genetic improvement relied heavily on quantitative and population genetics. More recently, new fields of knowledge, including molecular genetics, microbiology, physiology, statistics, bioinformatics, phenomics, and artificial intelligence are playing increasingly important roles in the implementa-

tion of genetic improvement programmes. To improve the accuracy of genetic predictions, geneticists have sought to include genetic markers and sequence data, microbiome, and metabolites information, and they are on the verge of adopting sophisticated analytics tools, including artificial intelligence and machine learning for data analysis. Thus, animal improvement professionals have welcomed inputs from other disciplines to advance their cause.

Why then are there misconceptions about animal genetic improvement and why are they important? At the very minimum, one progeny generation is required to evaluate the success or failure of a genetic improvement programme. Reproducing an offspring generation from the parental generation can be synonymous with the term 'breeding'. It is common that animal geneticists in pursuit of livestock improvement are referred to as breeders; the same label (title) is assigned to personnel performing animal mating and reproduction who are also called breeders. The layman does not know the difference. By definition, a breed is a group of organisms with distinctive appearance or characteristics. Whereas beef and dairy producers use predominantly distinct animal breeds, poultry, and pig producers often use breeds, strains, lines, or ecotypes. Comparisons among breeds for different goals are important for decision-making on different levels. However, mere breed, strain, or ecotype comparison for performance or other non-genetic criteria is not breeding and the practitioner of such activity does not meet the general expertise and qualification of a geneticist. The inability to distinguish between the different definitions of 'breeders' can be consequential in education and training as well as in the implementation of national animal genetic improvement programmes. According to the Career Explorer website, 'There is no educational requirement for animal breeders—anyone can become a breeder with extensive knowledge of animal breed' (https://www.careerexplorer.com/careers/animal-breeder/how-to-become/). Such misconception can go a long way to affect the development of personnel for animal genetic improvement. Under these circumstances, non-geneticists who are erroneously labelled as breeders may be chosen to lead an important genetic improvement programme.

Genetic improvement can be simplified to mean the increase in the frequency of favourable alleles and a simultaneous decrease in the frequency of unfavourable alleles in the progeny population based on the traits defined in the breeding goal. The education of animal genetic improvement geneticists should encompass the fundamental principles of population genetics, quantitative genetics, computational science, and an understanding of the other critical complementary disciplines such as molecular genetics, statistics, microbiome, metabolomics, artificial intelligence, and machine learning. It is imperative to understand the core and supportive drivers of modern breeding for the successful implementation of an animal genetic improvement programme. The study of genetics encompasses several disciplines or specializations. Specializations could include cytogenetics, molecular genetics, molecular ecology, veterinary genetics, microbial genetics, population genetics, quantitative genetics, and evolutionary genetics, to name a few. Thus, scientists educated and trained in the relevant expertise areas within a well-defined structure and by competent personnel should lead genetic improvement programmes on the continent. Genetic improvement is a component of the overall animal production system, and when executed properly should contribute positively to the overall performance of farm animals. The genetic gains together with the appropriate management of genetic resources should translate into positive economic, nutritional, and environmental impacts for the citizenry.

Genetic improvement education should be viewed in the context of the projected future demand and supply of animal protein, the nutritional requirements of the population, input resources for animal production, technological changes, genetic diversity (including conservation), climate change, and the appropriate strategy for the broader agro-ecological and socio-cultural environments in the continent more generally, and the productions systems of

the specific countries. The graduates of animal genetic improvement education must be able to balance the aforementioned factors in an economic, socio-cultural, and environmentally sustainable manner.

27.3 Lessons Learned from Past Capacity Strengthening Initiatives

Most institutions in Africa with the mandate for human capacity development in genetic improvement of animal resources lack the expertise in all disciplines in breeding and genetics. This has led to limited trained personnel, both in terms of numbers and skills. Even for those trained, the rapid increase in new knowledge and technological advances in tools for executing animal genetic improvement requires continuous education at all levels of the human capital involved in animal breeding and genetics. Capacity gaps in animal breeding training were recognized on the African continent about 40–50 years ago. As far back as the mid-1980s, the International Livestock Centre for Africa (ILCA) would organize training for the national agricultural research scientists (NARS) by hosting about 25–30 scientists at a time training them on the analysis and interpretation of data from on-station and on-farm breeding programmes. ILCA (which was headquartered in Addis Ababa, Ethiopia) and the International Laboratory for Research on Animal Diseases (ILRAD) which was headquartered in Nairobi, Kenya, merged to form the International Livestock Research Institute (ILRI) in 1995. Since its formation, ILRI has been the primary institution operating at the continental level to support significant programmes producing new MSc and PhD cadre personnel as well as a retooling of practising animal breeding/genetics professionals in both research institutes and universities. ILRI has also worked extensively with both national and international partners in areas of biotechnology for genetic characterization and improvement in farm animals, and in the process has trained/mentored a number of professionals in these disciplines.

Capacity strengthening in animal genetics and breeding was implemented under two main categories: (i) instruction only, and (ii) research and instruction. ILRI alone or in collaboration with African National Agricultural Research Systems (NARS) provided training for graduate students, group training courses, and individual short-term training. ILRI also offered fellowships and hosted fellows for part of their graduate research or postdoctoral research. These fellows were mentored with assistance from national and international networks of experts. In addition to pursuing training to meet their specific research goals, these fellows also participated in diverse programmes related to the work of ILRI and hence had significant international exposure. In addition to ILRI research programmes, the Biosciences Eastern and Central Africa (BecA) hosted by ILRI has also contributed significantly to the training of students and scientists at all levels in modern bioscience applications in agricultural sciences, including animal genetics and breeding.

ILRI has trained many MSc and PhD students in genetics and breeding, either through fellowships or in collaboration with NARS where ILRI hosted the fellows. Since 2004, the BecA-ILRI facility, especially the genomics and bioinformatics platforms, has been a major means of delivering high-quality training, including exposure to cutting-edge research facilities and methodologies (Rege et al. 2021). Many of the BecA fellows subsequently became research leaders in their own institutions, and some have retained intensive collaboration with ILRI and other international institutions. Consequently, many among the current generation of leading livestock geneticists in ILRI have trained an estimated 200 BSc, over 69 MSc, and more than 66 PhD graduates, as well as over 35 postdoctoral fellows in livestock genetics and breeding. This training model is one that can be built upon by all stakeholders.

In 1999, ILRI and the Swedish University of Agricultural Sciences (SLU) with funding from the Swedish International Development Agency partnered to provide capacity building on the sustainable use of Animal Genetic Resources (AnGR). The focus of this partnership was on 'training the trainers' to translate concepts and

knowledge to students, researchers, and policy-makers (Ojango et al. 2011). The objectives for the ILRI-SLU project were as follows: (i) strengthen subject knowledge and skills of NARS scientists in teaching, research, and supervision of animal breeding and genetics, (ii) strengthen communication skills of these teachers and researchers, (iii) catalyse curriculum development, review of course content, and use of new and expanded teaching methods in university education, (iv) develop computer-based training resources relevant for use by NARS teachers and researchers, (v) stimulate contacts and exchange of experiences and ideas among teachers/researchers from developing countries on research and training of students in animal breeding and genetics, and (vi) strengthen the human capacity base for work on animal genetic resources in developing countries. Between 2000 and 2010, the ILRI-SLU project trained 138 university lecturers and researchers across 46 countries in Africa and Asia in animal breeding and genetics (Ojango et al. 2011). After the training courses, 13 and 5 participants from Sub-Saharan Africa and Asia, respectively, enrolled in PhD education in animal breeding and genetics.

Despite these efforts by ILRI and those by national governments and other development partners, capacity in animal genetics and breeding remains well below what is expected across Africa. While rapid advances in the last decade in molecular and high throughput technologies have made it possible to accelerate farm animal genetic improvement, not much progress can be made in the absence of skilled professionals, especially in the areas of quantitative genetics, statistical genomics, and bioinformatics. Geneticists with the competency to combine classical and modern molecular tools to rapidly improve farm animal productivity and to develop and evaluate improvement programmes are a scarce commodity even in better-endowed African countries. Between 2015 and 2017, the BecA-ILRI facility, SRUC, and the University of Georgia organized training in quantitative and molecular genetics for 45 field personnel from 14 countries in Africa. The course was highly received, and the post-course reviews clearly pointed to a significant need for broader and long-term institutionalized training in Africa to build capacity in farm animal genetic genomics. In March 2022, the African Animal Breeding Network (AABNet) organized capacity training in Animal Breeding for 49 personnel from 25 countries representing all regions in Africa (West Africa, North Africa, East Africa, Central Africa, and Southern Africa). There are other short-term projects with animal breeding training content in Africa. One example was the University of Natural Resources and Life Sciences in Vienna, Austria, which led the training in the design of community-based breeding strategies for indigenous sheep breeds of smallholders in Ethiopia between 2007 and 2011.

Farm animal genetic improvement and conservation are not the responsibility of only technical personnel. Field technical staff conducting inseminations and collecting phenotypes, as well as laboratory technicians processing biological samples are equally important. Computational specialists and bioinformaticians are equally crucial for the successful implementation of animal breeding and conservation programmes. To that end, the ILRI livestock genetics team has trained a large number of support personnel from various Sub-Saharan African institutions. The BecA-ILRI facility has hosted large numbers of NARI scientists and technical associates undertaking non-degree related training in research methods, molecular laboratory skills, and bioinformatics.

27.4 Education in Animal Breeding—A Case for the Introduction of Agriculture Education in Primary School Curricula

Education in Animal breeding has to be viewed in the broader context of Agriculture Education in Africa. Whereas most disciplines including languages that are even foreign to Africa are taught in primary schools, agriculture is offered as part of electives in some High School programmes. Agriculture education has become either an after-thought, an add-on, or the quintessential orphan child of STEM (Science,

Technology, Engineering and Mathematics). Yet, it is an established fact that agricultural education contributes to poverty reduction (Wallace 2007). This therefore begs the question, why is agriculture not taught in primary schools in Africa? The knowledge needed for agricultural productivity within the socio-cultural environment and agro-ecological regions of Africa should start at the Primary School. Concurrent progression in advanced knowledge in STEM along the educational ladder can only create innovation in agriculture and shift the focus from agriculture as a means of food production to the broader goal of rural or suburban development. On the contrary, agriculture education is common in elementary, middle, and high school in countries in the global North, including the United States (Phipps et al. 2008). Incorporation of agriculture in elementary schools in rural America significantly spurred achievement and improved other STEM skills (Education 2011). There are relatively few agricultural high schools and agricultural colleges in most African countries, however, most universities offer agricultural science degrees with different specializations, such as Animal Science, Crop Science, Soil Science, Agricultural Engineering, Agricultural Economics, Agribusiness, and Agricultural Extension. The mere expansion of agricultural education at all educational levels may not improve productivity or alleviate poverty. Rather, agricultural education should be backed with a national strategy, infrastructure, both public and private sector investments, and research. Even though Malaysia and Ghana both gained their independence in 1957, per capita income in Malaysia is significantly higher than that of Ghana because of heavy investments in agricultural research and education among other areas (Diao et al. 2019). The development of incentives for retaining scientific and support personnel will help reduce brain drain. Such a strategy was pursued in Brazil. Public sector investments in the Brazilian Agriculture Research and Development Organization (EMBRAPA) have resulted in significant development of livestock and poultry in the country.

27.5 Post-Secondary Technical Education in Animal Breeding

Educational training at the post-secondary level is generally very important for a successful and progressive agriculture that is capable of identifying bottlenecks and applying the appropriate technological solutions in terms of advances in farming techniques, management, and technologies. The curriculum at this level is therefore aimed at producing individuals who have the practical knowledge of farm management and technical skills to be proficient in addressing practical problems.

In terms of animal breeding, some of the essential post-secondary skills needed to support breeding activities include heat detection, designing mating plans to avoid inbreeding, understanding artificial insemination, understanding the concept of estimated breeding values, and therefore the skill to select superior animals as parents of the next generation. Data is primary to every farm operation including breeding activities. Therefore, additional skills in the use of ICT to identify individual animals, record the performance of livestock on the farm, use summary statistics to undertake projections, and advances in reproductive physiology technologies such as the use of oestrus synchronization to produce calves targeted for a particular market or season should be part of such post-secondary training.

In general, these courses could be of short duration; for example, one-year duration leading to national certificates or diplomas in specific fields or part-time training for two years and should be very hands-on. These courses could be work-based learning (such as Modern Apprenticeships) and short skills-based training courses in an institute with the appropriate infrastructure. Throughout the course, students should be given the opportunity to develop independent learning skills and teamwork skills using a mixture of classroom-based activities and practical hands-on training on modern and progressive farms in local contexts. Several Agricultural col-

leges and Institutes offer a number of these short certificate or diploma courses with some content on activities related to animal breeding. For example, the Technical and Vocational and Training Authority recognizes the Kenyan YMCA College of Agriculture and Technology middle-level agricultural and technology courses that are needed to improve the overall workforce in Agriculture. The Zambia College of Agriculture (https://www.zcamonze.edu.zm/) is another example of colleges in Africa offering certificate and diploma courses in General Agriculture, both on campus and through Distant Learning. The Kita College (https://kitaghana.org/) is also a private agricultural college in Ghana that offers a wide range of technical and vocational training in Agriculture.

27.6 Graduate Education in Animal Breeding

According to the African Union Inter-African Bureau for Animal Resources (AUIBAR) (2019), the perceived complexity of courses in animal breeding and genetics, including biometrics, has been a contributing factor to low interest among potential students. Furthermore, some universities train students in animal breeding and genetics only at the PhD Level. These bring to the fore the need to introduce the subject in the early levels of university education. The pedagogic approach in training the next generation of animal breeders and geneticists also needs to be fine-tuned by revising the curricula and mode of teaching while making available technological tools including appropriate software to help students enjoy the uniqueness of animal breeding and genetics. The theory of both population and quantitative genetics hinges on a good understanding of statistics. Therefore, statistical genetics should be introduced to students of agriculture at the undergraduate level.

Most graduate students specializing in animal breeding first obtain a bachelor's degree in Animal Sciences or related degrees. Historically, the overview of genetic improvement is taught at the undergraduate level as Animal Breeding. However, at the graduate level, the specialization is often referred to as Quantitative or Statistical Genetics. Advances in molecular and high throughput technologies in the omics (e.g. sequences, transcriptomes, metabolome, and microbiome, bioinformatics, and artificial intelligence have made it possible to accelerate animal genetic improvement. However, in order to harness these technological advances for animal genetic improvement applications, highly skilled professionals and appropriate infrastructure are needed. Geneticists with the competency to combine classical and modern molecular and artificial intelligence tools to rapidly improve farm animal productivity and develop and evaluate improvement programmes are a scarce commodity even in the most developed countries.

Based on current and emerging opportunities and needs, a well-grounded animal breeder should acquire competencies in the following:

1. Population genetics
2. Quantitative genetics
3. Principles of selection and breeding strategies
4. Computational and programming skills, including artificial intelligence and machine learning
5. Setting up a breeding programme
6. Management and analysis of sparse and complete data
7. Understanding family relationships and estimation of genetic relationships, inbreeding coefficients in pedigrees
8. Evaluation of breeding programmes for genetic gain, diversity, and environmental impact
9. Understanding of traits and estimation of genetic parameters
10. Dissemination of improved genetics to end-users

As alluded to above, African research institutions generally lack opportunities for developing skills of both research staff (scientists) and support staff, including technicians and administrators. Inadequate numbers of staff with appropriate levels of research skills, science communication,

project and team leadership, and management, coupled with poor staff retention continue to bedevil the continent. Efforts for generation-long skilling and capacity development are generally lacking and instead, there are piecemeal ad-hoc training interventions not institutionalized and connected to clear long-term strategies. Higher degree training overseas that does not provide a conducive environment for return home is not of much help either.

It is highly unlikely that an Animal Science department in an African University can offer courses or programmes to cover all the required competency areas given some of the aforementioned limitations. As such, graduate-level animal breeding education in Africa should be re-imagined. Animal breeding education can be achieved through collaboration among institutions offering complimentary programmes or through well-designed programmes at regional hubs. Graduate-level education in animal breeding in Africa should also consider the heterogeneous production systems, socio-cultural value of animals, existing and future infrastructure, climate change, and the multipurpose goals for animal production in different countries, production systems, and economic situations.

Animal breeding education should explicitly cover the conservation of animal genetic diversity. The Food and Agricultural Organization of the United Nations (FAO 2007) recommends strengthening training and technology transfer programmes, and information systems for the inventory, characterization, and monitoring of trends and associated risks; sustainable use and development; and conservation, particularly in developing countries and countries with economies in transition. Furthermore, Africa needs to strengthen collaborative networks of researchers, breeders and conservation organizations, and other public, civil, and private actors, within and between countries, for information and knowledge exchange for sustainable use, breeding, and conservation.

Internships achieve several objectives including enabling students to obtain hands-on experience. They provide an opportunity for students to implement some of the theoretical concepts they have studied. Internships also provide an opportunity for students and their academic staff supervisors to interact with the stakeholders and potential employers to appreciate practical field situations. A typical internship programme that combines formal instruction and an opportunity to learn less formally, or more informally while serving in a particular community in order to provide a pragmatic and progressive learning experience is termed as 'service learning' (Nonnecke et al. 2015). This kind of internship ought to properly connect traditional classroom experiences with out-of-class or 'real-life' learning that results from the service. The need for a continental broad-based stakeholder strategy leveraging on higher learning and research institutes (HLRI) as well as networking in livestock breeding and genetic improvement in Africa has also been recommended (Refer to Chap. 28, Sect. 28.3) and must be pursued as a matter of urgency.

27.7 Retention of Animal Breeding Labour Force

Among the many constraints for efficient human and institutional capacity building for animal breeding development (Chap. 28, Sect. 28.3.2) are the lack of skilled personnel, facilities, inappropriate curricula, and teaching methods, as well as inadequate targeted research and collaboration among stakeholders. A recent assessment of African research organizations (universities, public and private research institutions, not-for-profit organizations) by the African Development Bank posited that the major hindrances to retention of animal breeding personnel are insufficient and irregular funding, high staff turnover due to low remuneration, and financial instability. The assessment presents a gloomy picture. Despite numerous efforts to strengthen capacity, knowledge-based institutions in sub-Saharan Africa remain small in size, scope, and influence. If Africa's capacity is to be transformed, these and other stumbling blocks need to be lifted or else, the status quo will remain for the foreseeable future. There should be an increase in fellowships for the labour force to upgrade their

skills and obtain new tools. Fellowships take different forms, however, those that are designed to enable selected graduate students to undertake advanced studies at a university or research institution could be more impactful. Well-designed fellowships enable the strengthening of linkages and collaboration between research institutions and or universities.

There are only a few countries with some form of grant system or a national strategy for animal genetics resource improvement. Scientists should be encouraged to take advantage of the current existing and emerging opportunities. For example, the current seed grant for new African principal investigators under the World Academy of Sciences supports early career returnees with grant support for equipment start-up, consumables, degree training, international conferences, industrial link, collaborative mobility, open-access international publication, skills-building workshop, and female scientist-after-child grants.

27.8 Proposing a Collaborative Animal Genetics and Breeding Graduate Training Model for Africa

More often than not, the agricultural education system does not align with the agricultural industry. In some cases, agricultural science and animal breeding graduates in particular do not have the skills required by industry. At the same time when skilled graduates are produced, the industry does not have the capacity to hire new graduates. This among many other factors has contributed in part towards graduate unemployment in Africa (Ogege 2011). For animal breeding education to contribute towards development, linkages between the education and local animal industry should be developed. The curricula need to be current and connected to the economy. In addition to the scientific and technical knowledge, the animal breeding entrepreneur and business value chain (opportunities) should be part of the overall curricula. The Institute of Agribusiness Management Nigeria (IAMN) (https://agribusinessnigeria.org/) has taken the lead in training organizations, business executives, farmers, agriculturalists, researchers, consultants, practitioners, etc., on the advancement of trade, capacity, and enterprise activities with the agribusiness industry in Nigeria. Animal breeding education should interface with a similar type of agribusiness education to spur growth and productivity in the animal industry. Vice Chancellors (VCs), Deans, and Head of Animal Science Departments in Africa should form strong collaborative networks with all stakeholders in order to obtain support to train relevant Animal Breeders for the African context. National Governments, international research organizations, and their donor partners should strategically support human and institutional capacity development for improved animal breeding that is able to take advantage of modern innovative approaches to enhance animal genetic resource development and improvement in Africa.

In pursuit of context relevance, effectiveness, efficiency, and sustainability, several collaborative models have been tried for MSc and/or PhD training in various fields of agriculture in Africa. Box 27.1 presents a case example—the Collaborative Masters in Agricultural and Applied Economics (MAAE). Given the capacity challenges that continue to constrain animal genetics and breeding and considering the fast pace of developments in disciplines critical for shaping genetic improvement of livestock, Africa needs a well-articulated set of collaboratives involving key institutions in each sub-region of the continent—Eastern, Southern, Central, West and North—building on experiences from these case examples.

The trend towards joint degree programmes offers an opportunity for quality training and enhancing collaboration instead of competition (Adipala et al. 2010). Through networking opportunities, universities in countries where political or economic conditions are unfavourable can be kept operating at the highest possible standard. This strategy can also be refined and developed to help participating universities adapt to change and expand their role within the National Agricultural Research and Extension Systems (NARES).

Africa can also make good use of its external partnerships particularly to expose Animal Breeding personnel to the current state-of-the-art technologies in the subject. In this regard AU-IBAR and national governments should encourage scientists, particularly students and faculty of animal breeding, to take advantage of opportunities such as the Australia Awards Africa Graduate and Post-Doctoral Training Fellowships (https://www.dfat.gov.au/people-to-people/australia-awards/australia-awards-scholarships) among others, to train a critical mass of skilled personnel in Animal Breeding and Genetics at all times. In this regard, we need to encourage North-South and South-South collaborative Capacity Building Programmes which have some bias towards animal breeding training and development in Africa. Best Practices and Lessons Learnt in past and ongoing programmes should be brought to bear on any future capacity-building programmes in Animal Breeding and Genetics Training in Africa. Other such useful capacity-building opportunities for Animal Breeding and Genetics in Africa include:

European Master in Animal Breeding and Genetics (EMABG) is a two-year MSc programme provided by six EU groups/universities and recognized by the EU as an Erasmus Mundus MSc programme. More information on this programme is available at https://lohmann-breeders.com/de/lohmanninfo/european-master-in-animal-breeding-and-genetics-international-collaboration-to-face-future-needs/; EU-funded Masters (MSc) Scholarships in Animal Breeding and Genetics available for developing country nationals https://www.advance-africa.com/MSc-Scholarships-in-Animal-Breeding-and-Genetics.html.

A few Animal Science graduates have already benefited from these programmes but annually many are unsuccessful because of the intense competition. Therefore, we suggest that similar models should be put in place by the African Union for African students to help train many more Animal Breeders and Geneticists for Africa.

Finally, and as recommended in Chap. 28 (Sect. 28.3.3) training of stakeholders through people-centred livestock community-based initiatives, training of trainers, and continuous education should be pursued. In all these, the roles of the AUIBAR, Pan African University, and the African Animal Breeding Network (AABNet) (Chap. 28, Sects. 28.3.4 and 28.3.5) will be crucial to ensure sustainable human and institutional capacity development for the improvement of animal genetic resources (AnGR) in Africa.

Box 27.1: Collaborative Masters in Agricultural and Applied Economics (MAAE)

CMAAE builds the capacity to conduct policy research in agricultural and applied economics to address food security, agricultural productivity, and environmental management. The specific programme objectives are to:

- Produce graduates in agricultural and applied economics with the knowledge and skills for transforming the agro-food sectors and the rural economies of the region in an environmentally sustainable fashion. By doing so, helping to fulfil the Sustainable Development Goals (SDGs) and addressing the persistent problems of food insecurity and poverty in Africa.
- Upgrade the teaching and research capacity of departments currently in the CMAAE Programme while initiating planning for a system to scale out the programme to other regions of Sub-Saharan Africa.
- Strengthen the research network to promote agricultural development.

The typical degree programme takes 18–24 months and is divided into three components:

(a) *Core Courses*

In the first year of study, students are required to complete eight core courses and one common course in Institutional and Behavioural Economics all scheduled for semesters 1 and 2.

Semester 1 (13–15 weeks): Microeconomics, Statistics, Mathematics, and Issues in Agricultural and Applied Economics.

Semester 2 (13–15 weeks): Production Economics, Econometrics, Macroeconomics, Research Methods, Computer Applications, and Institutional and Behavioural Economics.

(b) *Shared Facility for Specialization and Electives (SFSE)*

During the third semester covering four months, students from all the accredited universities converge at an SFSE to teach foundation and elective courses by visiting professors drawn from all over the world. Each student is expected to take one foundation course in his/her chosen field of specialization from the following four areas: Agribusiness Management, Agricultural and Rural Development, Agricultural Policy Analysis, and Environmental and Natural Resource Management. In addition, students take one common course and at least one elective course in the specific cluster/area of specialization. Over the years, SFSE has been held at the University of Pretoria (UP) in South Africa. This is based on the fact that UP has a world-class facility with an environment that is conducive to learning.

(c) *Thesis Research*

The last part—thesis research—starts at the SFSE where students present their concept notes during weekly seminar sessions. The concepts are developed in line with the four areas of specialization. The students return to their respective accredited universities to write their thesis. All students are required to complete a thesis and undertake an oral examination in their fourth and fifth semesters. Thesis supervision is provided by a designated supervisor, with the assistance of an additional thesis committee member, from within or outside the home university, providing specialized guidance.

Upon completion, all CMAAE graduates are encouraged to belong to an alumni association. To facilitate the association, the Programme runs an interactive alumni page which provides alumni with an opportunity to network and exchange ideas and experiences in their career path. https://aercafrica.org/training/cmaae/

27.9 Conclusion and Future Opportunities

Genetic improvement of Africa's animal resources will be key to breeding resilient, productive, and climate-adaptive animals for the current and future generations. Unfortunately, Africa continues to lag behind in both the institutional and human resource capacity for animal genetic improvement. Scientific and technical knowledge of locally trained personnel in charge of planning, implementing, and managing farm animal improvement and conservation programmes is abysmal in the whole of Africa. Most institutions in Africa with the mandate for human capacity development in genetic improvement of animal resources lack the expertise in all disciplines in breeding and genetics. Livestock Genetic improvement requires skilled knowledge in quantitative and population genetics, molecular genetics, microbiology, physiology, statistics, bioinformatics, phenomics, and artificial intelligence. Thus, scientists educated and trained in the relevant expertise areas within a well-defined structure and by competent personnel should lead genetic improvement programmes on the continent. At the same time, Africa has relatively few agricultural high schools and agricultural colleges although most universities offer agricultural science degrees with different specializations, such as Animal Science, Crop Science, Soil Science, Agricultural Engineering, Agricultural Economics, Agribusiness, and Agricultural Extension. Unfortunately, the mere expansion of agricultural education at all educational levels may not improve productivity or alleviate poverty.

Implementation of the Global Plan of Action on Animal Genetic Resources for sustainable food security, wealth creation, and enhanced livelihoods will require the training of a critical mass of Animal Geneticists. We therefore recommend that agricultural education should be backed with a national strategy, infrastructure, both public and private sector investments, and research. To fully characterize, sustainably use, and conserve its animal genetic resources, Africa needs to prioritize human and institutional capacity building in line with emerging and innovative technologies. On its part, ILRI has trained an estimated 200 BSc, over 69 MSc, and more than 66 PhD graduates, as well as over 35 postdoctoral fellows in livestock genetics and breeding. Stakeholders led by the AUIBAR, and national governments should follow this good example and collaborate with appropriate institutions such as the Centre of Tropical Livestock Genetics and Research (CTLGH) to help train the next generation of livestock geneticists. Fellowships designed to enable selected graduate students to undertake advanced studies at a university or research institution could be more impactful. Well-designed fellowships will also strengthen linkages and collaboration between research institutions and or universities. In this regard, we need to encourage North-South and South-South collaborative Capacity Building Programmes which have some bias towards animal breeding training and development in Africa. Through networking opportunities, universities in countries where political or economic conditions are unfavourable can be kept operating at the highest possible standard. Models such as the European Master in Animal Breeding and Genetics (EMABG) and Erasmus Mundus MSc programme can be replicated in Africa based on international collaboration between countries. Finally, there is a need for the African Union to encourage and motivate national governments on the need to provide sustainable funding schemes for Graduate Programmes in Agriculture in general and Animal Breeding and Genetics in particular.

Capacity Building in Livestock Breeding and Genetic Improvement in Achieving UN Sustainable Development Goals for Africa

Christian K. Tiambo, Oluyinka Opoola, Moses Okpeku, Isidore Houaga, Blaise A. Hako Touko, and Tadelle Dessie

Abstract

To achieve the Sustainable Development Goals of the United Nations (UN-SDGs) in Africa, livestock breeding efficiency is a prerequisite. Human capital in the form of professional, managerial, and technical skills, improved policies and institutional operation are the key enablers of performance for the smallholder livestock sector. Capacity building is central to guarantee African livestock efficiency along the value chains and ultimately transformed livelihoods. Currently, animal breeding and genetic improvement in Africa are constrained by a serious human and institutional capacity gap. The Livestock Development Strategy for Africa (LiDESA) seeks to transform the livestock sector for accelerated and equitable growth and for enhanced contribution to socio-economic development. Sustainable livestock development in Africa could be better realized through the development of customized capacity building strategies targeting (1) relevant participatory breeding education, hands-on training, efficient technical assistance, and collaborations / partnerships aiming to address farmers' present and future challenges, (2) enabling breeding systems for sustainable productivity, resilience of breeds, and animal seed stock management, and (3) market-led breeding solutions that are attractive for the younger and future generations.

Challenges facing capacity building in livestock breeding in Africa vary between and within stakeholders of specific value chains, and farmers lack training and suitable support programmes for their breeding activities. Beyond the lack of skilled human resources, financial capacity to enforce legislation and policies in Animal Genetic

Resources (AnGR) that may lead to the design and implementation of conservation and breeding programmes is a major limiting factor in most African countries. Currently, animal breeding programmes may not thrive, unless a new cohort of breeders, infrastructures, and policies are in place and backed by long-term investment plans. The main loopholes of the desired revolution reside in the current gaps and limitations of higher education and professional trainings, in terms of human resources, infrastructure, curricular content, research, and cooperation.

The required capacity development could also be through people-centred community-based breeding programmes (CBBP), training of trainers, and continuous education with major inputs/roles by agricultural training institutions (e.g. Pan African University), the African Union InterAfrican Bureau for Animal Genetics Resources (AU-IBAR) and the African Animal Breeding Network (AABNet), in the form of collaborations for teaching, research, and outreach.

Key capacity building intervention areas needing attention are: (1) Conservation and restoration of local animal genetic diversity, their improvement and dissemination of elite locally adapted and farmers-preferred genetics, and preservation of their natural habitat; (2) Demand-led capacity development in modern livestock breeding techniques; (3) Sustainable intensification of livestock farming practices; (4) Adaptation to extreme environmental conditions and livestock emergency guidelines and standards (LEGS); (5) Breeding for animal welfare, adaptability, and biosafety; (6) Big Data and artificial intelligence for smart farming and livestock breeding programmes; and (7) Infrastructural development and policies' integration for technology uptake.

28.1 Introduction

Livestock is central to achieving many of the United Nation's Sustainable Development Goals (SDGs) among which the most relevant are SDGs 1, 2, 3, 5, 8, 12, 13, 15, and 17 (FAO 2015; Schneider and Tarawali 2021; Macmillan 2016). Capacity building is recognized as a crucial means of operationalizing the Johannesburg Plan of Implementation (JPOI), which is appealing for improving and fast-tracking human, institutional, and infrastructure capacity building initiatives and for supporting developing countries in building capacity to access a larger proportion of multilateral and global research and development programmes.

To achieve the UN-SDGs for Africans, livestock productivity must increase to meet the projected demand for meat, milk, and egg within a few decades, while minimizing environmental impact. This is a challenge requiring skilled manpower to lead the development in the desired direction. Few initiatives have taken place on the continent. Unfortunately, many countries and regions still suffer from a shortage of personnel with expertise in animal breeding and genetics, both at research and academic institutions and in local organizations responsible for livestock development. Sustainable livestock development for small holder livestock producers who constitute the largest producer group in Africa could be better realized through the development of customized capacity building strategies targeting: (1) provision of relevant participatory livestock breeding education, hands-on training, effective technical assistance and new collaborations/partnerships to address present and future challenges, (2) enabling breeding systems for sustainable productivity, resilience of breeds, animal seed

stock management, and (3) market-led breeding solution that should be attractive for the younger and future generations.

While Chap. 27 addresses the specific issues around training and education to strengthen capacity of animal breeding practitioners—focusing on analysis of the status of animal genetic improvement education in Africa, major gaps, and recommendations of interventions to address these gaps (including re-examination of training curricula), this chapter examines capacity for livestock breeding more broadly—human, infrastructural, policy, and institutional, and roles and examples of initiatives of national, subregional, and continental bodies.

This chapter captures the four pathways through which livestock breeding and genetic improvement contribute to the achievement of all the 17 United Nation (UN) Sustainable Development Goal (SDG) targets and where capacity development should be strengthened in relation to the African development view from the Livestock Development Strategy for Africa (LiDeSA). It then maps the states of human resources and infrastructures to support capacity building and breeding programmes and the potential roles of African Union Commission via the pan African University (PAU) and the African Union—InterAfrican Bureau and Animal resources (AU-IBAR). Key capacity building intervention areas to contribute to achieving sustainable development goals in Africa are described, including conservation and improvement of AnGR and their environment, demand-led and market-led capacity development in modern livestock breeding techniques, sustainable intensification of livestock farming practices in Africa, adaptation to extreme environmental conditions and livestock emergency guidelines and standards (LEGS), breeding for animal welfare, adaptability, and biosafety, and Big Data and artificial intelligence for smart farming and breeding programmes.

28.2 Livestock Genetics Resources in the Context of the UN Sustainable Development Goals (SDG)

28.2.1 Contribution of Livestock Breeding and Genetic Improvement to the United Nation (UN) Sustainable Development Goal Targets

Animal-sourced foods make up 5 of 6 of the highest global value commodities (Wright 2017), and the growing demand for livestock products in developing countries, driven by population growth, higher incomes, and urbanization, makes livestock genetic resources central to achieving many of the UN Sustainable Development Goals (SDGs) and directly relevant to most of them (Macmillan 2016). This represents a huge opportunity for hundreds of millions of poor stakeholders of the various livestock value chains.

Four pathways based on livestock genetic resources directly contribute to the achievement of all the 17 SDGs, and the education system on the continent should ensure that capacity development is strengthened to preserve those assets (Fig. 28.1, FAO 2015):

- *Livestock breeding and genetic improvement for inclusive and sustainable economic growth*: The direct and indirect contributions are felt on SDGs 1, 8, and 9 through connection of poor farmers to markets. Best practices in animal breeding and genetic improvement could double the productivity of poor smallholder livestock keepers, while developing and implementing national and regional Livestock Master Plans to support effective investment will optimize livestock's contribution to continental economic growth.
- *Livestock breeding and genetic improvement for equitable livelihoods*: FAO (2014) postu-

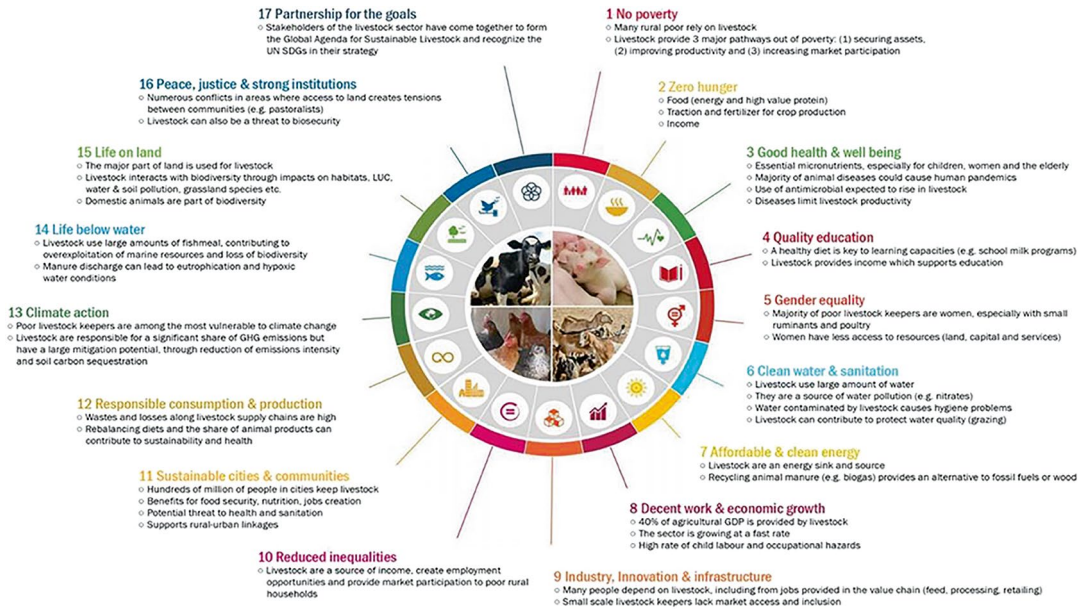

Fig. 28.1 Contribution of animal production to the different Sustainable Development Goals (SDGs). (Source: FAO (2015))

lated that 'Poverty is a largely rural phenomenon in Africa, with the majority of (farm) households keeping livestock, ranging from Poultry, small ruminants (sheep and goats) and cattle'. The proportion of people living on less than US$ 1.25 per day which defines the extremely poor ranges from less than 5% in North African countries to over 80% in some sub-Saharan economies, such as Burundi, Chad, and Madagascar.

However, agriculture and agribusiness, including livestock, have been among the fastest growing sectors since the 1990s, and the growing demand for food and high value agricultural products, such as meat and dairy in particular, is setting the stage for continued opportunities for investment.

It is gradually increasingly acknowledged that growth of food production and agribusiness, including the farm animal industry, is fundamental to reducing poverty. A large proportion of Africa's poor comprises smallholder farmers, the majority of whom keep animals. Increased livestock productivity can improve the livelihood of smallholder producers. Also, higher production can translate into lower food prices, to the clear equitable benefit of the majority of households who are buyers of animal protein. In addition, investments in farm animal productivity can encourage the development of agroindustries and value chains that generate employment as a substitute to farming.

Livestock breeding has potential for direct and indirect impact on SDGs 1, 4, 5, 10, and 16. Within some African countries, livestock breeding is helping to achieve gender equality and to empower all women and girls (SDG 5). It is important to consider that policies will go a long way to enhance equity in investment and livelihood of both low-input livestock keepers and business-oriented ones. This is done through regulation and application of gender-transformative approaches that give women in livestock raising, processing, and trading greater access to, and control over, livestock resources. Women empowerment is both directly and indirectly impactful on the short and long term. They directly play a significant role in maintaining rural livestock-food systems while remaining the pillars of youth education in African countries. The

impact of women empowerment will be also felt when developing labour-saving technologies for livestock feeding. At the regional and international levels, livestock breeding and genetic improvement could help buffer the inequality within and among countries (SDG 10). Government prioritization of the importation of commercial strains and foreign breeds used as breeding stock has proven not to be effective and sustainable for the mitigation of animal food and protein deficit in terms of quantity, quality, and economic growth. That has been the trend in sub-Saharan Africa in general and more pronounced in central African countries. Enabling policies should promote a dual track approach of addressing the gaps in the livestock food systems by mitigating short- and medium-term gaps through strategic planning of importations, while addressing long-term gaps with sustained genetic improvement of the local animal genetic resources and community-based management of more productive and resilient local stocks.

Capacity development for improved breeding techniques will safeguard pastoralists against catastrophic drought and loss of livestock in remote arid and semi-arid lands (ASALs) of Africa and develop options to reduce barriers to safe and sustainable domestic and regional trade in livestock products.

- *Livestock breeding and genetic improvement of animal-sourced foods, basic nutrition, and health*: Globally, two billion people suffer from micronutrient deficiencies, 151 million children under five suffer from stunting, and millions more have impaired cognitive development related to poor nutrition (Adegbola et al. 2019). This might be due to deficits in proteins of animal origin linked to insufficient consumption of animal-sourced foods (milk and dairy product, meat, fish, and eggs) by local or poor communities around the world. Animal-sourced foods stand as the perfect solution to the problem of malnutrition. The World Health Organization described animal-sourced foods as the best source of high-quality nutrient-rich foods for children aged 6–23 months (WHO 2014).

  Products of animal origin contain high quality protein and more bioavailable vitamin A, vitamin D3, iron, iodine, zinc, calcium, folic acid, and key essential fatty acids than plants, and consuming both animal-sourced foods and plant-based foods improves the absorption of iron in the latter (Neumann et al. 2002). Likewise, eating fish with vegetables improves the absorption of vitamin A and some fish species contain twice as high vitamin A concentration of vegetables as carrots or spinach (Kawarazuka and Béné 2010). Also, animal-sourced foods are reported to be the only natural source of vitamin B12. Vitamin B12 deficiency in individuals consuming low amounts of animal products in the developing world is linked with developmental disorders, anaemia, poorer cognitive function, and lower motor development (Stabler and Allen 2004).

  Within the scope of the UN SDG, livestock and food security and safe and healthy balanced diets, including animal-sourced foods, are the end goals of livestock breeding and genetic improvement which directly contribute to SDGs 2, 3, and 12: Thus, ending hunger, achieving food security and improved nutrition, and promoting sustainable agriculture (SDG2) should be part of the specific, measurable, achievable, relevant, and time-bound (SMART) objectives of livestock breeding in Africa, measurable through changing of the supply of animal-sourced foods through better feeding, breeding, and health and through the capacity of breeding techniques to reduce antimicrobial resistance through judicious use of antimicrobial drugs and antimicrobial alternatives in livestock production. This will also contribute to ensure healthy lives as well as promote the well-being of all and at all ages (SDG3), by reducing the burden of zoonotic diseases through better animal health and promotion of 'one health' approaches and improving food safety in informal markets.
- *Livestock breeding and genetic improvement for sustainable ecosystems*: According to the

EAT (a science-based global platform for food system transformation)—Lancet Commission report on food, planet, and health, animal-sourced food consumption is a global threat on sustainability and human health; this conclusion is not shared by many and judged overestimated as the tremendous variability in the environmental impact of livestock production seems to be ignored. According to Adegbola et al. (2019), the EAT-Lancet commission failed to adequately include the experience of marginalized women and children in low- and middle-income countries whose diets regularly lack the necessary nutrients.

The impact of livestock genetic improvement could easily be felt on SDGs 6, 7, 11, 13, 14, and 15. Ensuring access to water and sanitation for all (SDG 6) is achieved by improving livestock feeding regimes for efficient use of water resources and forage varieties and hence reducing and reversing land degradation and combatting desertification (SDG 15). However, it is important to structure livestock production around the world, especially in the local and poor communities where livestock intensification and the increasing adoption rate of technologies and innovations could not only be linked with income generation and improved intake of animal-sourced foods by the poor community, but also induce more carbon emission and environmental hazards. While policies and laws should be elaborated and implemented to secure the one-health approach in livestock-food systems, anticipated community programmes will certainly yield positive results.

28.2.2 African Development View from the Livestock Development Strategy for Africa (LiDeSA)

As clearly articulated in Chap. 30, Sect. 30.3.5, the Livestock Development Strategy for Africa (LiDESA) 2015–2035 seeks to transform the African livestock sector for accelerated and equitable growth and for enhanced contribution to socio-economic development. The strategy is in line with the ongoing African strategies, policy frameworks, and guidelines and is coherent with the Comprehensive Africa Agriculture Development Programme (CAADP), Frameworks and Agenda at the Continental, Regional Economic Community and Member States' levels.

28.2.3 The Challenge of Animal-Sourced Food Systems in Achieving the SDG and the Need for Genetic Improvement

The animal sector plays important roles in the context of sustainable development. These include, for instance, food security, transport, employment, financial security, and livelihoods (Keeling et al. 2019). There have been progressive advances associated with continuous growth and intensification of the animal sector to improve adaptability, resilience, and productivity. Animal-sourced foods are essential for the supply of adequate nutrients and nutrition for maintaining growth and longevity of individuals in every country, region, or continent. The SDG2 promises to ensure food security and nutrition within sustainable food systems (UN 2015; Fanzo 2019). However, achieving that goal is riddled with uncertainties as a result of the manner in which the world currently produces food. However, it is also essential to note that animal-sourced foods from animal-sourced food systems are not readily supplied in most countries due to the following: (i) poor breeding plans; (ii) low land spaces for agriculture; (iii) poor farmer knowledge on the animal-sourced food systems they practice; (iv) lack of incentives and funds to support farmers to practice animal-sourced farming systems; (v) lack of support from stakeholders involved in food systems and supply chains; and (vi) poor knowledge of individuals working with these farmers to provide support and adequate feedback to them. In addition, there are also challenges posed by the sundry environment where these animals are managed which directly

affect their performance and productivity. The challenges, although not exhaustive, have been mentioned in previous studies (Rege et al. 2011; Odero-watuhui 2017; Fanzo 2019). These challenges include gaseous emissions, water and soil pollution, and ecosystem damage, issues regarding animal welfare (animal abuse and negative consequences of intensive selection and production), and animal and human health (zoonotic diseases and inappropriate use of antimicrobials and anthelmintics).

28.2.4 Challenges in Capacity Building of Livestock Breeders

Chapter 27 extensively discussed issues related to human resources' capacity and limitations in animal breeding and genetics and subsequently suggested how to turn some of the challenges into opportunities. Building capacity with trained personnel, animal experts, or professionals in the livestock sector is one of the key parameters required to enhance and optimize breeding programmes in various species. A wide range of literature have reported the challenges of capacity building and livestock breeding in Africa (Rege et al. 2011; Besbes et al. 2018; Opoola et al. 2019; Wurzinger et al. 2021). These challenges are prevalent and at varying levels mostly faced by: (i) livestock farmers (animal keepers); (ii) stakeholders involved with the farmers; and (iii) other stakeholders involved in the livestock sector such as governmental and non-governmental bodies, livestock research-based institutions, and universities. Previous reports have shown that livestock farmers lack training and suitable support programmes for breeding activities.

28.2.5 Contribution of AnGR Breeding and Genetic Improvement to SDGs

Animal Genetic Resources (AnGR) represents the pool of domesticated livestock used for food. Although the world hosts a large variety of animal types, the percentage of those used for food is comparatively low. Africa is often credited as home to the largest animal diversity of AnGRs, where local AnGRs contribute significantly to the continents' food security through production of quality animal proteins, as biological machines on farms, providing needed draught energy to drive farm machineries, supporting crop lives with their compost, and economic sustenance, particularly in poor rural agricultural systems. However, the pressure of consumption as well as uncontrolled utilization outweighs the rate of reproduction and restocking. Furthermore, the scarcity of technical know-how needed for advanced breed improvement programmes results in colossal losses and erosion of local gene pools through uncontrolled/indiscriminate crossbreeding of local AnGRs. This is exacerbated by poor managerial skills and financial support for AnGR development and sustainable utilization, challenging climatic and environmental conditions, poor or inappropriate policies, and absence of government support in some countries and regions. The multiplier effect is seen in poor production, low input/output, and over-harvesting leading to extinction of important gene pools while many others are endangered.

The Sustainable Development Goal (SDG) recognizes the immense value of local AnGRs and sides with the Global Plan of Action for Animal genetic Resources (GPA-AnGR) in the fight to curtail erosion of unsustainable utilization of AnGRs. At various fora and through different media, local and regional representatives have agreed to, and put pen to paper to, endorse this struggle to reposition African local AnGRs for more sustainable utilization. The Interlaken Declaration of 2007 particularly recognized and detailed information gaps, poor national and international inventories, lack of or/and poor characterization of local and national breeds, and poor monitoring and conservation for sustainable utilization as key limitations upon which the SDG agenda is built.

In recent times, there have been more initiatives and researches supported by local, regional, and international institutions to tackle these recognized flaws in sustainable development and utilization of the AnGRs in Africa. Genetic

characterization of available AnGRs and phenomic characterization of usable metabolites from AnGRs on the continent have largely increased, bridging information gaps and providing base-line information for constructive development and improvement of indigenous AnGRs for more sustainable utilization. However, there is still a long way to go in drawing support locally and regionally to aid and implement SGD agenda of making AnGRs more sustainable. Okpeku et al. in 2019 and a host of other authorities suggested that a united private-public support is strongly needful in Africa for more sustainable solution.

28.3 Higher Learning and Research Institutions and Networking in Livestock Breeding and Genetic Improvement in Africa

According to Calestous Juma (2012), there is an urgent need to create a new generation of innovation-oriented agricultural HLRI that efficiently brings together agricultural research, training, commercialization, and extension. This requires upgrading the training, extension, and commercialization functions of existing national agricultural research institutes (NARIs). This would build on a strong research tradition of the leading Agricultural universities and colleges in Africa (Table 28.1), ongoing training efforts, connections with the private sector and farmers, and extensive international partnerships.

From Table 28.1, it appears that the capacity building may be disproportionate between regions of Africa, based on the number and quality of agricultural universities and colleges. Central Africa is the less endowed.

28.3.1 State of Human Resources and Infrastructures to Support Capacity Building and Breeding Programmes

Most countries in Africa have limited skilled human resources and financial capacity to implement legislation on policies for AnGR and to design and implement conservation and breeding programmes for AnGR (Rege et al. 2011). Moreover, animal genetic and breeding infrastructures and institutional capacities are too often inadequate or obsolete. This is in connection with the shortsighted capacity of planning and commitments from governments (Wollny 2003; FAO 2007; Boettcher and Atkin 2010). It generally appears that policy makers may not have enough knowledge about the importance of AnGR (Chagunda et al. 2015).

Very few African countries have commissioned studies on the state of their infrastructure and human resources for animal breeding and genetic improvement compared with the mapping done in the veterinary sector across the world. This constitutes one of the key issues identified in the Global Plan of Action (GPA) (FAO 2007). A recent study conducted by the African Animal Breeding Network in 38 African countries showed that lack of human capacity and infrastructures is the main challenge hindering livestock genetic evaluation and improvement in Africa (Houaga et al. 2023).

Current African animal breeding programmes will not succeed, unless a new generation of trained breeders and infrastructure such as physical facilities, operational livestock recording, and genetic evaluation systems is in place (Cardellino and Boyazoglu 2009). Skilled human resources, efficient organizations and institutions, national and regional long-term investment, and strong links between these elements are highly and urgently needed. Lack of necessary infrastructure is one of the most serious constraints in the African animal breeding sector (FAO 2011a; Philipsson et al. 2011).

28.3.2 Animal Breeding and Genetic Improvement Curricula: Gaps and Limitations of the African Higher Education Systems

Constraints are numerous for effective and efficient capacity building in Animal Breeding and Genetic improvement in Africa; these include the following:

Table 28.1 Representativity of top-50 leading agricultural universities and colleges in Africa in 2021

Africa regions	Countries (number of top Agric Universities and colleges)	Top-50 leading institutions (founding date)	Rank in		
			Country	Africa	World
North Africa	Algeria (1)[a]	Higher National Agronomic School (1905)	38

Source: compiled from Edurank (2021)
[a]No institution in the Africa's Top-50 agricultural universities from this country

- *Skilled personnel:* There are currently very few lecturers in animal breeding and genetics at agricultural institutions, and most of them have inadequate skills in biometrics and quantitative genetics, applications of molecular methods and other advanced technologies, and in the design of sustainable breeding programmes. In fact, the lack of a governmental vision in that domain and the existence of no breeding centres in most countries resulted in no applied training in teaching methods, pedagogies, and science communication in animal breeding and genetic improvement. As strongly recommended in Chap. 27 (Sects. 27.4, 27.5, 27.6, and 27.7), education in animal breeding has to be viewed in the broader context of Agriculture Education in Africa, extending from adapted curricula from primary to higher education and incentive systems to retain and grow the capacity of the trained staff.
- *Facilities:* Considering livestock in general and within the global agricultural sector, animal breeding is the poor arm in terms of equipment for training, informatics literacy, and limited access to power and internet in many African universities, which prevents access to world databases that could support up-to-date training and limit access to scientific literature and up-to-date textbooks.
- *Curricula and teaching:* there are many limiting issues in relation to curricula and teaching. Among them are the fact that most of the curriculum being taught in many African schools dealing with animal breeding and genetic improvement are obsolete and lag behind the rapid developments in knowledge of genetics, biological sciences, and bioinformatics.

Moreover, heavy teaching loads and large undergraduate class sizes contrasting with very low numbers of students at the MSc and PhD levels in animal breeding and genetic improvement and the quasi-systematic absence of experimental breeding farm in learning institutions could constitute a serious handicap to efficient animal breeding skills in Africa.

- *Philosophies and theoretical models for Africa:* There is a major gap in terms of theoretical and conceptual farming practice adapted to African context of livestock production and food systems. Academic manuals and books are shaped and modelled in the western context with no applications in the African context. The importation of foreign philosophies of research and innovation has been constant and persistent over decades. Global science and biotechnologies are driven by western priorities for extreme selection and intensification. It is evident that such context is not equitable for Africa and the majority of tropical countries where more than 60% of populations still depend on low input production systems to survive both economically and culturally. Unless this situation is addressed, the discrepancy between African livestock-food systems and both curricula and biotechnology gaps will not be bridged. An appropriate response to this may be the promotion of African scholar and academic manuals that contextualize science and technology for the sustainability goals.
- *Research and collaboration:* Most of the genetics research by local institutions in sub-Saharan Africa are limited to the typological and morphobiometrical characterizations, having no direct application in livestock improvement. Poor or no national animal performance and pedigree data recording systems exist, and the lack of data cannot support capacity development, nor provide the support needed to orient new research. Most lecturers are not sufficiently equipped to attract quality collaboration with research and development institutions within and between countries or overseas. Moreover, the separation of higher learning institutions and research institutions from producers, other key players, and sectoral ministries within countries hinders collaboration.

Despite the general picture of animal breeding on the continent being not as beautiful as in the technologically advanced countries, there are emerging opportunities for developing capacity in AnGR in Africa, such as: (1) Advances in computerization and the growing interest for bioinformatics by younger generations of African animal breeders, and the expansion of communications and information technology. (2) The existence of the African Animal Breeding Network (AABNet) as a pan African entity to interconnect the regional platforms that facilitate information sharing and resource mobilization (ASARECA, SADC, AU-IBAR, RUFORUM, FARA, and CCARDESA). (3) The Global Plan of Action (GPA) for animal genetic resources. (4) The African Union science and technology Agenda. (5) The Pan African University which could leverage on the availability of the African Diaspora for increased cooperation with advanced agricultural research institutions.

28.3.3 People-Centred Livestock Community-Based Breeding Programmes, Training of Trainers (ToT), and Continuous Education

- *Community-Oriented Research*

There is merit in developing and promoting community research schemes for many noble reasons, including: (1) It meets the immediate and future development needs of the communities; (2) It values the ancestral knowledge system; (3) It is the approach that fits the best with localized agroecosystems; (4) It provides sustainable solutions in localizing agro-food systems for food sovereignty and economic self-determination both at the local and the national levels and is therefore seen as a solution to mitigate trans-

boundary crises like COVID-19; and (5) Community-oriented research approach is the platform for the research-community-academia nexus for sustainable development and therefore, the pipeline to develop philosophy and theoretical models for Africa.

- *The Merit of People-Centred Community-Based Breeding Programmes*

There is no doubt that the achievement of food security and poverty alleviation as a global priority targets the underprivileged and marginalized strata of the global population and Africa in particular; hence, the opinion that meeting their needs is more likely to reduce the poverty gap. It is unanimous that about 70% of the vulnerable ones live in rural communities and thus constitute the first target of SDGs. The training of trainers and continuous education within the research-community-academia nexus platform will definitely contribute to securing people-centred livestock community-based breeding programmes.

Government's Intervention and Need for a Decentralized Scheme In most African countries where the required supportive infrastructure is largely unavailable to implement well-organized breeding programmes (Kosgey et al. 2006), some governments have alternatively tried centralized breeding programmes, usually nucleus breeding units (Haile et al. 2018). These centralized systems failed to sustainably deliver the desired genetic improvements to smallholders and also failed to involve the end users in the process. Continuous training and building local capacity to design strategies that consider the farmers' needs, views, decisions, and active participation, from inception through to implementation, is key for sustainable livestock breeding programmes in the African context. The success of such initiative is based on proper understanding of farmers' breeding objectives, infrastructure, participation, and ownership (Sölkner et al. 1998; Wurzinger et al. 2011; Mueller et al. 2015; Haile et al. 2018).

28.3.4 The Potential Role of African Union Commission via the Pan African University (PAU) and AU-IBAR

For the animal breeding and genetic improvement infrastructures to develop, reshaping higher education curricula is important. Ojango et al. (2009) pointed out the lack of trained staff in animal breeding and limited higher education possibilities in sub-Saharan Africa. According to Chagunda et al. (2015), most of the few animal breeders and geneticists work at universities and research institutions where limited breeding activities are effectively carried out. It is also known that most students shy away from animal genetics justified by the lengthy and cumbersome nature of the programme.

A cost-effective way of producing a critical mass of animal breeders in Africa could be to develop and implement continental programmes within institutions of higher learning and within countries, in response to current needs and the needs of both the existing and the perceived future needs of the African livestock industry. The Pan African University Institute for basic Sciences, Technology and Innovation (PAUISTI) and the African Union Inter-African Bureau for Animal Resources could be the best Troy horse, together with National universities and agricultural research organizations, to craft the current and future generations of professional animal breeders. Sustainable animal breeding, genetic improvement, and conservation programmes in Africa need to be given greater emphasis in higher learning curricula. Despite the current role being played by PAU, the learning curricula should include aspects related to animal quantitative genetics and genomics, sustainable breeding programme design, and simulation and optimization adapted to various livestock production systems in Africa. Additionally, teaching methods require modernization and increased activities in order to attract students who often shy away from the subject.

28.3.5 The Role of the African Animal Breeding Network (AABNet)

National agricultural research scientists and university professors need opportunities to strengthen their subject knowledge, didactic skills, and applied field and modern technology aptitudes in animal breeding and genetic improvement.

The creation of AABNet (https://www.animalbreeding-africa.org/) was driven by past experiences and opportunities offered through initiatives focusing on the development and application of tools, resources, and other innovations in genetics, genomics, animal breeding, and data science to support livestock genetic improvement in Africa. AABNet is a pool of top-notch experts in industry, academia, government, international research organizations and world leading animal breeders. Its contribution consists of supporting livestock genetic improvement in Africa through four main pillars: Multi-country animal genetic evaluation, professional development in animal breeding and genetic improvement, advocacy and awareness and business development, and collaboration, networking, and partnerships. The AABNet through organization of massive open online courses (MOOCs), annual summer classes, and research placements will strengthen the capacity of the African livestock breeders' community.

28.4 Key Capacity Building Intervention Areas

28.4.1 Conservation and Improvement of the Livestock Genetic Diversity and Their Environment

Pan African commitment and awareness creation to maintain and improve the diversity at livestock species and breed levels will be of great contribution in achieving the UN sustainable development goals.

Ensuring *Genetics for future use* and their environment is instrumental for successful breeding programs (Notter 1999) to secure the unique contribution of each breed. Breeds also contribute to national or regional identity and thus capacity building for their conservation has a cultural aspect and should require substantial public investments without immediate understanding of benefits.

Conservation of livestock genetic diversity (and their environment) has been addressed at the international and regional levels, assisting policy development at the national level. Almost all African countries are parties to the Convention on Biological Diversity (CBD) and recognize the need to conserve genetic resources for food and agriculture. Target 13 of the Strategic Plan for Biodiversity 2011-2020 required that 'by 2020, the genetic diversity of farmed and domesticated animals is maintained, and strategies developed and implemented to lessen genetic erosion and preserve their genetic diversity' (CBD 2010). This obligation has not been fulfilled largely because of the absence of capacities at various levels to understand, develop, and implement national and regional livestock diversity strategies and action plans or related sectoral programmes.

The importance of building capacities to conserve the diversity of locally adapted livestock breeds is also reflected in the Sustainable Development Goals of the United Nations Agenda 2030. Target 2.5 focuses on the maintenance of genetic diversity of domestic animals (https://unstats.un.org/sdgs/metadata/?Text=&Goal=2&Target=2.5, accessed on 21 September 2021).

Conservation and preservation of Animal Genetic Resources is a too heavy and complex task to be left to local communities of farmers alone. Faced with increasing demand for niche products and meat, both nationally and internationally, many endangered local breeds will face extinction if government actions do not secure and prioritize conservation and breeding programmes for local breeds. Maintaining livestock genetic diversity with strict control of inbreeding

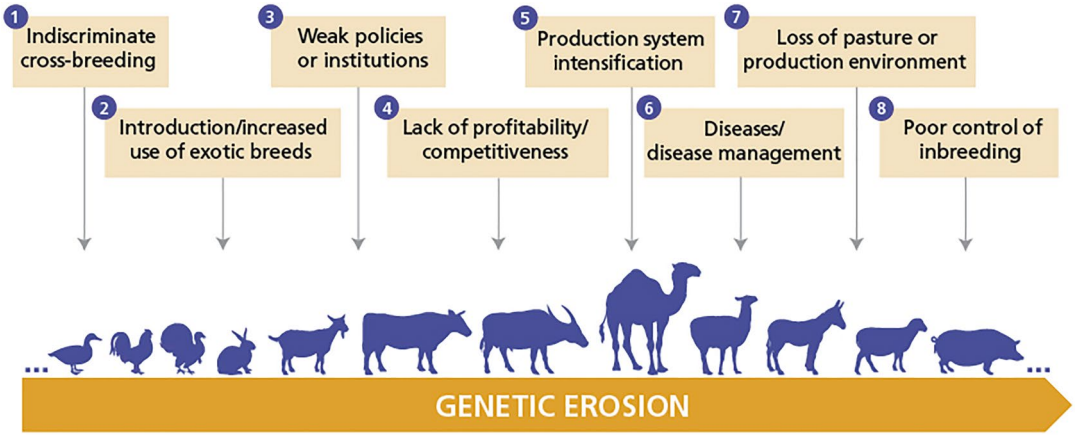

Fig. 28.2 Eight capacity building-related domains to address the causes of genetic erosion in African livestock genetic diversity. (Source: FAO (2021))

in consecutive generations under selection requires skills not only within the national breeding programme but also at the herd level. Those skills should be extended to the 8 others related sectors as proposed by FAO (2021) to address the main causes of genetic erosion (Fig. 28.2). Therefore, African breeders and livestock keepers should be trained to understand the importance of taking measures to avoid mating of related individuals and preserve genetic diversity in their herds. Such issues should be included in capacity building programmes for African farmers and breeders.

28.4.2 Demand-Led and Market-Led Capacity Development in Modern Livestock Breeding Techniques

The projection that demand for livestock products will double during the next twenty years presents the greatest opportunity for profitable increase in livestock production in Africa for the smallholders. However, this also presents emerging constraints in meeting the demands for quantity and quality preferences (Henriksen and Rota 2014). Smallholders therefore have to produce what is demanded. This also requires capacity building for animal breeding to be commercial-oriented.

To contribute to achieving the UN sustainable development goals for Africa, one of many goals of the African Animal Breeding Academy of AABNet is to maximize the benefits of African breeders' expertise for smallholder livestock keepers on the continent. For that to happen, the capacity development of animal breeders needs to be end users' demand-oriented. Generally, improved livestock breeds are a key focus of animal breeding research and development. This could highly contribute to achieving the SDGs, but technology solutions alone are not enough to bring the needed transformation. End users' demand is a critical success factor and should be catered for in the design of breeding programmes. Many capacity development programmes in Africa led by national, regional, or international livestock organizations are failing to achieve their objectives because instead of focusing on the demand from the end users of technology transfer, they have focused on the global trends in agri-biotech-innovations.

The discovery of new genes, research to understand their function, and incorporation of key beneficial traits into the best locally adapted, productive, and preferred breeds should be the building blocks of capacity building in animal breeding and genetic improvement. The emphasis which is frequently on technology should equally put customers at the heart of R&D. Capacity building has to involve end users

before the scientific work or technology adoption starts, considering not only farmers and consumers, but also all stakeholders along the value chain.

28.4.3 Sustainable Intensification of Livestock Farming Practices in Africa

Present and expected future increases in demand for livestock products in developing countries provide unique opportunities for improving livelihoods and stewardship of the environment. This improvement could be a complex procedure that requires to be strengthened by enabling policies and pro-poor investments in institutional capacities and innovant technologies (McDermott et al. 2010). If animal breeding in Africa is to satisfy that demand, production must become much more productive, efficient, demand-driven, and market-driven. The 'million dollars' question is to know if intensifying production by smallholders can be sustainable. The models of smallholder dairy in east Africa and small ruminant system in western and southern Africa (Kaitibie et al. 2008; McDermott et al. 2010) illustrate successful intensification. CIMMYT (2020) defines sustainable intensification as an approach using innovations to increase productivity on existing agricultural land with positive environmental and social impacts, where both, *sustainable* and *intensification*, carry equal weight.

The capacity development for sustainable livestock intensification should encompass technical, infrastructural, and policy aspects at pan African level, to jointly produce animal-sourced food and other goods for farmers and markets, while contributing to a range of valued public goods, such as clean water, wildlife and habitats, carbon sequestration, flood protection, groundwater recharge, landscape amenity value, and leisure and tourism opportunities. In its configuration, capacity building should capitalize on the synergies and efficiencies that arise from complex ecosystems, social and economic forces (NRC 2010) focusing on:

- Development and utilization of livestock breeds with a high level of productivity using internally and externally derived inputs, while avoiding the unnecessary use of external inputs
- Harnessing agroecological processes such as nutrient cycling, biological nitrogen fixation, allelopathy, predation, and parasitism
- Minimizing use of technologies and practices that have adverse impacts on the environment and human health
- Making valuable use of human capital in the form of knowledge and capacity to livestock adaptation and innovation and of social capital to bring integrated solutions to common landscape-scale and system-wide problems
- Minimizing the impacts of livestock system management on related domains such as GHG emissions, clean water, carbon sequestration, biodiversity, and spreading of pests and pathogens

Capacity building for sustainable intensification of livestock in Africa could target specific objectives with clearly defined expected impacts (Table 28.2).

The sustainable intensification of agricultural systems should thus be seen as part of a wide range of initiatives and efforts to create greener economies. Green growth and the greener economies have become important targets for national and international organizations, including the OECD (2011), UNEP (2011), World Bank (2012), the Rio+20 conference (UNCSD 2021), and the Global Green Growth Initiative (2012).

As clearly evidenced in other chapters of this book, sustainable intensification of livestock farming practices in Africa cannot overemphasize the role and considerations of indigenous, local, and locally adapted animal genetic resources in the application of novel production technologies and marketing practices, women and youth empowerment, and development of the

Table 28.2 Objectives and expected impacts of capacity building for sustainable intensification of livestock in Africa

Objectives of the action	Expected impact
Achieve primary goals of livestock farmers	Improved yields and incomes, improved natural capital in on- and off-farm landscapes, build knowledge and social capital
Knowledge development for breed improvement	Collaborations between relevant research/learning institutions and other stakeholders as key to emergence of agroecological design; participatory research and development leads to new technologies and practices
Knowledge dissemination, policies, and incentives to adopt sustainable intensification	Conventional extension combined with participatory dissemination via peer-to-peer learning
Stewardship of conservation, integrated disease management, and ecosystem services	Greater appreciation of the contribution of multiple ecosystem services provided by agricultural landscapes and awareness of the two-way relationship between agricultural and non-agricultural components of landscapes.

appropriate capacity building and legislative and policy structures.

28.4.4 Adaptation to Extreme Environmental Conditions and Livestock Emergency Guidelines and Standards

Sub-Saharan Africa remains one of the most vulnerable regions to impacts of climate change and variability (Niang et al. 2014). Mainstreaming of climate change adaptation into policy development is vital across all sectors (Chevallier 2010; England et al. 2018). However, most of the countries in Sub-Saharan Africa are failing to adapt sufficiently to impacts of climate variability and change (Ziervogel et al. 2014). The situation is aggravated by the interaction of 'multiple stressors', including high dependence on rain-fed agriculture, widespread poverty, and weak adaptive capacity (African Union 2014). The changing climate will have adverse effects on natural ecosystems and livestock production, with consequences on Africa's capacities to realize its SDGs targets. Therefore, there is an urgent need for Africa to design robust capacities and approaches to effectively address the challenges associated with extreme environmental risks. Capacity building efforts should give emphasis on supporting the improvement of climate data acquisition, information, and services, including the adoption of the climate strategy of the New Partnership for Africa's Development (NEPAD).

In Malawi, 2011 Capacity and Training Needs Assessments identified gaps for both state and non-state actors operating in the climate change field, which informed about the development of the National Climate Change Learning Strategy (NCCLS) (Malawi Government 2011a, b). The assessment highlighted inadequate knowledge of technical personnel to conduct 'critical analysis' and capacity gaps in the understanding of climate change-related concepts among different stakeholders and has recommended strengthening skills development in human resources as one of the priority areas.

The frontline extension workers in animal production are expected to be the principal stakeholders to teach farmers how to cope with climate change. Consequently, there is a need to develop suitable capacity building packages for their training on climate change issues and its effects (Ozor 2009), based on all the adaptation strategies and practices locally available and affordable.

On the other side, the Training of Trainers in Livestock Emergency Guidelines and Standards (LEGS) will reinforce the provision of tools and guidance for participatory design and implementation of timely and suitable livestock emergency responses. Such training should consider important topics such as emergency prediction and assessment, response identification, and technical aspects including destocking, veterinary services, water, feed, shelter, and restocking.

According to Watson (2011), the LEGS Handbook and training programme have been well accepted and plans have been sketched to expand the programme to additional regions, including North and Central Africa.

28.4.5 Breeding for Animal Welfare, Adaptability, and Biosafety

AU-IBAR in partnership with other organizations led the formulation of an Animal welfare strategy for Africa (AWSA) that furthered the LIDESA strategic priorities and the OIE's standards in the region. From the AWSA, the key animal welfare issues in Africa emanate from lack of adequate education and awareness, with top issues being: (1) Inadequate stakeholder's engagement and involvement, and (2) lack of home-grown science and research data (AU-IBAR 2019). For these reasons, the first priority of the strategy is to develop the capacity of national and regional institutions to coordinate multi-country and multi-regional animal welfare improvement efforts and forging partnerships with a range of stakeholders including the private sector, farming communities, regional organizations, international organizations, and the donor community.

Breeders should be equipped to improve animal health and welfare through selection, in addition to increasing economic performance. The adoption of such goals will contribute to the well-being of animals within smallholder and commercial production systems.

From research data, the performance of local AnGR is more often compared with improved or imported livestock rather than resilience and adaptability traits. This transferred knowledge system is a setback for conservation research actions. While improved or imported breeds are important to address the increasing demand for meat and animal proteins, the local livestock genetic resources remain paramount for their resilience, adaptability in challenging environment, and breeding conditions, and contribution to nutrition, income, and cultural well-being of rural farm families; hence, the importance of promoting home-grown science and research in Africa (AU-IBAR 2019).

28.4.6 Big Data and Artificial Intelligence for Smart Farming and Livestock Breeding Programmes

Smart farming is a development that emphasizes the use of information and communication technology in the cyber-physical farm management cycle (Wolfert et al. 2017). New technologies such as the Internet of Things and Cloud Computing are expected to leverage this development and introduce more robots and artificial intelligence (AI) in livestock breeding. AI using Big Data will support evidence-based decision-making.

In the perspectives of African Animal Breeding development, capacity development for Big Data will be key to provide predictive visions in livestock production operations, drive real-time operational decisions, and redesign business processes for game-changing business models. It is advocated that Big Data will cause major moves in roles and power relations among different stakeholders in current African livestock agri-food supply chain networks. Using Fig. 28.3, Wolfert et al. (2014) summarizes the concept of smart farming along the management cycle as a cyber-physical system.

In modern livestock breeding and improvement, Big Data applications in smart farming will boost farm processes, farm management, and the data chain (Lambert and Cooper 2000), the later being the sequence of activities from data capture to decision-making and livestock data marketing (Miller and Mork 2013; Chen et al. 2014). The livestock data chain will include all activities that are needed to manage data for farm management. Figure 28.4 illustrates the main steps in data chain.

The capacity development for Big Data application could be very instrumental for the development of smart farming in the African setting. Table 28.3 provides an overview of some of the applications.

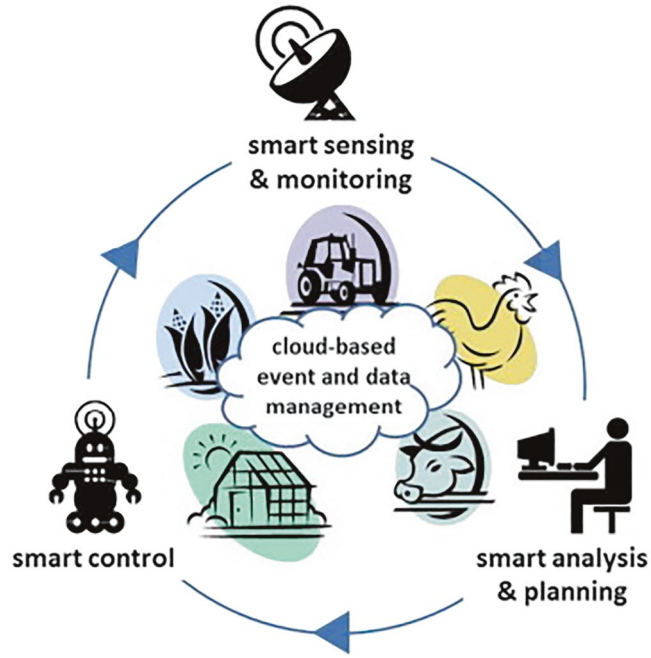

Fig. 28.3 The cyber-physical management cycle of smart farming enhanced by cloud-based event and Big Data management. (Source Wolfert et al. (2014))

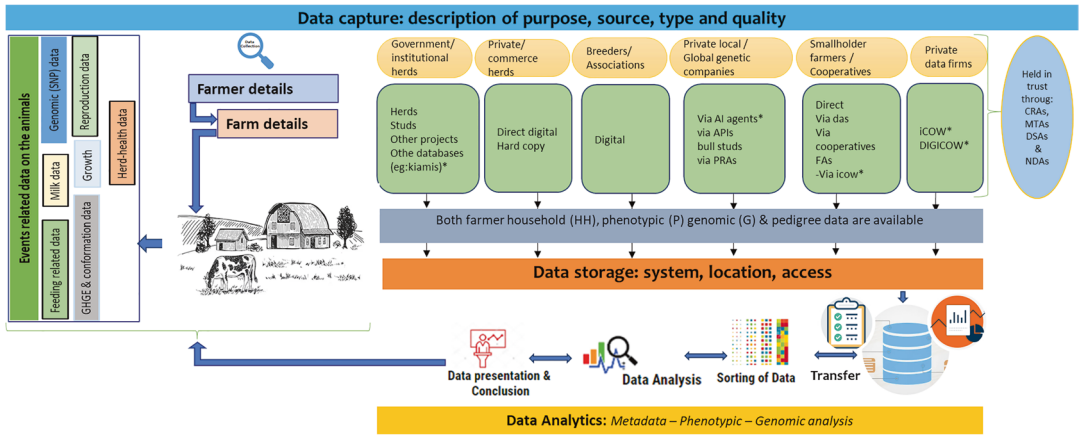

Fig. 28.4 The data chain of Big Data applications in livestock breeding. APIs Application Programming Interface, PRA Data Collectors/Performance Recording Agents, DA Direct Agreement between firm/farm & the programme, FA Farmer Assistants, MTA Material Transfer Agreement, CRA Collaborative Research Agreement, DSA Data Sharing Agreements, NDA Non-Disclosure Agreement

Nowadays, computers, sensors, cloud computing technologies, machine learning (ML), and artificial intelligence (AI) are essential tools to transform the livestock industry, by creating greater gains and more efficiencies. This supports the need for these advanced technologies to be incorporated into the academic curricula. Sensors, Big Data, and advanced AI & ML algorithms go hand in hand to provide a complete solution (Fig. 28.5).

Capacity building for sensors, Big Data, AI, and ML will constitute new possibilities to farmers who, instead of reacting to diseases after they become evident or pro-actively using the services of doctors, will provide an opportunity to constantly monitor key animal health parameters

Table 28.3 Examples of Big Data applications/aspects in livestock and fishery smart farming processes

Cycle of smart farming	Livestock	Fishery
Smart sensing and monitoring	Biometric sensing, GPS tracking (Sonka 2015)	Automated Identification Systems (AIS) (Natale et al. 2015)
Smart analysis and planning	Breeding, monitoring (Cole et al. 2012)	Surveillance, monitoring (Yan et al. 2013)
Smart control	Milk robots (Wolfert et al. 2017)	Surveillance, monitoring (Yan et al. 2013)
Big Data in the cloud	Livestock movements (Faulkner and Cebul 2014; Wamba and Wicks 2010)	Market data (Yan et al. 2013) Satellite data, (European Space Agency 2016)

such as movement, air quality, and consumption of food and fluids, detect diseases like mastitis, and estimate milk yield, reproductive performance, calving time, and breeding values among others (Neethirajan 2020) (Fig. 28.6).

28.4.7 Infrastructural Development and Policy Integration for Technology Uptake

It should be emphasized that capacity building in human resource and infrastructure to use the best breeding and genetics tools are not the only solutions to increasing livestock productivity to achieve UN SDGs in Africa. As recalled by Marshall et al. (2019), any intervention programmes should focus on strengthening the

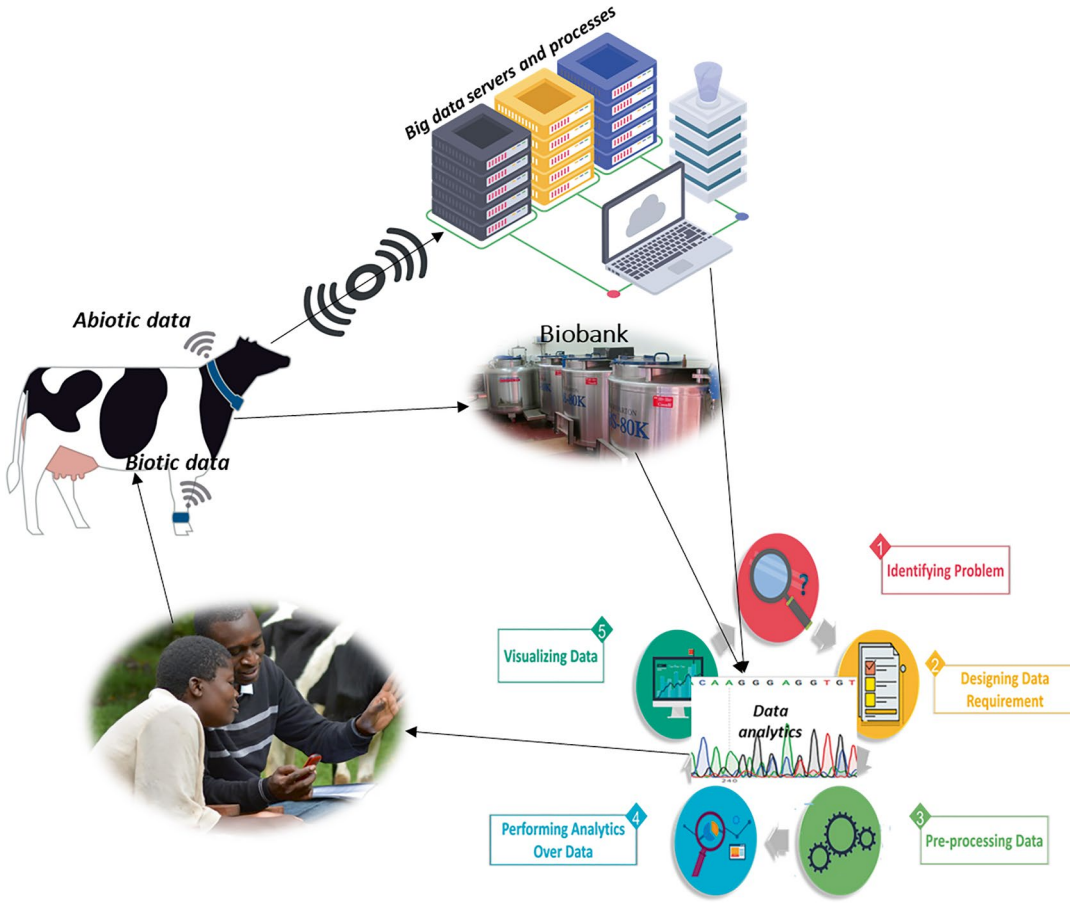

Fig. 28.5 The collection of technologies that we refer to as advanced technologies can help animal farmers create better outcomes

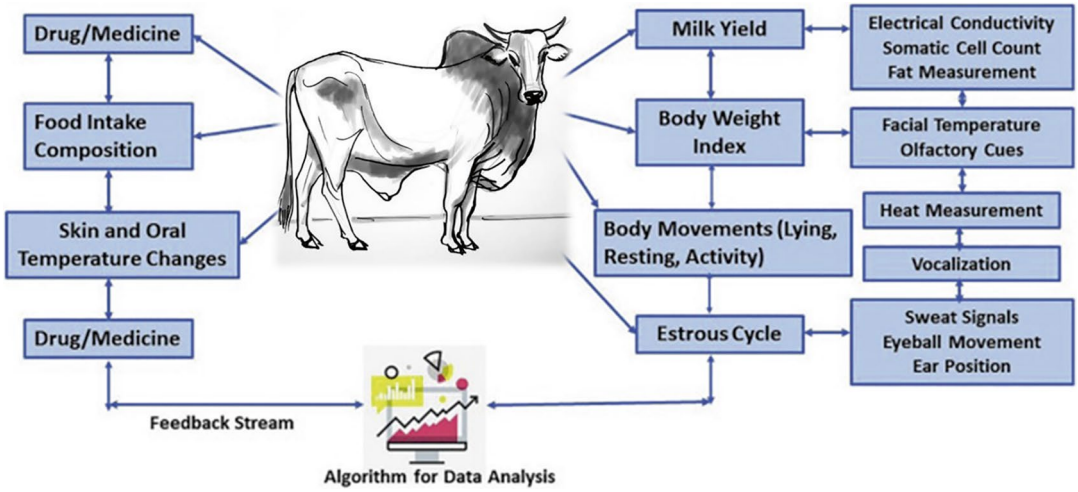

Fig. 28.6 Key domains of capacity building on machine learning algorithms to create optimal performance in livestock breeding. (Adapted from Neethirajan 2020)

capacity building of the livestock keepers and other value chain stakeholders, ensuring the availability and accessibility of inputs, provision of new technologies or customization of existing ones, support for involvement of the private and/or public sector, and most importantly, development of supportive policies.

Development of national and regional livestock strategies and policies requires in-depth understanding of various aspects of the current operation of the sector; hence, the need for capacity building for policy makers for subjects such as the legal and institutional framework, livestock production systems and their economic performance, genetic resources, available capacity, including human resources, and society expectation towards the sector (FAO 2011b).

Setting national and regional strategies should be accompanied by the development of animal breeding laws that address both the technical aspects of capacities in AnGR management (e.g. herd books, animal identification and registration, performance recording, selection and conservation programmes) and other factors that may influence the general implementation of the legislation (e.g. institutional arrangements, roles, and responsibilities of various bodies and decision making process) (Ingrassia et al. 2005). Policies should be clear on the establishment and activities of farmers' associations/breeders' societies and their role in the breeding and genetic improvement process. Policy makers should be trained to develop and enforce animal breeding laws that facilitate application of modern science-based breeding methods and adoption of balanced breeding objectives, taking into account traits supporting health and welfare and contributing to the achievement of sustainability in the sector.

On another note, capacity building and awareness creation for relevant legislations related to the implementation of the Nagoya Protocol and their implementation should target all stakeholders along the provider-user line, so as to alleviate obstacles in the regional exchange of elite animal breeds and their germinal products. Livestock research and development is often affected by the Access and Benefits Sharing (ABS) measures which can become substantial barriers to exchange when the stakeholders and policy makers are not on the same line of understanding (Martyniuk et al. 2018).

28.5 Conclusion and Future Perspectives

Livestock genetic resources play important roles in Agri-food systems and economies of African countries and the local and global demands for

animal-food will keep increasing in future decades. Importation of animal-sourced foods and the said 'improved' breed for intensification of the existing systems can only be a short-term strategic action to address urgent demand gaps, but could never be a sustainable solution to address the recurrent deficit of animal protein in Africa. As a sustainable approach, the promotion of research for novel productive genes and local livestock genetic improvement and conservation programmes are expected to close the long-term demand gap and effectively secure local livestock-food systems. The emergence of the strategic partnerships for achieving the UN SDGs and the African Union-InterAfrican Bureau for Animal Resources (AU-IBAR) through Livestock Development Strategic Agenda (LiDeSA) will certainly continue to be the major driver of national and regional joint efforts of multilateral partners. The identified gaps are to be addressed by the national government and regional and international institutions for the achievement of the goals. The training of trainers and continuous education within the academia-research-community nexus platform will definitely contribute to promoting home-grown science and research in view of securing people-centred and community-based livestock breeding and improvement programmes. This will require appropriate funding and efficient governance system. The efficiency of the extension services could not be over-emphasized at the intersection of the research, academia, and farmer communities. These approaches are paramount conditions for the building of decentralized and sustainable livestock-food systems that are more resilient to global and transboundary health and socio-economic crises. However, people-centred community-based models in low-input production systems are fragile and must be protected by effective government interventions. Resources and infrastructural gaps are to be addressed in the short and medium terms. Besides, equitable policies and effective regulatory and implementation framework of actions must be taken in the short term for the preservation, conservation, improvement, and sustainable utilization of local breeds in decentralized livestock-food systems from 'one health' approach. From the current context of capacity building in livestock breeding and genetic improvement in Africa, few key strategic areas could emerge as priority capacity investments: the capacity to (a) Harness the genetic potential of local and locally adapted and performant livestock seeds and their demand-led breeding and improvement. (b) Action research for development to cope with the desired production and productivity level and application of available technologies. (c) Regional integration for availability of inputs, efficient supply chain, and service delivery. (d) Efficient livestock emergency guidelines and standard. (e) Reduce post-harvest lost through value addition, biosafety, market information and infrastructure, and international competitiveness. (f) Improve and harmonize national policies, legislations, and institutional frameworks for effective AfCFTA. To those perspectives, the Africa Animal breeding Network (AABNet), as the convener of the Animal seed working group of the Africa Seed and Biotechnology Partnership Platform, has positioned itself as the credible body to support Africa in the followin:

- Multi-country genetic evaluations to be able to rank genetic materials
- Animal seed certification systems on the continent
- Professionalizing the African animal industry through development of capacity of livestock industry practitioners, including ethical practice to eliminate 'fake seed'
- Incubation of ideas and technologies to generate new animal genetic products or approaches and best practices and their injection in industry
- Advocacy and awareness, to make a business case for livestock genetic improvement and advice countries on genetics and livestock improvement.

29 Harnessing Multi-Country Cooperations, Initiatives, Facilities, and Technologies for Advancing Livestock Genetic Improvement in Africa

Ntanganedzeni O. Mapholi, Cuthbert Banga, Raphael Mrode, Oluyinka Opoola, Isidore Houaga, Lucy T. Nesengani, and Eveline M. Ibeagha-Awemu

Abstract

Multi-country initiatives have facilitated the development and adoption of technologies in developed nations, but such cooperations are less evident in Africa. National breed-specific genetic evaluations have been the most commonly practiced globally; however, there has been a growing interest and opportunities have arisen for across-country collaborations, or international consortiums combining data into large-scale multi-country genetic evaluations to achieve better genetic gains. Despite the need to establish multi-country genetic evaluation schemes for livestock production suitable for the African continent, few initiatives have been put in place to achieve this. This chapter draws attention to multi-country initiatives and benefits for performance recording as well as success stories in Africa (Sect. 29.2), the benefits of data sharing (Sect. 29.3), the role and importance of core facilities, especially those associated with the technologies of genomics, proteomics, metabolomics, metagenomics, and statistical/bioinformatics management of data (Sect. 29.4), germplasm centers for the storage of genetic materials or seed stock (Sect. 29.5), and the important place and prospect of multi-country genetic evaluations and practical application in Africa (Sects. 29.6 and 29.7). Such initiatives may provide an opportunity for genetic improvement of indigenous livestock populations and the possibility to open up new markets for African germplasm as well as inter-country germplasm trade within the continent. This would have a positive impact on the continent's livestock economy.

29.1 Introduction

Multi-country cooperations and initiatives (MCI) have been in the forefront of technology development and advancement in developed countries (Jit et al. 2021). They are a driving tool in strengthening and motivating the sharing of knowledge as well as building capacity within countries. This has been effective in implementing new technologies such as genomics for the benefit of human health and improving genetic material in livestock species (Opoola et al. 2020). A recent example of such initiative is the agreement and declaration for delivering across-border access to genomic information by 13 European countries. This agreement will see these countries linking genomic databases as a key factor in revolutionizing research to advance health standards. Such initiatives are, however, either limited or completely lacking in developing countries, especially in Africa. In Africa, where livestock productivity remains low, there is a greater need to improve and advance livestock genetics. Livestock genetic evaluation programmes are crucial to the establishment of sound breeding programmes and the achievement of high rates of genetic improvement (Mueller et al. 2015; Martin-Collado et al. 2021). Multi-country cooperations and initiatives can act as a driving tool to improve and implement livestock genetic evaluation programmes for the benefit of the continent at large.

Genomic evaluations for livestock selection are swiftly substituting traditional evaluation systems (Upshaw et al. 2021; Cesarani et al. 2021; Harris and Johnson 2010). This is influenced by the advancements in genotyping technologies, computational speed, and analytical approaches, as well as the growing need for higher rates of sustainable genetic change.

Implementation of across-country genetic evaluations is an evolving process in the livestock industry. Recently, there has been a rapid increase in initiatives to share livestock data and genetic material across countries, and even continents, in an effort to achieve higher rates of genetic improvement in livestock populations (Cesarani et al. 2021). For example, the benefits of across-country genetic evaluations have been reported in countries like Norway and New Zealand where de Oliveira et al. (2022) reported the feasibility of across-country genomic predictions of economic traits such as birth weight and weaning weight in a composite sheep population. The possibility to predict genomic estimated breeding values for traits not recorded in Norway using data from New Zealand was also indicated (de Oliveira et al. 2022). This is largely achieved due to improved accuracy of genetic evaluations, resulting from increased genotypic, phenotypic, and

pedigree information that is made available by the participating countries (Cardoso et al. 2021). Additional benefits of such programs include increased opportunities for trade in semen, embryos, and animals among the participating countries.

Exchange of biological materials or data remains a challenge in Africa, due to inadequate infrastructure, technical capacity, and financial resources (Mulder et al. 2017). African researchers are still exploring the opportunities for initiating collaborations in data recording, sharing, and analysis across countries. In the African context, the success of such initiatives will largely depend on collaboration and sharing of not only data and biological materials, but also resources and requisite facilities such as data management and genome centers. Therefore, there is a need for multi-country strategic plans, which include the development of multi-lateral collaboration frameworks and agreements. It is also important to build capacity in the skills that are needed for the effective implementation of such plans.

29.2 Performance Recording

Essentially, performance recording entails the measurement and recording of the performance of individual animals on traits that are desirable to improve. The primary objective of recording such data is to provide reliable information to breeders and farmers to be used as a selection aid to improve herd or flock performance. A sound performance recording system is based on sustainable and continuous recording of animal data to monitor livestock performance in various management systems. Many developed countries have achieved great successes in measuring and evaluating desirable traits such as production and functional traits. Genetic evaluation of these traits is obtained from phenotypic, pedigree, and genomic data of individual animals within the population under selection. See Chap. 20 for more details on performance recording tools and genetic improvement of livestock.

29.2.1 Animal Identification and Recording Schemes

Performance recording programmes in Africa are not as robust as the specialized recording platforms in developed countries. Livestock recording schemes in Africa are hindered by factors such as poor animal identification systems and inadequate infrastructure for collecting and processing data (Ojango et al. 2017). A general lack of sustainable performance recording schemes has hampered efforts to improve Africa's livestock production systems through genetic improvement. Genetic parameter estimates for genetic evaluation within livestock populations are mostly unavailable, due to the small herd sizes and lack of data. Lack of genotyping capacity also makes it difficult to implement genomic selection in these livestock populations.

29.2.2 Success Stories in Africa

29.2.2.1 South Africa

In South Africa, the Agricultural Research Council (ARC-SA) together with the Department of Agriculture, Land Reform, and Rural Development manages the national livestock database, known as the Integrated Registration and Genetic Information System (INTERGIS) (Van der Westhuizen et al. 2005; Zuma-Netshiukhwi et al. 2022). The INTERGIS caters for animal data recording needs of the livestock industry players, including performance recording agencies. This system has provided the South African livestock industry with a professional and internationally recognized recording and genetic improvement facility. Most of the recording and identification is, however, confined to commercial herds and flocks, with limited participation of smallholder farmers like in most African countries. A beef recording scheme for smallholder farmers, called Kaonafatso ya Dikgomo (KyD) scheme, was established in 1995 and collects basic data that are recorded on the INTERGIS. More than 8000 emerging and smallholder farmers are participating in this scheme (Ngarava et al. 2020).

29.2.2.2 African Dairy Genetic Gains

The African Dairy Genetic Gains (ADGG) project has carried out systematic performance recording from over 200,000 farmers in Kenya, Ethiopia, and Tanzania using simple mobile phone technologies (Mrode et al. 2021). The aim is to enhance country collaborations through data sharing to monitor future dairy improvements and provide feedback to the farmers who are the providers of the performance data.

29.2.3 Pedigree and Phenotypic Data

Phenotypic and pedigree data are vital inputs of a genetic evaluation programme. Although performance recording mainly serves to identify opportunities to improve livestock management systems, it also provides a means to generate the information needed to achieve sustained genetic change toward a defined bio-economic development objective. In performance recording for genetic improvement, there is a great need for maintenance of detailed records of phenotypic measures of performance as well as parentage and of genetic relationships among the recorded animals. The recording of such data must be sustained over time (animal generations) and maintained in a rigorously consistent manner in order to be effective.

Phenotypic measures of animal performance that are recorded in performance recording include output, product quality, life history, and adaptation traits. Animal production levels, or outputs, are an important component of overall animal merit. In dairy production, this involves recording of milk production levels at various points during lactation and of the duration of lactation. Such a set of measurements allows estimation of total milk production. When meat production is involved, measures of body size are the main indicators of production. Body size is ideally measured in all animals at similar ages and, assuming that birth dates are known, can be further adjusted to a constant age. Generally, measures of body size may be taken at weaning, at times when animals are chosen for marketing, and at times when management or nutrition change (for example, at transitions from wet to dry seasons or when animals are brought in from summer grazing for winter). In most cases, an indicator of body size at a relatively young age is desirable because, at least in suckling mammals, such a measure provides information on both the growth potential of the offspring and the mothering ability of the dam. Attention to product quality is appropriate only if improving product quality leads to increased food security and product prices or if measures of product quality are indicators of other favourable production characteristics (e.g. lean animals usually have higher feed efficiency). The most common measures of product quality in dairy production are fat and protein content of the milk. In fibre production, fibre diameter ("fineness") is the most common measure of value, although there are other potentially important quality attributes (including scouring yield and fibre length, uniformity, colour, strength, etc.). Life history traits are those that define critical events in the animal's productive life. They are generally time-related, including such things as dates of birth, weaning, mating, parturitions, sale, medical treatments, ending of lactation, and death. Evaluation of adaptation involves identification of the most important animal stressors, including diseases, climatic variables, endo- and ectoparasites, dietary deficiencies, and seasonal feed shortages. Appropriate and measurable indicators of susceptibility to these stressors are recorded as the adaptation phenotypes.

Limited recording of pedigree and phenotypic data is one of the major challenges to the development of sound genetic evaluation programmes in Africa (Opoola 2019). Most African countries do not have sustainable animal performance recording programmes, which makes it difficult to evaluate the genetic merit of animals under local conditions. South Africa is the only African country with a well-established and sustainable animal performance recording scheme and is a member of the International Committee for Animal Recording (ICAR). It is also one of the countries that has a performance recording scheme for the less developed livestock system through Kaunafatso ya Dikgomo (KYD), as

explained above. A few other countries, such as Botswana, Kenya, and Zimbabwe, have had either on and off or collapsed performance recording programmes. A recent study (Opoola et al. 2020) revealed that African countries can realize large benefits from pooling together available phenotypic and pedigree data and conducting across-country genetic evaluations. A critical requirement for the successful implementation of such across-country genetic evaluations is the standardization of trait definition across countries. This could be achieved by ensuring that within country performance recording programmes, all conform to ICAR guidelines on the definition of the various traits.

29.2.4 Joint Participation in International Committee for Animal Recording

The International Committee for Animal Recording (ICAR, https://www.icar.org/) provides a platform where its members are provided with guidelines and standards for measuring economically important traits of farm animals. The are only a few ICAR member organizations from Africa, such as the Agricultural Research Council and Studbook of South Africa and the Department of Veterinary Services of Botswana. These institutions have ICAR Certificates of Quality and routinely record production, fertility, and herd health data from exotic, indigenous, and crossbred animals in accordance with ICAR guidelines (Jorjani et al. 2003). Previous African member organizations include the Department of Research and Specialist Services and Zimbabwe Dairy Services Association of Zimbabwe.

Cost of membership is a major factor limiting the participation of African countries in ICAR. It is also desirable, although not a requirement, that prospective ICAR members already have ongoing animal recording schemes. As a way of broadening its membership by increasing the participation of developing countries, ICAR instituted a Developing Countries Working Group which later became reconstituted into the Outreach Working Group. This Working Group presents a good platform for African countries to lobby or request for conditions that will promote their participation in ICAR, such as joint membership or discounted membership fees. Alternatively, African countries could form consortia or regional recording organizations that could apply for ICAR membership. Such an approach would reduce the cost of membership to individual countries.

29.3 Data Access and Benefit Sharing

Initially, the issue of data sharing is examined in terms of multi-country genetic evaluations. Subsequently, issues relating to the sharing of genetic materials are briefly discussed.

29.3.1 Sharing Data for Multi-Country Evaluations

The success of multi-country genetic evaluation relies on the consented agreement to pool data across the various countries involved. Therefore, the advantages of the systems must explicitly and implicitly be obvious to the participating countries, and well-defined protocol to ensure data security and confidentiality should be in place.

Outputs from the multi-country evaluations should reflect shared benefits to all the participating countries. These benefits include increased accuracy of genetic predictions resulting from the use of information across the countries, the ranking of animals on the basis of genetic merit tailored to the production environment of each country and, finally, identification of the most genetically superior animals available to all the countries.

Several models are available for issues relating to impartiality, data security, and confidentiality. For example, joint genetic evaluations are taking place for dairy cattle in the Scandinavian countries of Denmark, Sweden, and Finland. The system comprises of a separate unit that handles the evaluations, with each country undertaking research and implementation of the evaluation

system for different traits. The separate unit ensures impartiality, with no concerns about data confidentiality as data flow freely among the countries. On a much wider scale are the multi-country evaluations undertaken by the International Bull Evaluation Services (INTERBULL) for dairy cattle, which involves about 35 countries. INTERBULL is a subcommittee of ICAR and has been involved in international genetic evaluations for dairy cattle since 1990. It is an independent unit which ensures impartiality in terms of the evaluation system. Sharing of phenotypic data among these countries, however, possesses a challenge in terms of security, confidentiality, and the huge size of the data sets. These challenges have been overcome by countries sharing only information on their bulls. Countries participating in INTERBULL multi-country genetic evaluations send the so-called de-regressed breeding values which represent the average daughter performances for these bulls in addition to the number of effective daughters. In addition, each country joining the multi-country evaluations of INTERBULL signs a code of practice (https://interbull.org/ib/cop_chap4) with INTERBULL. This code of practice outlines the responsibilities of each party and defines certain legal frameworks governing the use of the data submitted to INTERBULL for evaluation, research, or any other requirements.

Similar to the dairy cattle system, INTERBULL also undertakes across-country evaluations for beef cattle and the systems is referred as INTERBEEF. In contrast to the dairy system, participating countries send to INTERBEEF actual phenotypic records for the evaluation system. Again, INTERBEEF acts as an independent unit ensuring impartiality, security, and confidentiality. Similar to the dairy situation, each participating country signs the INTERBEEF code of practice, and in addition, ICAR, the mother organization of INTERBULL and INTERBEEF, clearly states it aims to protect personal data and commitment to privacy (https://www.icar.org/index.php/about-us-icar-facts/protection-of-personal-data-and-commitment-to-privacy/).

The situations examined so far involve the sharing and joint utilization of phenotypic and pedigree information. The picture is slightly different when it comes to sharing of genotypic data. For example, INTERBULL is unable to undertake full genotypic analysis for the Holstein breed, due to the unwillingness of participating countries to share bull genotypes. Countries only share the genomic breeding values and their associated effective number of daughters and INTERBULL undertakes the Genomic multi-country evaluations (GMACE). However, for the Brown Swiss breed, the participating countries were able to share genotypes and INTERBULL implements a genomic analysis referred to as Intergenomic (Durr and Philipsson 2012) involving genotypes and phenotypes. These activities are undergirded by the INTERBULL code of practice mentioned earlier, providing a legal framework for data sharing and utilization.

In Africa, national genetic evaluations are only conducted in a few countries such as South Africa, Kenya, Tanzania, and Ethiopia. For the latter two countries, this is through the African Dairy Genetic Gains Project (ADGG) (Mrode et al. 2021). Research on the feasibility of across-country evaluations was carried out recently (Opoola et al. 2020) and involved pooling together data from Kenya, South Africa, and Zimbabwe. Permission to use the data was obtained from the countries' respective organizations hosting the data.

Reviewing the existing models for multi-country genetic evaluation, initial steps that will promote data sharing for a joint genetic evaluation system in Africa will include: (i) encouraging countries to establish routine systems of data collection and national genetic evaluation; (ii) establishment of an independent body to undertake the joint evaluations to ensure impartiality, data security, and confidentiality; (iii) establishment of a technical committee with the know-how as part of the independent body; (iv) implementation of an efficient evaluation system that provides clear benefits to all participating countries in terms of increased accuracy, evaluations expressed on the country scale, and identification of top genetic merit animals across all

countries; and (v) putting in place government systems to promote more liberal movement of animals or semen or embryos across African countries.

29.3.2 Sharing Genetic Material

The sharing of genetic material (Deoxyribonucleic acid (DNA) or samples with DNA) for the purposes of genomic characterization requires additional protocol for fairness and confidentiality as such analysis may generate data relevant for intellectual property claims. The general recommendation from FAO (Food and Agricultural Organization of the United Nations, www.fao.org) is that a formal agreement for acquisition and exchange of the material is made with the provider of the material prior to the start of the study. The standard approach is for all involved parties to sign a material transfer agreement (MTA), which stipulates the terms of the material exchange and describes how the material will be used and handled after characterization and analysis (FAO 2021). Such an MTA should provide a legal framework and certainty as to what can be done with the material and any data resulting from the study. Details of what such an MTA should include and sample MTAs are presented in the FAO (2021) document on "Genomic characterization of animal genetic resources—updated technical guidelines".

29.4 Core Facilities

29.4.1 What They Are and Their Importance

Efforts to advance livestock improvement in Africa will require multiple technologies/approaches, including genomics, proteomics, metabolomics, metagenomics, statistical/bioinformatics management of data, and involvement of multidisciplinary teams. New technologies, including genomics technologies (see Chap. 20), are expensive and their application requires significant know-how in following rigorous procedures while maintaining transparency, acquisition of the necessary infrastructure, equipment, and reagents, and the ability to keep pace with evolving processes and technologies. It will be futile for individual researchers, laboratories, or institutions to keep pace with the cost of acquisition/maintenance of expensive equipment and the ever-evolving technologies. This is particularly critical for developing countries which have less funds devoted to research and development. A smart solution would be the creation of core facilities through which resources, expertise, infrastructure, and quality services can be effectively managed for the benefit of all stakeholders.

A core facility or laboratory generally is a centralized technology-driven facility or laboratory that maintains and supports sophisticated equipment, integrates expertise, maintains highly qualified personnel, and builds networks to support optimum use in a cost-effective manner. Thus, consolidation of state-of-the-art technologies, equipment, and expertise under the umbrella of a core facility is a crucial environment for access to up-to-date technologies by all, irrespective of funding level, collaborative research, which is necessary for competitive science, and a necessary driver for breakthrough discoveries. Given the present life sciences ecosystem, core facilities are regarded as essential and an important route to providing cutting-edge technologies and expertise in a cost-effective or affordable manner (Meder et al. 2016; Gould 2015). Moreover, core facilities generate a significant and increasing portion of the research data produced by academic science and biomedical research facilities as well as serve as a central storehouse for knowledge and expertise in technology and its applications (Mische et al. 2020).

The concept of core facilities was necessitated by the fast-evolving nature of new technologies, the cost of the technologies, the expertise to maintain the technologies, and the evolving nature of research questions needing advance technologies. Starting in the early 2000s with the coming together of a large group of researchers to sequence the human genome and the need for advanced technologies to get the job done, a

paradigm shift from individual-based to team-oriented research supported by diverse technologies started. Thus, several institutions in Europe and North America established core facilities which specialized in specific technologies or disciplines, such as genomics, proteomics, metabolomics, metagenomics, bioinformatics, etc. The main goals of core facilities are to (1) provide expected services using state-of-the-art technologies; (2) act as support units to research teams; (3) act as independent expert units open to all; (4) provide consultation services to users; (5) acquire and maintain state-of-the-art technologies and expertise to support research; (6) provide high quality services within reasonable time frames; (7) provide services to all interested users, both internal and external; and (8) provide cost-effective services based on a funding model which combines institutional and user fees (fee-for-service-based). For effective service delivery, institutions understand the importance of specializing in one or a limited number of technologies or disciplines, leading to the establishment of alliances to share expertise between institutions' core labs, country-wide core facilities, or across-country core facilities. Examples include (1) Life Sciences Complex Core Facilities at McGill University, Canada (https://www.mcgill.ca/life-sciencescomplex/facilities) which includes an Advanced Bioimaging Facility, an Animal Resources Centre, a Biology Platform, Cystic Fibrosis Translational Research Centre Platforms, a Flow Cytometry Core, a Histology Core, an Infection and Inflammation Core, a Mass Cytometry Core, a Metabolomics Core, Pharmacology and Therapeutics Platforms, a Structural Biology Centre, and a Transgenic Core. (2) Core For Life (https://coreforlife.eu/) established in 2012 as an Excellence Alliance of Core Facilities in Europe, bringing together about eight institutions with each having several core facilities. The member institutions for Core For Life are: The Centre for Genomic Regulation in Barcelona, Spain; EMBL (European Molecular Biology Laboratory) core facilities with headquarters in Heidelberg, Germany; The Center for Technological Resources and Research of Institut Pasteur, Paris, France; Max Planck Institute of Molecular Biology and Genetics, Dresden, Germany; Vienna Biocenter Core Facilities, Wien, Austria; Functional Genomics Center, Zurich, Switzerland; VIB Core Facilities in several locations in Belgium and CurieCoreTech Facilities of Institut Curie, Paris, France.

Core facility operational models include (Meder et al. 2016): (1) Service provider—provides services and training to users; (2) User laboratories—provides laboratory space to users as well as guide users in every stage of laboratory analysis and data management; and (3) All-inclusive service provider—provides services as well as laboratory spaces for users.

29.4.2 Genome Centres

Developments in the study of the genome were aided by advances in second- and third- (offer long read sequencing solutions) generation sequencing technologies, which over the last 20 years were accompanied by multiple generations of sequencing technologies and platforms, increased speed of data generation, and data quality. Although the genomic technologies have greatly impacted our appreciation of biology including disease and livestock production, the sheer volume of data outputted by these technologies requires a certain expertise to manage them. Consequently, developing standardized procedures, data formats, and comprehensive data quality management practices became a necessity (Endrullat et al. 2016; Hutchins et al. 2019). Moreover, the fast pace of the technologies necessitates adaptation by users, making it difficult and expensive for individual researchers, laboratories, or institutions to keep pace with the constantly evolving technologies. Therefore, Genome Core or centres (GC) were established by most institutions or countries to specialize in adapting genome technologies and in providing quality services to multiple users.

Most GC specialize in offering critical genomics-based technologies and applications in one or more genome subspecialties including DNA sequencing, next-generation sequencing (NGS), gene expression, genotyping,

metagenomics, gene editing, etc. to their users (both academic and industry) and to establish, optimize, and share standard operating procedures and best practices of fast growing technologies with users and partner core facilities. For further illustration, genome and high-performance computing/data management centres are discussed in more details below.

29.4.2.1 Genome Centres: What They Offer

Most GC offer the following services (Fig. 29.1):

1. *GC house state-of-the-art equipment*: State-of-the-art equipment are used for performing genome-related applications like DNA sequencing, NGS, genotyping, protein sequencing, metabolome profiling, and sample processing services, among others. Considering NGS as an example, GC acquire and maintain state-of-the-art equipment from major providers like Illumina SOLiD, IonTorrent, PacBio, and Oxford Nanopore, etc. to support a variety of services, from sample preparation, amplicon sequencing to whole genome sequencing.
2. *Develop standard operating procedures to ensure quality and reproducible service at all times*: To render quality services, GC develop standard operating procedures (SOP) related to equipment handling and maintenance, sample handling, analysis workflows, data management, and laboratory management. SOPs are updated regularly and also adapted to suit specific environments as well as ease of understanding and adoption by personnel. According to Gargis Amy et al. (2016), NGS has contributed enormously to the enhancement of clinical diagnostics and public health surveillance efforts in the United State of America (USA). However, public health laboratories in the USA face a number of challenges when implementing NGS procedures such as: (1) difficulty in adapting to frequent updates to sequencing chemistries, platforms, softwares, and workflows; (2) difficulty setting up protocols and in troubleshooting them; (3) difficulty in implementing multistep processes with numerous potential sources of variation; (4) constantly evolving and significant personnel training requirements; and (5) difficulty in evaluating the quality of materials and data as sequencing progress through the NGS workflow (Kozyreva et al. 2017; Association of Public Health Laboratories

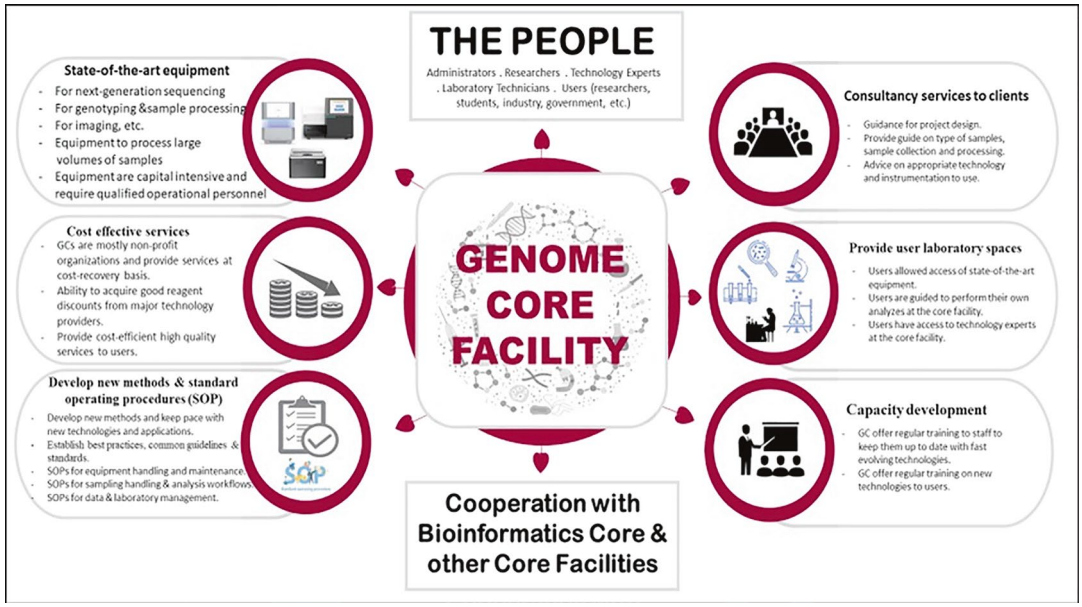

Fig. 29.1 Organization and core elements of a typical Genome Core facility

(APHL) 2016). To address these issues within Centers for Disease Control and Prevention (CDC) laboratories in the USA, a CDC NGS Quality Workgroup composed of laboratory scientists, quality managers, technicians, and bioinformaticians was formed in 2015, with the mandate to assess problems faced by member laboratories, develop and implement NGS, leverage best practices, and develop practical guidance or SOPs for laboratories conducting NGS within a quality management system (QMS) (Hutchins et al. 2019). Twelve quality system essentials (QSEs) identified by the Clinical and Laboratory Standards Institute (CLSI) as their QMS framework have been adopted by many laboratories. The 12 QSEs (facilities and safety, personnel, organization, equipment, information management, customer focus, process management, purchasing and inventory, documents and records, assessments, nonconforming events management, and continual improvement (https://clsi.org/standards-development/) (Hutchins et al. 2019)) were used by the CDC NGS Quality Workgroup as a reference point to develop a number of SOPs and information documents designed to provide a solid foundation for individual laboratories to use in developing assay-specific documentation by public health laboratories performing NGS (Table 29.1) (Hutchins et al. 2019).

3. *Qualified personnel*: Applications offered in GC are complex requiring deep understanding and commitment by a multidisciplinary staff to understand the processes and to perform them proficiently. For example, NGS equipment, reagents, and workflows are constantly evolving, requiring frequent training of personnel. Following installation of newly acquired equipment with the help of providers or with the arrival of each new process, staff have to commit time and be willing to gain new knowledge related to each technology and process. To implement NGS technology, basic understanding of system requirements is necessary and laboratory personnel must be proficient in maintaining and using them. To

Developed by the Center for Disease Control NGS quality Workshop (Hutchins et al. 2019)

ensure that staff perform proficiently and are well equipped to handle evolving technologies, GC develop training SOPs as well as offer regular training to staff and also to users of the platform. Therefore, to provide high quality services at all times, GC personnel must be highly qualified, possessing the necessary fundamental knowledge, and follow regular training processes.

4. *Consultancy services*: Most GC specialize in offering a number of services. To help users benefit optimally from their services, GC offer consultancy services to clients, mostly in the area of project design, sample type, sample collection/processing, and appropriate

applications for each project or research question. Thus, GC offer to clients the needed expertise, guidance from project design, and all critical aspects necessary for successful experimentation and generation of quality data.

5. *Provide cost-effective services*: Most GC are non-profit organizations obtaining most of their initial funding through government grants and donations. GC have large basin of users, granting them access to very good reagent discounts from major technology providers like Illumina, Pacific Biosciences, Qiagen, Agena, etc. Because GC are non-profit organizations, they apply the discounted products to the price of their services, which translates into competitive prices to the research community. It is quite difficult for individual researchers or university laboratories to reach such high-volume discounts from providers. Therefore, the services of GC are cost beneficial to users.
6. *Provide training*: GC offer regular training to staff and to users. Staff are trained to be proficient in handling constantly evolving technologies and processes. Staff are trained in process management which covers the lifespan of samples and associated processes from receipt of samples, processing, and data or output reporting. Users, on the other hand, are trained on the various applications offered by GC, sample requirement of each process, and expected output. GC, therefore, offer regular workshops and training sessions to staff and users.

29.4.2.2 Examples of Genome Centres and Mode of Operations in Various Countries

Canada Canada, by not participating in the *Escherichia coli*, *Saccharomyces cerevisiae*, or the human genome sequencing projects of the late 1990s and early 2000s, lagged behind in genomics research, and to address this, the federal government created Génome Canada (https://www.genomecanada.ca/) in year 2000 and six regional genome centres (Genome British Columbia, Genome Alberta, Genome Prairie, Ontario Genomics, Genome Quebec, and Genome Atlantic) starting in year 2002. The goals of Genome Canada are to (1) lead the vision in genome research in Canada and to speed up genome research through funding of large-scale genome research projects (to the tune of $10 M in 4 years); (2) support genomics researchers across Canada in the pursuit of their research objectives; and (3) support genomics researchers financially and technologically in all areas of the life sciences: human and animal health, agriculture, forestry, and environment. Genome Canada is funded by the federal government while the regional centres are funded by provincial governments. For example, Génome Québec (https://www.genomequebec.com/) is funded by the Ministère de l'Économie et de l'Innovation (MEI). Since its creation, Genome Quebec has invested and managed more than one billion dollars in genomics research in Québec. Its mission is to promote development and excellency in genomics research as well as its integration and effective utilization. Genome Quebec is the pillar of Quebec's bioeconomy, contributing to its social and sustainable development and influence.

Genome Québec is the only centre out of the six regional centres of Genome Canada to operate a technology platform: Centre d'expertise et de services Génome Québec (CES) (https://cesgq.com/). The CES offers high-quality genomic services to the scientific community, and it is a resource and networking platform for varied research activities in human health, infectious diseases, agriculture, forestry, and sustainable development. The CES offers a range of complete RNA and DNA services and processes from a few samples to thousands of samples per week. The range of services include (1) Genomic DNA and RNA extraction from a range of sample types (blood, buffy coat, hair saliva, bacteria, soil, leaves and cultured cells, etc.); (2) Next-generation sequencing, which includes library preparation and the following applications—Whole genome sequencing (WGS), Exome sequencing, Ribonucleic acid (RNA) sequencing (RNA-Seq), Single cell sequencing (scRNA-

Seq), Chromatin immunoprecipitation sequencing (ChIP-Seq), Whole genome bisulfite sequencing (WGBS), High-throughput amplicon sequencing with the Fluidigm Access ArrayTM System, and Amplicon sequencing. Its NGS services are based on the sequencing technologies of Illumina NovaSeq6000, Illumina MiSeq, and PacBio Sequel; (3) Sanger sequencing and single nucleotide polymorphism (SNP) discovery; (4) Genotyping (SNP genotyping and microsatellite analysis) services using TaqMan® genotyping, Agena® iPLEX® Gold®, Illumina® Infinium HD, and Affymetrix Axiom technologies; (5) Gene expression (RNA quality testing, gene expression arrays such as GeneChip or Clariom S, transcriptome arrays such as Clariom™ Assays, gene expression FFPE analysis, RNA and small RNA sequencing, scRNA-Seq) using ThermoFisher (Affymetrix) microarrays, Illumina NovaSeq6000, HiSeq4000, Illumina MiSeq, and PacBio Sequel II technologies; (6) Methylation (quantitative) analysis of genomic DNA using Agena® EpiTYPER®, Qiagen PyroMark® Q24, Illumina® Infinium Methylation, Methylation FFOE analysis, and Whole-genome bisulfite sequencing (WGBS) technologies; (7) Cytogenetics or copy number variation analysis services using OncoScan™ FFPE Assay, CytoScan, Illumina® Infinium HD, and TaqMan® CNV technologies; and (8) Bioinformatics services. These services are supported by solid infrastructure, state-of-the-art equipment, a web tool for sample submission and data transfer (Nanuq), and unique expertise in bioinformatics through close collaboration with the Canadian Centre for Computational Genomics (www.computationalgenomics.ca).

To support effective delivery of its services, the CES has a staff of 38 fulltime employees (directors, managers, technical personnel, informaticians/bioinformaticians, and a client management office) to support and provide access and services to a community that averages about 1000 research teams annually. Genome Quebec is a private non-profit organization and operates on a cost-recovery basis, meaning that the salaries of its employees and the price of reagents (sequencing, genotyping, etc.) are imbedded directly in the price of the services it provides to the community. Services provided by the CES generate approximately $15M annually. The operational costs of the CES are majorly covered by the services provided while 10% funding is provided by the provincial government (MEI). Other institutions across Canada like universities, hospitals, research institutions, etc. also operate core facilities in various disciplines.

United Kingdom (UK) The UK National Health Services (NHS) operates 13 Genomic Medicine Centres in 13 different locations in the Kingdom (www.england.nhs.uk/genomics/nhs-genomic-med-service/). The centres were established with main goal to support delivery of the 100,000 genomes project launched in December 2012 (Wheway et al. 2019) and to harness the power of genomic science and technologies to advance human health. Other major goals include: (1) offer whole genome sequencing as part of routine patient care; (2) transform healthcare for maximum patient benefit through knowledge generated from sequencing whole genomes of 100,000 people; (3) make accessible molecular diagnostics and routine genomic testing to patients with cancer and other conditions; (4) use genomic data to provide new treatments and diagnostic approaches; (5) develop and operate common national SOPs, specifications, and protocols; and (6) support industry and academic research and development through establishment of a national genomic knowledge base. Several institutions and universities also operate core facilities, providing services to users in the UK. For example, the Edinburgh Clinical Research Facility (www.ed.ac.uk/clinical--research-facility/core-services) operates scientific cores and specialist support services in the following areas: Nursing and Clinical; Imaging and Image Analysis; Genetics, Mass Spectrometry; Education, Epidemiology and Statistics; Information Technology and Research Support.

South Africa In South Africa, core facilities are linked to national institutions like the Agricultural

Research Council (ARC), the National Institute of Communicable Diseases, and universities. For example, the ARC operates a Biotechnology Platform (BTP) (www.arc.agric.za/Pages/BTP.aspx) which makes available high-throughput technologies and resources necessary for implementation of genomics, marker-assisted breeding, quantitative genetics, and bioinformatics know-how to the agricultural sector. The ARC-BTP is both a service provider and research-driven institution, providing an enabling environment for highly skilled personnel and users. The services offered by the platform are available to members of the ARC community, collaborators, industry, science councils, researchers, and students in South Africa. The services offered by the ACR-BTP include NGS, SNP genotyping, and high-throughput nucleic acid extraction. Another example is The African Centre for Gene Technologies (ACGT, https://acgt.co.za/) which is an initiative involving four institutions. Namely, the Council for Scientific and Industrial Research, the University of Pretoria, the University of Johannesburg, and the University of the Witwatersrand. The main goal of the ACGT is to create a collaborative network of excellence in advanced biotechnologies, with main focus on gene and genome analysis, and associated applications. In addition, individual universities also maintain platforms, but they are small in scope and mainly support the research needs of limited research groups. Presently, the genomic analysis needs of researchers at universities are outsourced to commercial companies (e.g. Inqaba biotech, https://inqababiotec.co.za/). Developing initiatives like The African BioGenome (AfricaBP) Project (https://www.earthbiogenome.org/affiliated-project-networks) may set the stage for the creation of a network of core laboratories across Africa to support successful delivery of the project.

29.4.2.3 Sequencing and Genotyping Platforms, Infrastructures, and Technologies

Sequencing Platforms Starting with developments that led to the first-generation sequencing technology, also known as Sanger sequencing in 1977, and successful sequencing of the genome of phage φX174 (Sanger et al. 1977a, b), second-generation and third-generation sequencing technologies and platforms have advanced our ability to sequence the genomes of living things at unprecedented depth and accuracy. Following the appearance of the first high-throughput platform in 2005, the Roche 454 pyrosequencer (Margulies et al. 2005), numerous NGS platforms have been developed by major providers like Illumina, Life Technologies, IonTorrent, Pacific Biosciences and Oxford Nanopore, etc., which perform a variety of services from amplicon sequencing to whole genome sequencing. The amount of data, accuracy, and reproducibility among the different platforms is influenced by many factors, including the intrinsic features of the platform and the desired analysis types and pipelines (Li et al. 2014; Shin and Park 2016; Mardis 2017). More details on available sequencing platforms, their uses, and attributes are presented in Chap. 20.

Genotyping Platforms Developments in the ability to sequence the genomes of animals and plants, and bioinformatics processing of data, led to the identification of a high number of sequence variations in the genome and knowledge of their association to traits or characters began to emerge. The sequence variations which include single nucleotide polymorphisms (SNP), insertions, deletions, copy number variations, inversions, and translocations have been used to produce genotyping arrays (microarrays) by major technology providers (Illumina, IonTorrent, etc.) and are frequently used to genotype (at a lower cost) and to document the genotype of individual animals in a population. Low-density (a few hundred markers) and high-density (thousands of markers) genotyping arrays are available for genotyping in livestock species (see Chap. 21 for details on the available livestock genotyping assays). Genotyping platforms acquire the necessary genotyping equipment and the genotyping assays in bulk and in turn offer genotyping services at cheaper rates to their clients.

29.4.3 High-Performance Computing/Data Management Centres

The information for making and implementing breeding decisions is extracted from different types of data including genotype, production, phenotype, and environmental variables among others. In particular, genomics and related areas like transcriptomics, proteomics, phenomics, metagenomics, metabolomics, etc., based on NGS and related technologies, are advancing our understanding of livestock health and production and providing the necessary information to advancing livestock health and productivity. To benefit from these technologies and data sources, the required strategies, skills, and resources must be put in place to support generation of genomics data, processing, and storage of that data. Next-generation sequencing of a few livestock genomes can generate terabytes of data requiring substantial high-performance computer resources for data processing and analysis and storage. Thus, information technology and high-performance computing (HPC)/data management capabilities are basic requirements for the effective management of big data. Therefore, it is necessary to put in place cutting-edge digital transformation technologies, infrastructure, and manpower that can cater to the compute challenges and large data presented by the NGS revolution for the advancement of livestock agriculture in Africa.

29.4.3.1 Available HPC/Data Management Infrastructure and Accessibility

High-performance computing is generally regarded as the ability to process big data and perform complex calculations at high speeds. HPC is achieved by using hardware and software to divide tasks into groups of discrete and independent computations allowing them to be processed in parallel and with seamless integration of output/results. A number of possible HPC solutions/areas that can be tailored to meet computational demands such as clusters, graphics processing units (GPUs), cloud computing platforms, and field-programmable gate arrays (FPGAs) (Wiewiórka et al. 2014; Lightbody et al. 2019; Mushtaq et al. 2015) are summarized in Fig. 29.2. These systems range from small numbers to several thousands of interconnected computers (compute nodes), and each approach differs in technology, performance, scalability, cost, and ease of implementation.

Information technology and HPC are capital-intensive requiring concerted efforts and pulling of resources by many institutions to acquire sufficient resources. To fulfill the conditions for effective data transformation and utilization, Stephens et al. (2015) indicated that access to adequate and affordable compute resources and efficient exploitation of that infrastructure through the use of algorithms that can reduce big data bottlenecks associated with genomics data and other data sources is necessary. This consequently led to unparalleled growth in adaptation and development of compute technologies and analytical workflows within the genomics community. Moreover, the need for adequate and easily accessible HPC propelled some institutions and national governments to set up HPC facilities. For example, to meet the computing and data management needs of Canadian researchers, the government of Canada established "compute Canada" (www.computecanada.ca), which delivers world-class and up-to-date advanced research HPC infrastructure/support to Canadian innovators and researchers. Compute Canada is composed of a nationally coordinated network of hardware and software resources, which provide a broad spectrum of advanced computing services in support of research, as well as technical support, training, application, and development. Compute Canada supports diverse disciplines such as aerospace engineering, agriculture, chemistry, computational criminology, medicine, as well as the analysis of works of fiction. The compute Canada network or federation is made up of 38 universities and four regional organizations (WestGrid, Calcu Quebec, Compute Ontario, and Atlantic Computational Excellence Network (ACENET)). Together, they play critical roles in supporting research computing needs in Canada, such as provision of essential advanced research computing infrastructure,

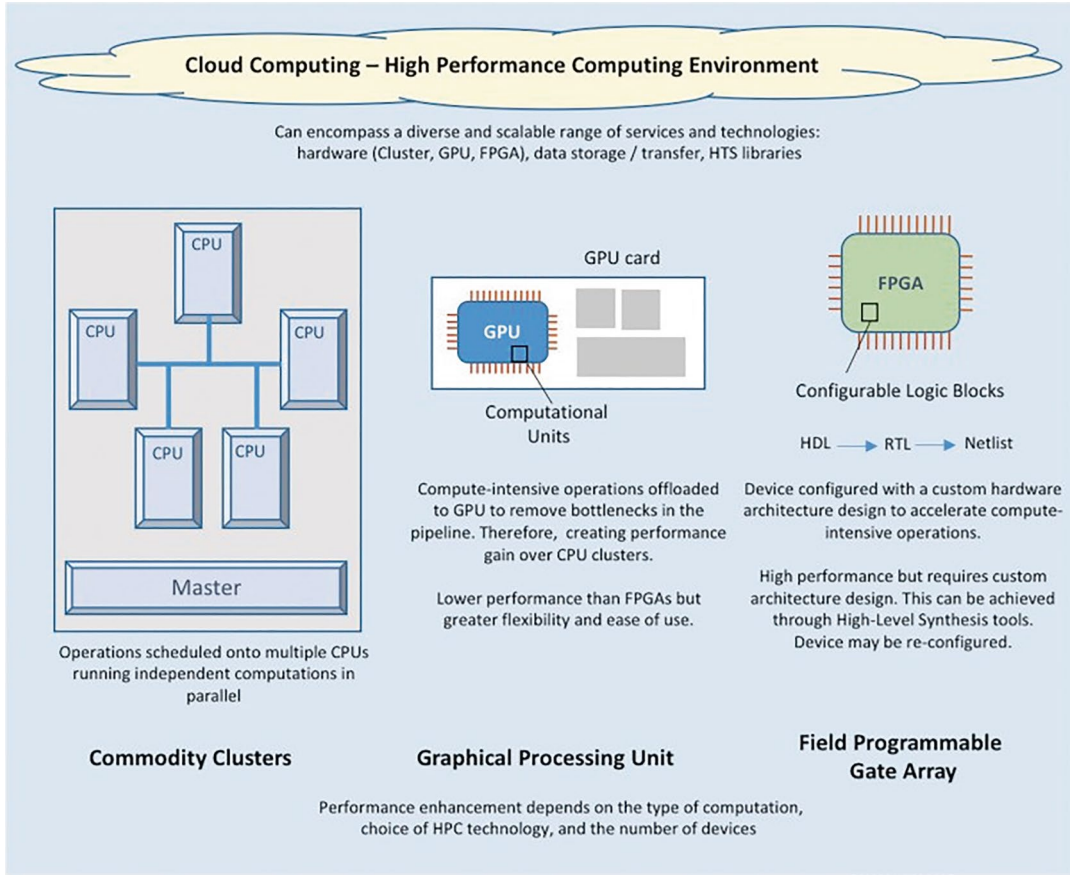

Fig. 29.2 Overview of high-performance computing options showing common clusters (e.g. GPUs, FPGAs, and cloud solutions) and highlighting differences in flexibility, performance, and options for custom design. CPU: Central Processing Units; GPU: Graphics Processing Unit; FPGA: Field Programmable Gate Arrays; HDL: Hardware Description Language; RTL: Register-Transfer Level. (From Lightbody et al. (2019), licensed under a CC BY 4:0)

software and services to supporting research needs across a wide-ranging spectrum of scope/needs, from small individual projects or initiatives or collaborations to large scale big science projects. The highly qualified staff (programmers, analysts, and computational science specialists) of Compute Canada offers a range of computational needs to researchers and users across Canada such as (1) HPC/big data and GPU computing and storage; (2) a variety of specialized softwares; (3) a portal (Globus) to share and transfer data in a fast and secure environment; (4) portals for specialized data and tools according to research disciplines; (5) ownCloud on dedicated managed servers offers data integrity and storage space across multiple devices; (6) platform to access and use genomic datasets (GenAP); (7) cloud environment development space; and (8) data storage and back-up systems with adequate stability and security. Many western countries (Australia, Germany, etc.) have set up national HPC facilities to support life science research among others (Tauch and Al-Dilaimi 2019; Schneider et al. 2019).

The growing need for adequate HPC/data management infrastructure has propelled the adaptation of cloud technologies in genomics and big data science with the need to algorithmically tackle vast amounts of data where volume, velocity, variety, and veracity are important (Langmead

and Nellore 2018; Navarro et al. 2019). While the instrumentation technological needs of genomics are increasing at unprecedented rates, there is dire need of robust technical solutions to meet diverse data and HPC/data management requirements. Thus, there has been sustained efforts in the recent past to address the growing needs of hardware and software requirements for large data (genomics, etc.) management via large-scale efforts like Jetstream (Stewart et al. 2015, 2018), Cyverse (Merchant et al. 2016), Galaxy (Afgan et al. 2018), etc. which have played major roles in enabling and training bioinformaticians and supporting research data management. In addition, there has been a rise in commercial cloud-based services for genomics data management such as Amazon Web Services (AWS) (https://aws.amazon.com/health/genomics), Microsoft Azure (https://azure.microsoft.com/en-gb/services/genomics/), Google Cloud life-sciences (https://cloud.google.com/life-sciences), International Business Machines (IBM) Watson-health genomics solutions (https://www.ibm.com/uk-en/marketplace/watson-for-genomics), Illumina BasSpace Sequence Hub (https://emea.illumina.com/products/by-type/informatics products/basespace-sequence-hub.html), and 10x Genomics Cloud Analysis (https://www.10xgenomics.com/products/cloudanalysis). These providers accord customers or users the opportunity to innovate by making genomics data management more accessible and useful. In the same light, efforts to meet data management needs have seen the development of data analysis pipelines suitable for different data management applications for community use such as nf-core (Ewels et al. 2020) (https://nf-co.re/pipelines). A practical guide to processing and analyzing large-scale genomic data to extract meaningful information was provided recently (Tanjo et al. 2021).

A typical HPC core facility is made up of the computing hardware, skilled data management personnel (e.g. bioinformatician, computational biologist, data scientist, etc.), administrative personnel, specialized service units or centres, and the users (Fig. 29.3). The main functions of a typical HPC core facility are the following: (1) provide HPC services such as hardware design and acquisition; (2) cluster installation and maintenance; (3) HPC software and operating system maintenance; (4) data and system security; (5) HPC user training and onboarding; (6) storage services; (7) user support; (8) data access and transfer; (9) consultation service on HPC code optimization and assessment of HPC needs; (10) cloud-ready research applications; and (11) letters of support for grant proposal development. Bioinformaticians, computational biologist (genomics/genetics), and data scientists are the largest group of users of HPC and also the main drivers of HPC digital transformations. Highly qualified personnel of these categories will determine the success of HPC cores. HPC success in Africa will depend on the availability of skilled bioinformaticians and data scientists. The H3ABioNet, a Pan-African Bioinformatics Network (Aron et al. 2021a), is providing bioinformatics training in Africa with the goal of developing bioinformatics and big-data management capabilities of the continent.

29.4.4 Establish Core Facilities for Smart Solutions, Easy Access, and Shared Opportunities for Africa

As indicated in sections above, genomic technologies, HPC/data management infrastructure, and technologies offered by other core facilities not discussed above are capital-intensive requiring expensive equipment and technologies and highly qualified personnel to operate equipment and technical know-how in the application of the technologies. The implication is that it is futile for individual researchers or institutions to acquire the capital-intensive equipment, technologies, and the know-how to optimally benefit from these technologies. For present Africa to benefit from these advanced technologies, setting up GC, HPC/data management centres, and other core facilities at country or regional levels will leverage fund resources while providing cost-efficient high quality services through shared usage and funding. A schematic representation of a typical GC is shown in Fig. 29.2. Some

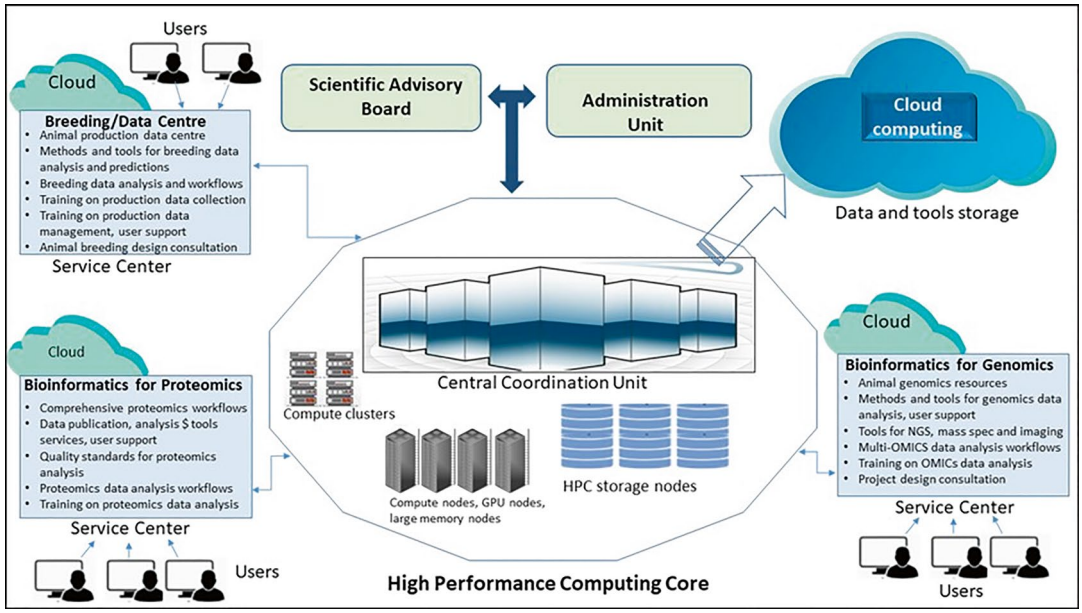

Fig. 29.3 Overview of a high-performance computing core with service centres in other locations

platforms providing genomic solutions in Africa are summarized in Table 29.2.

Therefore, establishment of a network of GC and HPC/data management centres, at least one in each region and similarly for other core facilities (metabolomics, proteomics, etc.), will be beneficial for stimulating and advancing quality research at shared cost across Africa, for the following reasons (Figs. 29.1, 29.2, and 29.3):

1. Exploits fast evolving technologies of modern biology and informatics to the fullest through pooling resources such as the necessary expertise to implement, run, improve, and adjust technologies to the needs of individual researchers, research groups, laboratories, institutions, and countries.
2. Pull resources to acquire and maintain necessary infrastructure and equipment as well as expensive technologies and make such available to all interested persons (researchers, students, laboratories, institutions and industry, etc.).
3. Pull resources to attract highly qualified personnel to operate core facilities and lead relevant technological advancements in their areas of expertise.
4. Fulfil the needs of today's research questions and projects requiring advanced technologies, large funding, and technical knowhow.
5. Fulfil the needs of interdisciplinary research teams by maintaining all the advanced technologies suitable for the needs of each project, which otherwise would be near impossible for individual laboratories, institutions, and individual countries to support.
6. Bring together an excellence alliance of highly qualified persons (core laboratories, universities, research institutions and industry, etc.) working together to solve common problems.
7. Harness and share expertise, resources, and technologies across laboratories, institutions, countries, and continents to speed up scientific discoveries and advance knowledge for the benefit of all.
8. Establish best practices, common guidelines and standards, and best operating procedures for sound science, and sharing of such with participating core facilities and users.
9. Enable optimum use of expensive technologies and equipment through shared usage.

Table 29.2 Some centres that provide genomic and high-performance computing services in Africa

Genome centre	Country	Services	Goal	Website
National Centre for Biotechnology Research (CRBt)	Algeria	Services are performed by a network of 17 laboratories: Animal biotechnology laboratory, Bacteriology and virology laboratory, Biochemistry laboratory, Bioremediation and ecotoxicology laboratory, Cell culture laboratory, Electrophoresis laboratory, Environmental analyses laboratory, Food testing and analysis laboratory, Genomics platform, GMO detection laboratory, Microscopy and genetic diagnosis platform, Molecular biology laboratory, Quality analysis laboratory, Molecular and macromolecular synthesis and characterization laboratory, Mycology laboratory, Plant in vitro culture laboratory, Immunology laboratory, Proteomics platform, and Bioinformatics unit	Coordinate research networks and support research activities in applied biotechnology in agriculture, aquaculture, animal health, human health, food, and the environment	https://www.crbt.dz/
Centre for Proteomic and Genomic Research (CPGR)	South Africa	Genomics Proteomics Transcriptomics Metabolomics	All-encompassing ecosystem that nurtures and drives Omics research and life science innovation in Africa to create a community of empowered scientists	https://www.cpgr.org.za/training/
South African Medical Research Council Genomics Centre	South Africa	Genomics Proteomics Transcriptomics Metagenomics	Capacity development in not only genomic sequencing but data science	https://www.samrc.ac.za/innovation/genomics-centre
Indalo Bio	South Africa	Genetic testing services Screening services	To bring advanced genetic services accessible to everyone on the African continent. With collaborations in the tertiary educational and research institutions, they aim to contribute greatly towards future genomic discoveries across sub-Saharan Africa.	https://www.indalobio.com/

Genome centre	Country	Services	Goal	Website
The African Centre for Gene Technologies (ACGT)	South Africa	Genomics and its subsets. Functional genomics (gene function and regulation). Structural genomics (structural analysis of gene and protein families). Proteomics (evaluation of all-expressed proteins). Transcriptomics (genes expressed through mRNA). Bioinformatics. Computational biology.	To create a collaborative network of excellence in advanced biotechnology, with specific focus on the "-omics" The ACGT addresses research priorities that focus on Africa's needs in health and agriculture and will derive value from Africa's genetic diversity.	https://acgt.co.za/about-us/
Ingaba biotech, Africa's genomic company	South Africa, Tanzania, Kenya, Nigeria, Senegal, and Ghana	MassARRAY genotyping Oligo synthesis Sanger sequencing Next-generation sequencing Bioinformatics Animal genetics qPCR analysis Fragment analysis Instrument services Workshops	To contribute to further develop science and technology in sub-Saharan Africa.	https://inqababiotec.co.za/
Biotechnology platform—Agricultural Research Council (ARC-BTP)	South Africa	Next-generation sequencing SNP genotyping High-throughput nucleic acid extraction Bioinformatics Proteomics Genomics Liquid handling robotics systems and services Laser capture micro-dissection microscope services	To create the high-throughput resources and technologies required for applications in genomics, quantitative genetics, marker-assisted breeding, and bioinformatics within the agricultural sector. The focus of the ARC-BTP is to establish itself as both a research and service-driven institution, providing an environment in which highly skilled researchers can be hosted and trained	http://www.arc.agric.za/pages/btp.aspx

Table 29.2 (continued)

Genome centre	Country	Services	Goal	Website
African Biscienses Ltd (ABL)	Nigeria	DNA testing Agriculture and food DNA testing Next-generation DNA sequencing Sanger DNA sequencing Lab setup and management Molecular diagnostics PCR primers	ABL provides life science research services, such as reagents supply, technical training, research consultancy, molecular diagnostic/ DNA testing, lab-for-rent, and contract research services to African scientists and students.	https://www.africanbio.com/
The Council for Scientific and Industrial Research (CSIR) centre for high-performance computing (CHPC)	South Africa	Introduction to Linux, scripting, and Python for scientists Parallel programming Users' induction course	The CHPC seeks to advance scientific boundaries and foster innovation through effective partnership and through the training of a new generation of computationally skilled researchers in areas underpinned by high-end computing, particularly those of national and continental strategic importance, to the benefit of basic and applied research in the public and private sectors	https://www.chpc.ac.za/
Laboratory of Applied Biotechnology in Agriculture	Tunisia	Use molecular tools to promote biological control of pests and disease. Use in vitro and molecular markers to the tolerance of cereals to abiotic stress	Develop biotechnological processes to promote biological control of pests and diseases. Develop marker-assisted selection procedures to breed abiotic stress-resistant cereal crops, among others.	http://www.inrat.agrinet.tn/index.php/en/research/laboratory-applied-biotechnology-in-agriculture.html

10. Ability to acquire large volumes of materials at cost-effective basis and to provide services at a cost-effective rate to users.
11. Accord affordability of advanced technologies to individual researchers and students.
12. Enable joint scouting, validation, and application of emerging technologies.
13. Enable establishment of a training network of personnel across core facilities.
14. Enable shared usage of equipment, capacity as well as technology investments across core facilities and countries.
15. Lower cost of establishing and maintaining core facilities through joint funding by participating countries or bodies.

29.4.4.1 Case Study 1: Biosciences Eastern and Central Africa-International Livestock Research Institute (BECA-ILRI) Hub

The BECA-ILRI Hub (https://hub.africabiosciences.org/), established as part of the AU/NEPAD (AfricanUnion/New Partnership for Africa's Development) and ABI (African Biosciences Initiative), is a shared biosciences and agricultural research platform. Headquartered in ILRI, Nairobi, Kenya, the BECA-ILRI platform provides access to state-of-the-art laboratories to African and international scientists conducting research on all aspects of African agricultural challenges. The main goal of BECA-ILRI hub is to mobilize bioscience research for Africa's development through supporting research, capacity building, and product development by African scientists and by empowering institutions in the Central/Eastern African region to leverage the power of advanced and emerging innovations for improved agricultural productivity, food/nutritional security, and incomes. In support of its goal of training, the BECA-ILRI hub offers regular training activities and workshops to researchers and students, such as training/workshops on Breeding Management System, Introduction to Molecular Biology and Bioinformatics, Animal Quantitative Genetics and Genomics Training, Basic Molecular Biology and Genomics Training, Introduction Workshop and Advanced Genomics and Bioinformatics, etc. BECA operates regional nodes in universities in Cameroon (University of Buea), Ethiopia (Ethiopian Institute of Agricultural Research), Uganda (National Agricultural Research Organization), and Kenya (University of Nairobi and Jomo Kenyatta University of Agriculture and Technology). The BECA-ILRI hub is funded by financial contributions from the Canadian Government through the Canadian International Development Agency (CIDA), AU-NEPAD, ILRI, various governments, foundations, and through various partnerships such as the Bill and Melinda Gates Foundation, Syngenta Foundation for Sustainable Agriculture, Swedish Funded Partnership on Food Security and Climate Change Adaptation, the UK Government through the Department for International Development (DFID), the United States Defense Threat Reduction Agency, the United Kingdom's Biotechnology and Biological Sciences Research Council, and the Alliance For Accelerated Crop Improvement in Africa and the European Commission—Horizon 2020.

29.4.4.2 Case Study 2: Sustainable Bioinformatics Network for Africa (H3ABioNet)

The Human Heredity and Health in Africa (H3Africa) consortium created a Pan African Bioinformatics Network (H3ABioNet) comprising 28 Nodes which are distributed among 17 countries, in which 16 are African countries (The-H3Africa-Consortium 2014). The consortium was established as an initiative to support genomics research through building bioinformatics capacity in Africa. It was developed through funding from the United States' National Institutes of Health Common Fund and the Welcome trust. The specific aims for H3ABioNet include (1) implementation of a Pan African informatics infrastructure; (2) development of an H3Africa data coordinating Centre; (3) make available high-quality informatics support to H3Africa; (4) enable enhanced innovative translational research; and (5) address outreach, development, and sustainability.

This consortium was established to build capacity in bioinformatics skills in Africa. The

need was borne out of the lack of expertise in bioinformatics skills in African research institutions resulting in poor bioinformatics research capacity in Africa. Thus, the H3ABioNet provides training and opportunities that ensure the content and quality of bioinformatics capacity of African researchers. Some of the notable challenges affecting the process of delivering bioinformatics training in Africa are due to inadequate infrastructure, unstable internet connectivity, limited access to training facilities, and lack of human expertise. The H3ABioNet overcomes these challenges by making use of multi-faceted approaches through distance, face-to-face courses at various levels, webinars, hackathons, internships to mixed-model online training (Aron et al. 2021b). The learning process includes theoretical and practical sessions to allow participants to gain experience in using various tools and resources applied in bioinformatics. For example, internship programmes are offered to facilitate one-on-one interaction with experts in bioinformatics. During internship training, interns are encouraged to: (1) work on their own data; (2) improve skills and professional development; (3) perform specific research activities; (4) attend courses at the host institution; (5) gain exposure to human genetics and/or bioinformatics/high-performance computing environments; (6) gain experience in grants/project development; (7) develop educational materials, and (8) establish/further existing collaborations.

29.4.4.3 Case Study 3: Open Institute of the African BioGenome Project

A recent initiative named The African BioGenome Project (AfricaBP, https://africanbiogenome.org/) which is a coordinated pan-African effort to build capacity (and infrastructure) and to generate, analyse, and deploy genomics data for the improvement and sustainable use of biodiversity and agriculture across Africa seeks to sequence the genomes of 105,000 endemic animals, plants, fungi, protists, and other eukaryotes species on the African continent with the goal to make available genome information to facilitate the development of resilient animal and plant species for sustainability of African food systems (Ebenezer et al. 2022). The project is a continent-wide initiative which involves about 200 African scientists with expertise in genomics, molecular biology, bioinformatics, mathematics, etc. and over 50 institutions in Africa and out of Africa. This initiative births the creation of an Open Institute to facilitate the genomics and bioinformatics knowledge exchange programs for the AfricaBP (Sharaf et al. 2023). To achieve this aim, the AfricaBP has developed the 2030 Strategic Plan that builds on the position paper published in Nature in 2022 titled—Africa: Sequence 100,000 species to safeguard biodiversity (Ebenezer et al. 2022). The strategic plan is underpinned by AfricaBP's unique value proposition and strategic position as an enabler of genomics practices, integrator of discovery science, applications to deliver crop, fungi, animal, and livestock genetic innovations across Africa. With this strategic plan, AfricaBP aims to mobilize its key partners (i.e. Technology Innovation Agency (TIA), University of South Africa (UNISA), Agricultural Research Council (ARC), Centre for Proteomic and Genomic Research (CPGR), South African Medical Research Council (SAMRC), University of Cape Town (UCT), University of Port Harcourt (UniPort), and Mohammed V University). Under this case for support, AfricaBP and UNISA will focus on research, capacity building, and knowledge exchange to leverage strategic partnerships to contribute to more resilient, productive, efficient, and environmentally sustainable tropical livestock production systems, while Science for Africa (SFA) Foundation will focus on coordination and resource mobilization.

29.4.5 Funding of Core Facilities in Africa

Core facilities play a central role in facilitating research and the speed of discovery. Funding of research is capital-intensive and genomic, bioinformatics, and HPC services and supplies are even more expensive. Therefore, establishment of GC, HPC/data management centres, and other

core facilities is for the public good and the initial start-up capital should come from public funds. Thereafter, core facilities can run on a cost-recovery basis whereby the cost of maintaining the facilities can be factored into the cost of the services provided. Core facilities can also be funded through grants (international development partners), endowment funds, and donations.

29.5 Germplasm Centres

Germplasms are genetic materials of germ cells, such as seeds, pollen, rootstock, semen, or tissues that are conserved for animal and plant breeding for the purpose of preservation and other research purposes. These resource materials could take the form of seed collections stored in seed banks, trees growing in nurseries, animal lines maintained in breeding programs, and genebanks. Therefore, the germplasm centres (i.e. genebanks) are where these genetic materials are stored under specified regulations for utilization in breeding and research.

Germplasm centres were set up in 2012 via FAO guidelines to ensure the cryo-conservation of Animal Genetic Resources (AnGR). The main aim is to cover fundamental issues involved in development and operation of genebanks as part of national strategies for the management of animal genetic resources for food and agriculture. The essence of germplasm centres is to ensure the goal of conservation and preservation and generally emphasize the goal of conservation to reconstitute a population that has gone extinct in vivo.

The establishment of germplasm centres is essential for Africa's food security and strategic contributions to livelihood and income of its growing population. The FAO's Global Plan of Action (GPA) for AnGR has recognized the relevance of gene banking in the conservation of AnGR. Therefore, governments and the international community have agreed on concerted and collaborative measures to ensure implementation and sustainability of genebanks at both regional and continental levels.

29.5.1 Opportunities for Setting Up Regional Biological Banks

Several initiatives have been taken up to ensure the conservation of both foreign and indigenous breeds currently in Africa. For instance, Taurus Jersey and Jersey South Africa (Nyamushamba et al. 2017) (www.jerseysa.co.za) ensures the dissemination of Jersey germplasm to countries within and outside the Southern Africa regions. The Nguni programme of South Africa was established to preserve the Nguni breed in the Eastern Province (Bester et al. 2003; Gwala 2013). This was in response to uncontrolled mating procedures reported among communal and small-scale commercial areas which threaten the existence of the indigenous breed (Obert 2012). The Inter African Bureau for Animal Resources with funding from the European Union has set up five regional animal genebanks across Africa (Fig. 29.4). However, the animal genebanks are yet to be operational due to non-availability of legal framework regulating genetic material transfer, conservation, and uses across the participating countries.

The feasibility of multi-country collaborations to support the conservation of genetic resources in Africa has been reported (Morandini et al. 1977; Rischkowsky and Pilling 2007). However, the strengthening of such collaboration through data sharing, germplasms, and capacity building is plausible and rather challenging. Most countries in Africa lack national genebanks majorly due to intricacy in governance and complexity in national policies that inhibit the establishment and sustainable operations of national genebanks. Therefore, in an attempt to mitigate these complexities in African countries, the African Union Inter-African Bureau of Animal Resources (African Union Secretariat 2020) has been able to establish five sub-regional genebanks in strategic locations in countries throughout the continent funded by an European Union project. These locations have regional representations which include Eastern Africa (National Animal Genetic Resource Centre and Data Bank (NAGRIC & DB) Entebbe, Uganda), Southern Africa (Department of Agricultural Research (DAR),

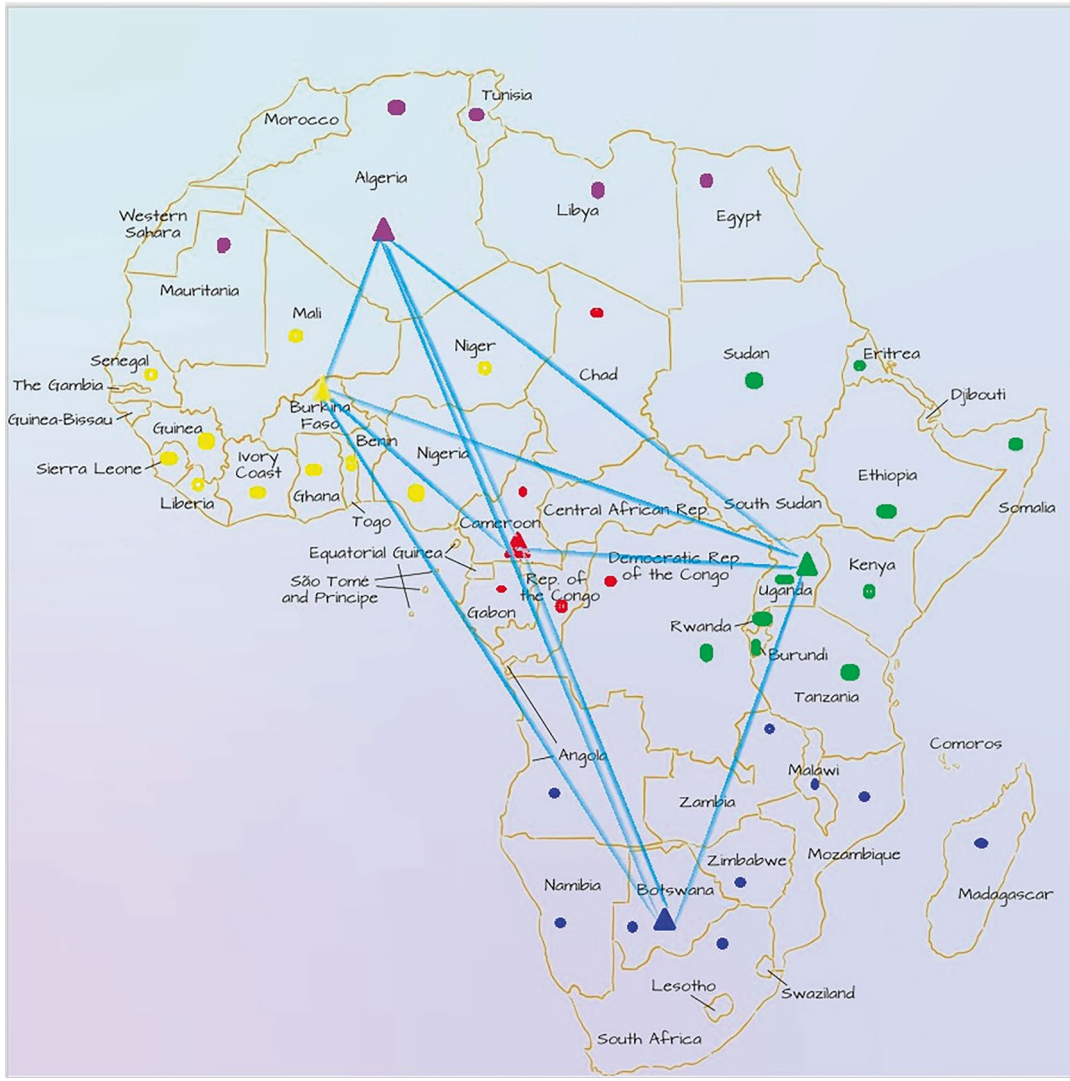

Fig. 29.4 Mapping the five African Regional Animal Genebanks. African regional Genebanks (large triangles-pink, yellow, red, blue, and green colours) showing interconnections between them (blue lines) and countries served by each Genebank (small circles in the colours of their respective regional Genebanks)

Gaborone in Botswana), Western Africa (CIRDES (International Centre for Research and Development on Livestock in Sub-Humid Areas) in Bobo-Dioulasso, Burkina Faso), and Central Africa (Centre Régional de Recherche Agricole de Bambui-Mankon, Bambui, Cameroun). For Northern Africa, Algeria was previously selected as the potential animal germplasm centre. However, recent communication has shown that the current germplasm centre for Northern Africa is Tunisia (Banque de gènes Tunisienne). In addition, the African Union Pan African Veterinary Vaccine Centre (AU-PANVAC) is mandated to support the regional genebanks in Africa through holding regional germplasm samples and the preservation of germplasm copies available in each regional genebank to prevent accidental losses. Figure 29.4 shows the five (5) African regional genebanks with countries linked to each of the genebanks.

29.5.2 Available Infrastructure and Accessibility

The introduction of foreign germplasm has played a key role in improving desirable traits of interest for most livestock breeds. These efforts have been made through the introduction of assisted reproductive technologies (ART) to prevent undefined use of other reproductive methods such as natural mating. The ART mainly practiced in Africa include artificial insemination and embryo transfer techniques using foreign germplasm. Therefore, various breeding policies, breeder's organizations, breeding companies, and germplasm centres have been set up in some countries to monitor utilization of germplasms and ensure efficient performance recording and genetic and genomic evaluations in Africa. These include Kenya Stud Book and Kenya Livestock Breeders Association of Kenya, The BreedPlan of South Africa (Marle-Koster and Webb 2014), Limousin Cattle Breeders Society of South Africa, etc. Approaches to strengthen capacity in animal breeding in Africa have been developed. These include, for example, the Africa Bioscience Challenge Fund Programme developed by the Bioscience Eastern and Central Africa (BecA-ILRI Hub) and The African Animal Breeding Network (AABNet) (http://animalbreeding--africa.org/) (Djikeng et al. 2024). The BecA-ILRI Hub, through the ABCF programme, has trained for years students and research professionals in various aspects of animal breeding including genomics, bioinformatics, and quantitative genetics. AABNet has been recently established and hosted by the Egerton University in Kenya. Establishing robust systems for livestock genetic evaluation across multiple countries in Africa is the flagship pillar and a long-term and strategic objective of AABNet. Through the AABNet platform, animal breeders and livestock development professionals will access methodologies, tools, and technical support for multi-countries' collaboration in livestock genetic evaluation in Africa. The AABNet, through its inaugural training being organized, will support educators and students in Africa by strengthening their skills in animal quantitative genetics and genomics.

29.5.3 Dissemination of Superior Germplasm

After identification and selection of superior animal germplasms, the next step is the multiplication and dissemination of the improved strains within the country and from one country to another. The transfer of genetically improved strains will require a material transfer agreement as well as the access and benefits sharing protocol between organizations and countries involved.

29.5.4 Funding of Germplasm Centres

The value of traditional local livestock breeds to rural families in African communities needs to be acknowledged, monitored, and assisted for increasing productivity. Despite the availability of crossbred livestock in Africa, the need to conserve and maintain the indigenous local livestock breeds and their genetic resources in Africa cannot be overemphasized. The reliance on foreign commercially improved germplasm hinders efforts to develop independent breeds that could compete at international levels and threatens the long-term sustainability of local smallholder production systems and the potential to adapt to global climatic changes. Therefore, multiple well-funded and specific goal-oriented programmes are needed to characterize and preserve traditional breeds at national and regional levels.

29.6 Multi-Country Genetic Evaluations

Unlike non-ruminants, breeding activities in ruminant livestock such as dairy, beef cattle, sheep, and goats involve many individual farmers and several breeding companies. In addition, developments in reproductive technologies such as artificial insemination and semen and embryo freezing have led to widespread usage of breeds in several countries (see Chap. 20). Moreover, transboundary breeds such as the Boran imply these animals are reared in several countries.

The widespread usage of breed across countries has necessitated the developments of methods for fair comparisons of breeds across several countries. In developed countries and particularly in dairy cattle breeding, considerable research has resulted in the development of procedures for across-country genetic evaluations of bulls under the guidance of INTERBULL as mentioned in Sect. 29.3.

The current methodology used for multi-trait across-country evaluation (MACE) by INTERBULL for dairy cattle is a multi-trait Best Linear Unbiased Prediction (BLUP) procedure (Schaeffer 1994). MACE regards records on the same trait from different countries as different traits. This implies that good genetic links are required among the participating countries to estimate genetic correlations among the countries for the trait being evaluated. Usually these genetic correlations tend to be high with values varying from 0.8 to 0.95 for production traits such as milk yield but lower for reproductive and fertility traits (Simm et al. 2021). The use of different values of genetic correlations in MACE between traits in different countries results in different rankings of evaluated sires among countries. This multi-trait approach allows MACE to account for differences among countries in terms of the heritability of the trait and differences in scale used to express or measure the traits in the different countries. It also accounts for genotype-by-environment interaction, for example, milk yield in different production environments such as intensive versus grazing management systems. This highlights one of the advantages of MACE as it produces separate estimates of genetic merit for sires for each country involved in the evaluation which are expressed on the local scale and are therefore ready to be used. Second, the use of daughter information across several countries implies that MACE produces more accurate genetic evaluations for bulls which can be used across countries.

Although much of the research on across-country genetic evaluations have been developed in the evaluation of dairy sires, a similar service was recently introduced for beef cattle and it is referred to as INTERBEEF (Phocas et al. 2006; Bonifazi et al. 2020a, b). It is based on the same methodology as MACE but uses actual phenotypic records from the several countries.

In summary, some of the important factors for the implementation of across-country evaluation include (i) routine data collection systems, (ii) existence of within-country national evaluation systems validated to be efficient and accurate, and (iii) existence of genetic links among the countries through exchange of genetic materials (semen, embryos, etc.) or use of related animals.

29.6.1 Prospects for Across-Country Genetic Evaluations

The multi-country approach to genetic evaluation provides a good opportunity for transboundary breeds such as the Ankole or Boran beef breeds in Africa to be evaluated. However, in the dairy cattle situation, a lot of cross-breeding of indigenous breeds with important European dairy breeds such as the Holsteins, Friesians, Ayrshires, Jerseys, and Guernsey have taken place in many African countries. It is possible that the same bulls or related bulls have been utilized in these cross-breeding efforts in many African countries and this therefore provides an opportunity to investigate and implement across-country evaluations for dairy production traits. The critical question to address is whether there is adequate data and genetic links to enable an across-country evaluation in the Africa setting. If adequate and sufficient links exist, procedure such as MACE or an approach similar to that in INTERBEEF can be implemented.

However, when genetic links are inadequate for the estimation of the genetic correlations among countries, a simplified across-country evaluation that assumes a genetic correlation of unity can be implemented at the initial step. The disadvantage of this approach is that only a single ranking of bulls is produced for all countries involved in the system and it is unable to account for genotype by environment interaction. However, such pool of data across countries will result in more accurate genetic merits for animals which are related across several countries. Opoola et al. (2020) utilized the across-country approach assuming a genetic correlation of unity

to examine several production and reproductive traits in the Holstein and Jerseys cattle breeds in South Africa, Kenya, and Zimbabwe. Results showed that the genetic variance and heritability were not always estimable within-country, but were significantly different from zero in the across-country evaluation. In all three countries, there was greater genetic gains accrued in all traits from an across-country genetic evaluation due to greater accuracy of selection compared to within-country. Collated data showed that Kenya stood to benefit most followed by Zimbabwe then South Africa from an across-country evaluation. If genetic links exist across countries, an across-country breeding programme using joint genetic evaluation is feasible and would provide a platform for accelerated genetic progress through selection and germplasm exchange between sub-Sahara African countries.

29.6.2 Genetic Evaluations Funding

Across-country evaluations are usually funded by the participating countries. For instance, in the case of MACE for dairy cattle run by INTERBULL, participating countries are charged a fee based on the number of registered cows by ICAR. In Africa, where well-established systems are lacking, initial funding could be based on the size of the data submitted for the joint evaluations by each country. In addition, the availability of data in the centre undertaking the joint evaluations implies that the centre can support research activities for post-graduate studies in several universities under well-defined protocols that do not comprise data confidentiality and security.

29.7 Perspectives and Practical Application of Across-Country Genetic Evaluation in the African Context

Practical application of across-country genetic evaluation in Africa will depend on the fairness cooperation between countries involved. This will require governments to play a role in providing adequate tools for African scientists/researchers to generate, store, analyse, and interpret genomic data by African researchers for the benefit of the African continent. Mulder et al. (2017) also emphasized that the most critical point in establishing cross-country cooperation in the African context is to create an environment of fairness and equity in data sharing. This is an important and critical factor that needs to be well negotiated between countries involved. In this context, it is of pivotal importance that adequate survey literature is available to help make informed decisions.

29.7.1 Surveys and Literature

There are few available literatures on the implantation of genomics programme for across-country genetic evaluation from the African context. This might be explained by the element that the genomics technology is still relatively new and not well implemented across Africa. There is no doubt that implementation of across-country genetic evaluation will see greater results in advancing livestock production, especially in diverse African indigenous breeds. However, such approach will require adequate planning and efforts from different bodies and disciplines. van Marle-Kőster et al. (2015) emphasized that livestock scientists and their co-workers from developing countries such as Southern African Development Community (SADC) will need to integrate genomics, quantitative breeding, nutrition, physiology, and management with a careful consideration of the production system and the socioeconomic environment to ensure food security. They (van Marle-Kőster et al. 2015) further suggested that the use of genomic tools will be of importance for traits associated with adaptation and disease resistance and unique product traits. This will be realized with establishment of effective cross-country genetic evaluation initiatives to increase accuracy and statistical power. The immediacy of initiating this cooperation will be driven by the need to initiate genomic programs in developing countries. Africa is largely represented by smallholder farming which can be

challenging to implement genomic evaluation programmes. Muchadeyi and team (Muchadeyi et al. 2020) also highlighted difficulties associated with setting up transcriptome experiments in largely uncontrolled smallholder farming systems of developing countries. There is still a need for surveys and literature on this subject from the African context. This will be useful in making informed decisions and sourcing of funds to support the setting up of cross-country genetic evaluation programmes/initiatives.

29.7.2 Case Studies

To date, there are few case studies on across-country genetic evaluations from the African context. There has been an interest for across-country studies using genomics across different fields which can provide an important baseline to establish across-country genetic evaluation programmes. A study by Olivieri et al. (2021) investigated the complexity of ticks' microbial communities from livestock, wildlife, and pets across three countries (Egypt, Kenya, and Ethiopia). In this study, they employed metagenomics, genomics, and ecology to demonstrate the dynamics, with possible important consequences on human and animal health, economy, and on the preservation of endangered species for an in-depth analysis of the interactions among the tick-borne microorganisms. Conversely, in a classic study on multi-country genetic evaluation, Cardoso et al. (2021) pooled tick resistance phenotype reference populations from three countries (Brazil, South Africa, and Australia) from three continents. The team then jointly analysed existing tick infestation datasets to assess the possibility of improving host resistance in cattle through multi-population, multi-trait genomic selection (Cardoso et al. 2021). They indicated that a joint genomic evaluation of Angus, Hereford, Brangus, Braford, and Brahman using multivariate genomic best linear unbiased prediction (BLUP) can be readily implemented to improve tick resistance. These studies have proven and provided baseline on the potential benefits and scientific power that can be realized with implementation of across-country programmes such as multi-country genetic evaluation programmes.

29.7.3 Information Dissemination Across Countries

Information dissemination is one of the critical aspects that should be handled with care and professionalism. In addition to Sect. 29.3.1 above, this will require establishment of MTA to ensure fairness and confidentiality in the use of the shared materials between associated countries. This can be realized with involvement and commitments from governments and associated institutions.

29.7.3.1 Facilitate Access to Training and Research Facilities

The experience in recent decades in Africa is that the development of the sciences of animal breeding and genetics, and in particular genomic breeding and genetic evaluation programmes, is limited due to the shortage of professionally trained capacity. Although a number of cooperative graduate training programmes in animal genetics and breeding have been established globally, Africa still has limited expertise in genetic evaluations and in statistical/bioinformatics management of large data. Moreover, there are a limited number of established genomic centers necessary to generate the needed genomic data, and these pose challenges in initiating training facilities across the continent. These essential skills are required to achieve the ability to develop proper genetic evaluation programmes, theoretical and statistical frameworks for the analysis of large datasets suitable for cross-countries analysis, and these can only be achieved through multiple strategic partnerships with major breeding companies, research institutions, government ministries, and other industry partners. Building international professional networks among research and development staff, who have been working at a small scale in different African countries, is of vital importance. However, in some countries, the major barriers are stringent

livestock breeding policies and practices, which are set by following government policies. These problems have declined in some countries as governments have reduced their activities and control of the livestock breeding practice. Currently, the implementation of livestock improvement programmes depends on the availability of appropriately trained technical staff. This applies in the areas of animal management, data management, and in the management of the infrastructure required for a modern breeding scheme.

29.7.3.2 Available Infrastructure for Knowledge Dissemination/Training and Accessibility

Currently, there are few research institutions that provide training in genetic evaluation and genomics services in Africa. However, the sharing of resources between African countries has the potential to unlock the challenges of training facilities. Recently, the Africa Biosciences Challenge Fund Bioinformatics Community of Practice (BixCoP) launched an 8-month residential training course which gave 14 early-career scientists from eight African countries the chance to gain and apply critical skills in bioinformatics data analysis, including programming (Linux and shell scripting/Python/R), NGS analyses, quantitative genetics, and phylogenetics. This training programme aimed at equipping African scientists with the skills to deploy third-generation genomics, particularly for Agri biosciences. This is one of the cross-countries initiatives that can be utilized to build training capacity in Africa. In the same context, in recent years, Africa has seen development of few genomics companies (Table 29.2) established, mostly based in South Africa. Companies such as Inqaba biotech - Africa's genomic company, Biotechnology platform, Agricultural Research Council (ARC-BTP), The African Centre for Gene Technologies (ACGT), Centre for Proteomic and Genomic Research (CPGR) and South African Medical Research Council Genomics Centre, as well as African Biosciences in Nigeria. These companies provide a wide range of genomic services to many countries in Africa (Table 29.2). Most of these companies have played an integral part in advancing genetic services and collaborations with tertiary educational and research institutes.

29.7.3.3 Formal and Informal Qualifications

As discussed above (Sect. 29.7), the limitation of expertise in key research areas such as genetic evaluation, bioinformatics, and adequate genomic facilities has been a major challenge in Africa. There have been initiatives by universities such as University of Cape Town and Stellenbosch University, etc. to provide short courses in bioinformatics in an effort to build capacity. This proved to be effective only in providing basic skills to researchers and academics. There is a greater need to establish and enhance this effort at a larger scale to build effective capacity. Conversely, on the same effort, there are companies that offer informal and formal training such as Centre for Proteomic and Genomic Research (CPGR) (www.cpgr.org.za/) outside universities that provide training and qualifications in OMICs technologies in South Africa. Despite these efforts, Africa has seen a slow growth in experts with notable bioinformatics and genomic skills and establishment of genomic centres. The slow and lack of interest into these fields may be driven by inadequate infrastructure and low support structure. Today, we have very few institutions dedicated to genomics and bioinformatics in Africa. This, in part, may explain the lack of experts in genomics and bioinformatics to enforce cross-country genomic consortium such as across-country genetic evaluations. For one to develop genetic evaluation skills, it is recommended to have a fair background on mathematics or statistics.

29.7.4 Perspectives, Practical Application, and Opportunities for Regional/Continental Training Centres

Advances in computational speed and analytical processes have resulted in remarkable progress in livestock breeding. This progress has made it possible to envisage the idea of cross-country

collaboration to pull together pedigree and performance data for the purpose of cross-country genetic evaluations to achieve a better production rate. These efforts have proven to be generating better results in developed countries. To see this effort to fruition in our continent, Africa needs to establish a more vigorous initiative in terms of knowledge sharing and training capacity between researchers and academics across the continent. This can only be realized with efforts and commitments from governments, private institutions, and educational and research institutions. Institutions such as Agricultural Research Council in South Africa and Research institution of Zimbabwe had such agreement previously, which saw exchange of scientists to share research skills in genetic evaluation. Such agreements are necessary to build capacity and enforce collaboration. These efforts need to be escalated to a larger scale for it to be effective. Other funding institutions/bodies such as Erasmus and National Research Foundation of South Africa have funding programmes to motivate such initiatives and to encourage sharing of research skills and establishment of collaborations.

29.7.4.1 Case Study 1: Capacity Building and Appropriate Skilling

A key factor in establishing and enhancing capacity within African researchers is to identify required skills and build capacity (see Chaps. 27 and 28). An example is the capacity building programme in genomics recently initiated by the BECA-ILRI Hub. The training follows three phases, the first two phases being residential in ILRI (Nairobi, Kenya), and a third phase being conducted remotely at the participants' home institutions. Below is a summary of the activities envisioned as part of this programme:

Development phase: for 4 months, participants will be exposed to in-depth training modules on molecular biology and bioinformatics skills for next-generation sequencing (high molecular weight DNA extraction protocols, Unix command line, Python programming, genomics, theory, and practice of genome assembly, etc.). These training modules are comprised of formal lectures and hands-on sessions. Besides the series of lectures being delivered by internationally recognized scientists, a team of tutors (including trainees from previous BixCoP batches) provide ad-hoc supervision to trainees during individual and group exercises.

Demonstration phase: Intertwined with the Development phase and extending for 1.5 months and beyond, this phase engages trainees in project-based learning, building on the skills learnt during the Development phase, and demonstrates their use in real-life research projects in genomics for agriculture or conservation, co-designed with the training team.

Deployment phase: during this last phase of the training, the trainees return to their home institutions, where they launch a small third-generation genomics unit and implement a research project to address agricultural challenges with direct relevance to their home country or region. Wherever possible, this project will be integrated into research partnerships with ILRI or another CGIAR institute (www.cgiar.org) in their home country. Trainees benefit from the support of highly experienced mentors from the BecA-ILRI Hub, its UK-based partners, and the CGIAR consortium. For Africa to achieve success in building capacity and skills, initiatives like these are needed to effectively build capacity at larger scale.

29.7.4.2 Case Study 2: The African Animal Breeding Network (AABNet)

The African Animal Breeding Network (AABNet, http://animalbreeding-africa.org/) was formed in 2019 by bringing together some of the world's leading animal breeders and related scientific disciplines in academia and industry (Djikeng et al. 2025). The primary goal is to drive the development and dissemination of livestock-improved genetics and broader genetic improvement solutions in Africa. It comprises of different pillars, multi-country genetic evaluation which will drive the establishment of robust systems for genetic evaluation of livestock across African

countries. This will serve as a long-term and strategic objective of AABNet. It will also serve as a hub to access methodologies, tools, and technical support by animal breeders to determine how different genotypes interact with environmental factors. It will ensure a comprehensive portfolio of activities and available data by adequately collected and well annotated and synthesized data on countries with ongoing and robust national evaluations. Available national data to demonstrate the value of multi-country evaluation and to build relevant systems that will support genetic evaluation focusing on key livestock productivity and resilience challenge. The second pillar is professional development which will focus on capacity building in animal breeding and associated expertise and developing new and promising talents and innovations, specifically in quantitative genetics, animal breeding, bioinformatics, genomics, data science, animal performance recording/phenotyping, reproductive technologies, and animal biotechnology. The third pillar comprises advocacy, awareness, and business development which will focus on building and making available relevant expertise to support the development of business cases for livestock improvement and credible data as well as communication that will enable governments, development partners, farmers, and other stakeholders to demonstrate compelling need for investments and other support to ensure profitable, productive, and resilient production systems in Africa that serve livestock producers. The fourth pillar of AABNet comprises collaboration, networking, and partnerships which will see operational engagements between academia, industry, farmers organizations, public sector, philanthropic, and development agencies that will be a driving factor for development and dissemination of livestock-improved genetics in Africa.

29.7.5 Funding and Collaborations for Genetic Evaluations

For across-country genetic evaluations and collaboration to be effective, these efforts will need financial support to establish proper infrastructure and maintaining logistics. Funding can be sourced from involved government and private sectors. In addition to what has been discussed in Sect. 29.6, there are few funding opportunities within countries that can provide funding for across-country initiatives. Most of these funding will depend on the countries involved. For example, in South Africa, funding bodies such as the National Research Fund (NRF) and Red Meat Research and Development South African (RMRD SA) can be useful bodies in these initiatives.

29.8 Conclusion and Future Perspectives

Multi-country cooperations and initiatives (MCI), involving the sharing of facilities, data, biological materials, and human and other resources, are key to applying efficient technologies for advancing livestock genetic improvement in Africa. Currently, such across-country cooperations and initiatives are few in Africa. African countries are generally faced with many challenges when it comes to implementing genetic evaluation and improvement schemes, as well as new technologies such as genomics, which provides strong motivation for MCIs. There have, however, been notable initiatives aimed at addressing such challenges through MCIs. These initiatives include H3ABioNet, which aims to build bioinformatics capacity, and AABNet, which focuses on development and dissemination of improved livestock and broader genetic improvement solutions in Africa. These initiatives serve as valuable successful examples of how capacity to adopt and implement technologies for achieving genetic improvement can be achieved through cooperations in Africa. Within-country facilities schemes, such as the integrated registration and genetic information system (INTERGIS) and Kaonafatso ya dikgomo (KYD), which have been used successfully to facilitate livestock improvement in commercial and smallholder farms in South Africa, can be replicated in other African countries. Alternatively, they can be shared with other

African countries, which would enable standardized performance recording protocol to promote livestock genetic improvement programs across the continent. Infrastructure and facilities for providing genomics research, such as genotyping platforms, genome sequencing, and high-performance computing/data centres, are particularly scarce across the African continent. Implementation of MCIs to advance livestock genetic improvement can go a long way towards addressing these needs. This should be underpinned by capacity building programmes using shared training facilities at higher education institutions or research councils in Africa.

Policies, Frameworks, Strategies, and Action Plans for Conservation and Sustainable Use of African Animal Genetic Resources

John E. O. Rege and Mure Agbonlahor

Abstract

Animal genetic resources (AnGR) refer to all animal species, breeds, and strains (and their wild relatives) that are of economic, scientific, and cultural interest to humankind in terms of food and agricultural production for the present or in the future. There are more than 40 species of animals that have been domesticated (or semi-domesticated) during the past 10,000–12,000 years which contribute directly or indirectly to food and agriculture. Common species include cattle, sheep, goats, chickens, pigs, horses, and buffalo, but many other domesticated species such as camels, donkeys, elephants, various poultry species, reindeer, rabbits, etc. are important to different cultures and regions of the world. In developing countries, AnGR also play an important role in the subsistence of many communities and the sustainability of crop–livestock systems. Within these species, breeds in certain regions and production systems are increasingly endangered and many have been lost, many more are at risk of loss, and the situation has been getting worse over the recent decades. Yet, it is the extensive genetic diversity in these breeds that allows the existence of livestock in diverse environments across the globe, providing a range of products and functions even in the most extreme production environments.

African nations are increasingly aware of the need for better understanding and safeguarding the diversity of the continent's unique AnGR. It is increasingly evident that the most significant threat to indigenous AnGR is the marginalization of traditional production systems and the associated neglect of local breeds, driven by the rapid spread of intensive livestock production, often large-scale, and utilizing a narrow range of increasingly exotic breeds. As the availability of adapted local breeds decreases, these changes are also marginalizing smallholder farmers who depend on the adaptive attributes of indigenous AnGR.

Unfortunately, policies and legal frameworks influencing the livestock sector are not always favourable to the conservation and sustainable use of indigenous AnGR. This chapter examines the global policy and strategy landscape on AnGR that is relevant for Africa, past and present initiatives to develop AnGR policies and strategies, the extent to which

these are being translated into plans, and institutionalized practices by African countries, and the challenges being faced and opportunities for interventions going forward. It concludes that, while the African Union, through the Inter-African Bureau for Animal Resources (AU-IBAR), in partnership with Regional Economic Communities, has created significant awareness in Africa around global AnGR policy frameworks/instruments and actions needed at national levels, these efforts have delivered only limited change—with only a few countries having developed or in the process of developing policies and strategies, but even these largely remain on shelves, with little evidence of implementation.

30.1 Introduction

Animal genetic resources (AnGR) refer to all animal species, breeds, and strains (and their wild relatives) that are of economic, scientific, and cultural interest to humankind in terms of food and agricultural production for the present or in the future. There are more than 40 species of animals that have been domesticated (or semi-domesticated) during the past 10,000–12,000 years which contribute directly or indirectly to agricultural production. Common species include cattle, sheep, goats, chickens, pigs, horses, and buffalo, but many other domesticated species such as camels, donkeys, elephants, various poultry species, reindeer, rabbits, etc. are important to different cultures and regions of the world. These AnGR are vital to the economic development of most countries in the world. In developing countries, they also play an important role in the subsistence of many communities and the sustainability of crop–livestock systems. The world's domestic animal genetic resources represent an important resource of economic development and livelihood security. Within these species, breeds in certain regions and production systems are increasingly endangered and many have been lost, many more are at risk of loss, and the situation has been getting worse over the recent decades. Yet, it is the extensive genetic diversity in these breeds that allows the existence of livestock in diverse environments across the globe, providing a range of products and functions even in the most extreme production environments.

African policymakers are increasingly aware of the need for better understanding and safeguarding the diversity of the continent's unique animal genetic resources (AnGR). African indigenous livestock breeds have, over centuries, adapted to diverse, stressful tropical environments by undergoing natural and artificial selection. They have acquired a range of unique adaptive traits, such as tolerance to disease and heat, water scarcity, and ability to cope with poor-quality feeds. However, this unique pool of AnGR is threatened with extinction. Several causes are contributing to the loss of these genetic resources. These include the lack of supportive policies and legislation and inadequate measures to ensure the conservation and sustainable use of these resources. Policy gaps include absence of policies and strategies for conservation, genetic improvement, and sustainable use of indigenous AnGR.

Moreover, these genetic resources are also being directly undermined by some existing policies and practices. Policies and legal frameworks influencing the livestock sector are not always favourable to the conservation and sustainable use of indigenous AnGR. These include overt or hidden subsidies which promote large-scale production based on exotic breeds and crossbreds at the expense of the smallholder systems that utilize local AnGR. Moreover, development and

post-disaster livestock rehabilitation programmes do not assess potential impacts on genetic diversity to ensure that the breeds used are appropriate to local smallholder production systems, and disease control strategies do not incorporate measures which are disproportionately harmful to indigenous breeds. As the availability of adapted local breeds decreases, these changes are also marginalizing smallholder farms who depend on the adaptive attributes of indigenous AnGR.

A look at livestock (production and productivity) strategies, plans, and programmes across the African continent reveals that attention is consistently given to animal health, feed production and management, and markets—traditionally considered to be the most productivity-limiting factors—while, other than their role in crossbreeding, only occasional and casual reference is made to conservation and use of indigenous animal genetic resources. The gaps include lack of accurate and up-to-date information on indigenous AnGR, trends in their population sizes, and drivers of these trends—to inform planning the conservation of these resources. Yet, these resources are key to productivity and resilience of smallholder systems today and hold promise for dealing with production challenges in the uncertain future, especially in the face of climate change. There is evidence that historical attention to animal health in Africa since pre-independence has delivered visible results, for example, the eradication of rinderpest. In the introduction to its current (2018–2023) strategy, the African Union-Inter-African Bureau on Animal Resources (AU-IBAR) recognizes that it has not done well in certain areas, including AnGR, and explicitly refers to "… *the need to build on its success in achieving important targets such as in animal disease prevention, control and eradication*".

This chapter examines the global policy and strategy landscape on AnGR that is relevant for Africa, as well as initiatives on development and implementation of AnGR policies and strategies in the continent, and the extent to which these are being translated into strategies and practices by African countries and the challenges being faced and opportunities for interventions going forward. Definitions of terms used in this chapter are in Box 30.1.

Box 30.1 Definition of Terms

1. *Animal Genetic Resources* include all species, breeds, and strains of animals that are of economic, scientific, and cultural interest to agriculture, now and in the future. Common species include cattle, sheep, goats, pigs, chickens, camels, and donkeys. There are many other domesticated animals that are important for food and agriculture in different regions and cultures of the world. These include horses, buffaloes, elephants, rabbits, and rodents, *inter-alia*.
2. *Biosafety* involves the reduction and elimination of potential risks resulting from the use of biotechnology and its products. Biosafety has also been defined as the avoidance of risk to human health and safety, and to the protection of the environment, resulting from the use of genetically engineered organisms.
3. *Characterization* of animal genetic resources is the assessment of the attributes of the animal populations and their production environments to establish their status and identify strengths that can be enhanced and weaknesses that need to be overcome, for example through genetic improvement programmes. It can also help to inform conservation strategies.
4. *Conservation* of animal genetic resources refers to measures taken to prevent the loss of genetic diversity in livestock populations, including to protect breeds from extinction. It can involve both the conservation of live populations and the cryopreservation (preservation through freezing at low temperatures) of material such as semen or embryos.
5. *Genetic improvement* (animal breeding) is based on the principle that the products (milk, meat, eggs, wool, etc.) and

(continued)

services (e.g., transport, draught power, or cultural services) provided by animals are a function of their genes and the environmental influences that they are exposed to. Improvement can be achieved by selecting genetically superior animals to be the parents of the next generation. "*Genetically superior*" means possessing gene combinations which confer superiority in terms of a particular sets of characteristics, which usually include productivity in the environmental conditions now and/or expected in the future, but should also consider traits such as fertility, disease resistance, or longevity that relate to costs of production.

6. *Policy*. A policy is a *statement of intent* and is implemented as guidelines, procedures, or protocols. Policy has also been defined as a set of ideas or plans that are used as a basis for making decisions—that is, what to do in particular situations, especially in politics, economics, or business. Policies are generally adopted by a governance body within an institution to assist in both subjective (based on the relative merits and demerits of multiple factors and changing contexts) and objective decision-making.
7. *Sustainability*. Sustainability, as used in this chapter, means practices that fulfil the needs of today's generations without compromising the needs of future generations, while also ensuring a balance between economic growth, environmental care, and social well-being. Thus, the three pillars of sustainability, "profit", planet, and people.

30.2 Global Instruments Relevant for the Management of AnGR

30.2.1 The Convention on Biological Diversity (CBD)

While concern for the environment is not new—and has featured in development discourses through the last century—there was heightened concern about human impact on the environment and loss of species and ecosystems in the 1970s. In 1972, the United Nations Conference on the Human Environment in Stockholm, Sweden, resolved to establish the United Nations Environment Programme (UNEP). Governments signed several regional and international agreements in this regard, including those targeting the protection of wetlands and regulation of international trade in endangered species and controls on toxic chemicals and pollution. However, these turned out to be stopgap actions only. It has subsequently been recognized that what is ultimately needed is for humans to learn to use biological resources in a way that minimizes their depletion. The challenge is to put in place economic policies that motivate conservation and sustainable use by creating financial incentives for those who would otherwise over-use or damage the resource.

In 1987, the World Commission on Environment and Development concluded that economic development must become less ecologically destructive: "*Humanity has the ability to make development sustainable—to ensure that it meets needs of the present without compromising the ability of future generations to meet their own needs*".

In 1992, the largest-ever meeting of world leaders—dubbed the "Earth Summit"—took place at the United Nations Conference on Environment and Development in Rio de Janeiro, Brazil. Among the raft of instruments signed at this Summit were two binding agreements, the

Convention on Climate Change, which targets industrial and other emissions of greenhouse gases, and the Convention on Biological Diversity (CBD). The latter was the first global agreement on the conservation and sustainable use of biological diversity. This treaty gained rapid and widespread acceptance and was signed by over 150 governments at the Rio conference. To date, more than 196 countries have ratified the CBD.

The CBD has three main goals: The conservation of biodiversity; Sustainable use of the components of biodiversity; and Sharing the benefits arising from the commercial and other utilization of genetic resources in a fair and equitable way. The CBD recognizes that the conservation of biological diversity as "*a common concern of humankind*" and is integral to the development process. It covers all ecosystems, species, and genetic resources. It links traditional conservation efforts to the economic goal of using biological resources sustainably. It also covers the rapidly expanding field of biotechnology, addressing technology development and transfer, benefit-sharing, and biosafety. Even more importantly, the CBD is legally binding: countries that join it are obliged to implement its provisions. While past conservation efforts were aimed at protecting species and habitats, the CBD recognizes that ecosystems, species, and genes must be used for the benefit of humans, but in a way and at a rate that does not lead to the long-term decline of biological diversity. To date, the CBD has 193 Parties—a near universal participation among countries. Indeed, only four Member States of the United Nations—Andorra, South Sudan, United States of America, and the Holy See (the Vatican)—are not Parties to the CBD. Thus, other than South Sudan, all African countries have ratified the CBD. Although action is highly variable among countries, Member States of the African Union recognize the critical importance of biodiversity and ecosystem services—and their contribution to economic growth, sustainable development, livelihoods, and human well-being in Africa and to achieving the African Union Agenda 2063 and the 2030 Agenda for Sustainable Development.

The conservation, use, and transfer of biological diversity at national, regional, and international levels are governed by a number of international agreements, global plans of action, and other instruments, all of which are intended to facilitate the operationalization of the CBD. Three such global instruments that have direct relevance for Animal Genetic Resources are covered in this chapter. They are: The *Cartagena Protocol on Biosafety to the CBD*; the *Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization to the CBD*; and the *Global Plan of Action for Animal Genetic Resources*. With regard to international Treaties, Conventions, and Protocols, Box 30.2 summarizes descriptors that explain level or status of engagement by countries. These descriptors are applicable in the rest of this chapter.

Box 30.2 Treaty State Descriptors—Ratification, Accession, Approval, and Acceptance

The legal incidents or implications of *ratification*, *accession*, *approval*, and *acceptance* are the same:

The instrument (e.g. treaty) becomes legally binding on the State or the regional economic integration organization. All the countries that have either *ratified, acceded to, approved, or accepted* the Treaty, Convention, or Protocol are therefore *Parties* to it.

Ratification and Accession

The primary (and traditional) distinction is only between ratification and accession. In this regard, it is only States which have signed a treaty, when it was open for signature, that can proceed to ratify it. Signature of itself does not establish consent to be bound, hence the need for the further act of ratification.

States which have not signed a treaty during the time when it is open for signa-

(continued)

ture can only *accede* to it. Therefore, the term "*accession*".

Acceptance and Approval

The terms "*acceptance*" and "*approval*" are of more recent origin and apply under the same conditions as those that apply to ratification. The legal effect is the same as ratification. The uses of these terms have to do with the diversity of legal systems across countries. Certain countries, especially some East European States, use the terms acceptance or approval for purposes of participation in treaties. The terms are also used in cases where organizations rather than States become Parties to an international treaty, for example the EU.

Succession

Succession occurs when one State is replaced by another in the responsibility for the international relations of territory. Generally, a newly independent State which makes a notification of succession is considered a party to a treaty from the date of the succession of States or from the date of entry into force of the treaty, whichever is the later date.

30.2.2 The Cartagena Protocol on Biosafety

Concerns have been raised regarding the potential adverse effects on biological diversity of the use of living modified organisms (LMOs, also known as genetically modified organisms or GMOs). The Cartagena Protocol on Biosafety seeks to address these safety concerns at the international level. The Protocol also covers potential toxic effects of insect-resistant crops on non-target organisms and potential ecological effects of gene flow from modified crops, fish, microorganisms, or insects to wild species or counterparts. The Protocol was adopted on 29 January 2000 as a supplementary agreement to the Convention on Biological Diversity and entered into force on 11 September 2003. It focuses primarily on transboundary movements and is therefore relevant to international trade. It includes provisions on import decision-making, risk assessment and management, information-sharing, documentation, capacity-building, compliance, liability and redress, public awareness and participation, and socio-economic considerations.

Key Elements of the Cartagena Protocol

The Protocol promotes biosafety by establishing rules and procedures for the safe transfer, handling, and use of LMOs/GMOs and facilitates information sharing. The five main pillars of the Protocol are: Procedures for moving LMOs across borders; risk assessment procedures; the biosafety clearing house; capacity building; and public awareness. It provides Parties the opportunity to obtain information before new biotech organisms are imported. It acknowledges each country's right to regulate bio-engineered organisms, subject to existing international obligations. It also creates the framework to help improve the capacity of developing countries to protect biodiversity. Specifically, the Protocol (CBD 2000):

(a) Establishes an online portal, *Biosafety Clearing-House*, to help Parties share scientific, technical, environmental, and legal information about living modified organisms (LMOs).
(b) Creates an advanced informed agreement (AIA) procedure that in effect requires exporting entities to seek consent from destination (importing) country before the first shipment of an LMO meant to be introduced into the environment (seeds—and by extension animal semen and ova, fish for release, or microorganisms).
(c) Requires shipments of LMOs (e.g. cereals) that are intended for direct use as food, feed, or for processing, to be accompanied by documentation stating that such shipments "may contain" living modified organisms and are "not intended for intentional introduction into the environment (i.e. use as seed)." The Protocol establishes a process for considering more detailed identification and docu-

mentation of LMO commodities in international trade.

(d) Sets out information to be included on documentation accompanying LMOs destined for contained use, including handling requirements and contact points for further information and for the receiving entity (consignee).

(e) Includes a clause which states that the agreement shall not be interpreted as implying a change in the rights and obligations of a Party under any existing international agreement, including, for example, WTO agreements. This is termed a *savings clause*.

(f) Calls on Parties to cooperate with developing countries in building their capacity for managing modern biotechnology.

With regard to an importing Party's decision-making process regarding the import of an LMO, there is a precaution with reference to Principle 15 of the Rio Declaration on Environment and Development. This precaution (hence the *precautionary approach*) states that where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental damage, that is:

> Lack of scientific certainty due to insufficient relevant scientific information and knowledge regarding the extent of the potential adverse effects of a living modified organism on the conservation and sustainable use of biological diversity in the Party of import, taking also into account risks to human health, shall not prevent that Party from taking a decision, as appropriate, with regard to the import of that living modified organism in order to avoid or minimize such potential adverse effects.

Thus, both the substantive content of the Protocol's precaution provisions and the preambular savings clause make clear that a Party's use of precaution in decision-making must be consistent with the Party's trade and other international obligations. Moreover, the Protocol states that the *transboundary movement of living modified organisms between Parties and non-Parties shall be consistent with the objective of the Protocol*. The implication is that, although the Protocol only requires trade between Parties and non-Parties in LMOs to be consistent with the objective of the Protocol, entities (individuals and institutions) in non-Party countries wishing to export to Parties will need to abide by domestic regulations put in place in the importing Parties for compliance with the Protocol.

Cartagena Protocol and Animal Genetic Resources in Africa

A total of 173 States and Regional Integration Organizations have ratified the Cartagena Protocol (CBD 2023a). To date, 49 African States are Parties to the Protocol (Table 30.7).

The Cartagena Protocol marked a significant milestone in how countries cooperate towards the safe transfer, handling, and use of living modified organisms that come from modern biotechnology. However, the ultimate success of this international agreement depends on the capacity of Parties to fully implement the agreement. The Global Environment Facility (GEF), as the financial mechanism to both the Convention on Biological Diversity and the Cartagena Protocol, has played an important role in building the capacity in biosafety since the adoption of the Protocol. The GEF, together with UNEP, UNDP, and the World Bank, has assisted countries in developing and implementing National Biosafety Frameworks (NBFs) and participating in the *Biosafety Clearing House* mechanism.

An NBF is a combination of policy, legal, administrative, and technical instruments put in place to address safety for the environment and human health in the context of modern biotechnology. These frameworks often focus on GMOs and have been generally driven by the crop sector, but they are meant to cover broader biotechnology research and applications. Although NBFs vary from country to country, they usually contain certain common elements. These include policy on biosafety, often as part of a broader policy on biotechnology; regulatory regime for biosafety including an act and regulations; and a system to handle notifications or requests for authorizations for certain activities, such as registration of activities ("*contained use*") and field releases of GMOs into the environment. This involves public participation and risk assessment, a mechanism for monitoring and inspections, and

a system for public awareness and public information, i.e. how to inform stakeholders about the development and implementation of the NBF (UNEP 2006).

The road to the establishment of NBFs across the continent has been long, and countries remain at significantly different stages of putting in place the various components of functional NBFs. At the same time, countries are benefiting from regional integration activities being advocated for by the African Union and the Regional Economic Communities to seek common mechanisms that would complement NBFs. For example, COMESA Member States have developed their biosafety frameworks under the UNEP-GEF project during 2001–2004 (UNEP 2006). Beyond ratification and domestication of the key international agreements, political goodwill as well as human and financial capacities are important determinants of successful establishment of NBFs and their practical application in a country. Rege et al. (2022) have summarized the status of sub-Saharan Africa (SSA) countries on the development and implementation of NBFs (Table 30.1) and classified SSA countries based on the prevailing enabling environment (including policy and legislation) for biotechnology application in livestock.

In their assessment of enabling environment for biotechnology applications, Rege et al. (2022) used the following broad criteria: existence of a biosafety framework—incorporating policy and the extent to which this recognizes the potential of biotechnology and promotes improvement in the biological efficiency of livestock through such technologies; existence of acts of parliament, legislation, regulation, and responsible authority or agency mandated to implement the framework; the extent to which the framework has been operationalized; and level of investment in livestock biotechnologies. Table 30.2 summarizes the clustering of SSA countries into five categories and shows that most countries are in the "very weak" (21) and "weak" (8) categories, with only 10 in the "medium" category. Although improvements (especially in relation to investments) are still needed in all countries, Kenya and, to some extent, Nigeria ("strong") and South Africa ("very strong") currently have, overall, better enabling environment for livestock biotechnology applications than other African countries.

Implications of Developments in Transgenic Technologies

There has been an increase in research and development in Africa aimed at addressing constraints to agricultural productivity in recent years. Examples in crops include: Insect-resistant (IR) maize in Kenya; IR cotton in Ghana, Kenya, Nigeria, South Africa, and Uganda; Virus-resistant (VR) cassava in Kenya and Uganda; Fungus-resistant banana in Uganda; Drought-tolerant maize in Kenya, Mozambique, South Africa, Tanzania, and Uganda, and nutritionally enhanced sorghum in Burkina Faso, Kenya, and South Africa.

In the livestock sector, the increasing availability of GM animal feeds—e.g. soya, maize, and alfalfa—is of great relevance to Africa since feed is one of the major constraints to livestock production in the continent. Approval, local availability, and access to cheaper, more productive crops used as animal feeds will have significant implications for Africa in terms of movements into Africa from other continents and between African countries. From a biosafety standpoint, African countries have to be alive to the risks, if any, that are associated with these crops.

Globally, transgenic technologies today form the core of "*interventional genetics*"—approaches involving analysing and interfering with gene function in whole animals. In livestock, transgenic animals are being engineered to improve production and/or adaptive traits, for example, increased milk yield or milk protein, or enhanced disease resistance. With regard to transgenic meats, an example is the *GalSafe* pig (Dolgin 2021), already approved for commercial use in the US, which has been developed to be free of detectable alpha-gal sugar on its cell surfaces. People with Alpha-gal syndrome (AGS) may have allergic reactions to alpha-gal sugar found in red meat (e.g. beef, pork, and lamb). Another example is GM Salmon, the

Table 30.1 Status of National Biosafety Frameworks in SSA countries

Country	Biosafety Act	Biosafety legislation, regulation, policy	Regulatory agency
1. Botswana	Bill under review	National Biosafety policy 2013	
2. Burkina Faso	Act 2006; revised 2013	Biosafety Decree 2004; Biosafety Law 2011; Policy on Biotech	National Biosafety Authority

AquAdvantage Salmon (Clifford 2014), which has been genetically modified to reach a critical growth point faster and has been approved for commercial release in the USA.

The above examples of commercially released GM animals notwithstanding, to date, transgenic technology have mainly been used in basic research, in studies of gene expression, gene function, and disease processes. For example, targeting of genes encoding toxins to specific cell types in the mouse (specific cell ablation) has been used to answer questions of mammalian development and cell lineage analysis. Mutagenesis or disruption of the functioning of endogenous genes by insertion of transgenes (insertional mutagenesis) has also been used both to identify and to clone developmentally important genetic loci. Animal modelling of human disease is an area in which transgenic technology has made a huge impact. The use of large transgenic animals or "*bioreactors*" has been attempted, e.g. for the cost-effective production of high-value pharmaceuticals in the blood or milk of transgenic sheep or cows. Another promising area for the exploitation of the transgenic technology has been in the field of xenotransplantation, where transgenic pigs are engineered to express immunological characteristics that would make their organs well tolerated after transplantation into humans.

Infectious diseases adversely affect livestock production as well as animal welfare and have direct impacts upon human health and public opinion of livestock production. Using transgenic animals for the benefit of animal/human health is becoming increasingly common, driven by the combination of new technologies that facilitate the efficient production of genetically modified animals, new tools to modify gene expression, and advancement of basic understanding of causative agents and the mechanism of disease.

Clearly, African States need to be aware of the implications of these technological advances, even if their application in Africa remains relatively limited for now. Genetic engineering of animals, ethical issues, and implications for the environment have been a subject of review over recent years (e.g. Ormandy et al. (2011) and Maksimenko et al. (2013)).

The number of genetically modified organisms that can potentially harm animal diversity and the environment is staggering. This is especially so given the increasing ease of movement

of genetic material across the globe. The Cartagena Protocol is, therefore, of great relevance and importance to Africa. Thus, the fact that only 21 countries have some form of biosafety laws and regulations (in the form of NBF) in place (Table 30.1), despite the fact that nearly all countries are Parties to the Protocol (Table 30.7), is worrying. Moreover, even among those countries with NBFs in place, there are those without capacity and government commitment to effectively operationalize the frameworks. Indeed, capacity building for biosafety regulators must be a key priority for African states (Obonyo et al. 2011). There is also a need to address the general lack of awareness of biosafety issues by the public and the lack of harmonized biosafety regulations at the sub-regional and continental levels. While the development of the 2007 African Model Law on Biosafety in Biotechnology is applaudable, it takes a more stringent approach than the Cartagena Protocol (Gupta et al. 2008). In any case there is need for a harmonized framework for operationalization of regulations to ensure effective biosafety enforcement without creating unnecessary hurdles to movement of genetic material.

30.2.3 The Nagoya Protocol

The *Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization to the Convention on Biological Diversity (CBD)* (CBD 2010) is an international agreement which aims at sharing the benefits arising from the utilization of genetic resources in a fair and equitable way. It was adopted at the tenth meeting of the Conference of Parties (to the CBD) on 29 October 2010, in Nagoya, Japan, and entered into force on 12 October 2014. The Protocol is a supplementary agreement to the CBD with a focus on the implementation of one of the three objectives of the CBD, that is, the *fair and equitable sharing of benefits arising out of the utilization* of genetic resources, so as to contribute to the conservation and sustainable use of biodiversity. It sets out obligations for the providers and users of the genetic resource in question as well as other contracting parties to take measures in relation to access to genetic resources, benefit-sharing, and compliance.

The Protocol significantly advances the CBD's third objective on fairness and equity by providing a strong basis for greater legal certainty and transparency for both providers and users of genetic resources. Specific obligations to support compliance with domestic legislation or regulatory requirements of the party providing genetic resources and contractual obligations reflected in mutually agreed terms are a significant innovation of the protocol. By promoting the use of genetic resources and associated traditional knowledge, and by strengthening the opportunities for fair and equitable sharing of benefits from their use, the Protocol has potential to create incentives to conserve biological diversity, sustainably use its components, and further enhance the contribution of biological diversity to sustainable development and human well-being.

Under the Protocol, domestic-level benefit-sharing measures aim to provide for the fair and equitable sharing of benefits arising from the utilization of genetic resources with the contracting party providing genetic resources. Utilization includes research and development on the genetic or biochemical composition of genetic resources, as well as subsequent applications and commercialization. Sharing is subject to mutually agreed terms. Benefits may be monetary or non-monetary, such as royalties and the sharing of research results. In summary, the domestic-level access measures aim to:

- Create legal certainty, clarity, and transparency.
- Provide fair and non-arbitrary rules and procedures.
- Establish clear rules and procedures for prior informed consent and mutually agreed-on terms.
- Provide for issuance of a permit or equivalent when access is granted.
- Create conditions to promote and encourage research contributing to biodiversity conservation and sustainable use.

- Pay due regard to cases of present or imminent emergencies that threaten human, animal, or plant health.
- Consider the importance of crop and livestock genetic resources for food security.

The Nagoya Protocol and African Animal Genetic Resources in Africa

Working as a Group, African States were very active in the Nagoya Protocol negotiations because access and benefit-sharing are issues of major importance for Africa—the continent having rich heritage of biological diversity, genetic resources, and associated traditional knowledge. These assets have often been misappropriated or utilized without fair and equitable sharing of the accruing benefits with the countries of origin or indigenous and local communities. The African Group therefore considered that, because Africa is primarily a provider of genetic resources and associated indigenous knowledge, preventing injustices of this nature had to be a priority for the continent.

However, Africa is increasingly also a user of genetic resources, and crop varieties and livestock breeds originating from other parts of the world make (or can potentially make) major contributions to Africa's agriculture and food security. Most African countries are Parties to the International Treaty on Plant Genetic Resources for Food and Agriculture, and the continent has participated, and continues to participate, in negotiations at the FAO Commission on Genetic Resources for Food and Agriculture on Access and Benefit-Sharing measures both for plants and other groups of genetic resources, including animals, aquatic organisms, invertebrates, microorganisms, and forestry resources.

African institutions also form part of international research networks around, for example, taxonomy (requiring access to specimens), health (requiring access to human, animal, and plant pathogens), and climate change adaptation (requiring access to genetic resources adapted to different environmental conditions). Ensuring that Africa benefits from such research has substantial access and benefit-sharing implications. With increasing scientific and technological capacity, Africa has great potential to turn its genetic resources and associated indigenous knowledge into novel biotechnology products. Thus, access and benefit-sharing, if properly implemented, with appropriate training, technology transfer, and investments offer opportunities to increase Africa's ability to add value to, and benefit from, its natural and cultural resources and to help alleviate poverty, stimulate inclusive economic development while also serving as an incentive for sustainable use and conservation of biodiversity.

The adoption of the Nagoya Protocol was seen by African stakeholders as opportunity for a more coordinated approach to access and benefit-sharing that is coherent and in synergy with agreed African positions and related regional and international instruments (AUC 2015). Thus, the provisions of the Protocol were analysed against the background of *The African Common Position for the Negotiations of the International Regime on Access and Benefit-Sharing (IR-ABS)* which was adopted by the African Conference of Ministers in charge of Access and Benefit-Sharing held in March 2010 in Windhoek, Namibia. This process included a reflection on how Africa could best implement the Nagoya Protocol in synergy with relevant regional instruments such as the 2001 *African Model Law for the Protection of the Rights of the Local Communities, Farmers and Breeders and for the Regulation of Access to Biological Resources* ("the African Model Law") (AUC 2015). Building on this, the 14th meeting of the African Ministers Conference on the Environment (AMCEN), held in Arusha, Tanzania, in September 2012, resolved "*to encourage the African Union Commission to continue its ongoing work in the development of Guidelines to support the coordinated implementation of the Nagoya Protocol in Africa*".

These processes culminated into the *African Union Policy Framework and Guidelines for the Coordinated Implementation of the Nagoya Protocol in Africa* (AUC 2015), and this was adopted by the AU Assembly at its 25th Ordinary Session held in Johannesburg, South Africa, in 2015. The Guidelines for the Coordinated

Implementation of the Nagoya Protocol in Africa provide guidance for the implementation of the Protocol and for an access and benefit-sharing system at national and regional levels.

The Guidelines urge AU Member States to become Party to the Protocol and emphasize that Member States should exercise their sovereign rights over their natural resources in the implementation of the Protocol by establishing in their domestic law that Prior Informed Consent is required for access to, and utilization of, their genetic resources—including those held by indigenous and local communities and associated traditional knowledge. The Guidelines also remind Member States to take note of the definitions of "*utilisation of genetic resources*", "biotechnology", and "derivatives" in Article 2 of the Nagoya Protocol to ensure that domestic legislative, administrative, or policy measures comprehensively cover the full scope of utilization of genetic resources, in order to trigger an effective benefit-sharing mechanism.

Objectives of the Guidelines

The stated objectives of the *African Union Policy Framework and Guidelines for the Coordinated Implementation of the Nagoya Protocol in Africa* are to:

(a) Provide practical guidance to African Union Member States on how national Access And Benefit-Sharing (ABS) systems can be implemented in a regionally coordinated manner, consistent with the provisions of the Nagoya Protocol, so as to preserve key African interests and positions while preventing a "race-to-the-bottom" scenario in which users of genetic resources and associated traditional knowledge play off African Union Member States and/or African indigenous local communities against one another.
(b) Establish a coordinated and cooperative regional approach to preventing misappropriation of African genetic resources and/or associated traditional knowledge and to punishing such misappropriation when it occurs.
(c) Encourage utilization of Africa's genetic resources and associated traditional knowledge assets in ways that support regional objectives and strategies on human resource development, technology transfer, scientific and technical capacity building, food security, and economic growth, while encouraging conservation and sustainable use of natural and human capital, including the rights of indigenous local communities.
(d) Facilitate the establishment of common African Access and Benefit-Sharing standards to inform benefit-sharing arrangements.

The Guidelines also provide guidance to Member States on institutional arrangements to regulate and manage Access and Benefit-Sharing, Prior Informed Consent, and Mutually Agreed Terms under the Protocol, including steps for establishing application and permitting processes. Suggested institutional arrangements include the establishment of National Focal Points and Competent National Authorities, including those of Indigenous Local Communities. These institutional obligations are intended, inter alia, to provide legal certainty for applicants seeking access to genetic resources and associated traditional knowledge. The Guidelines further advise that African Union Member States may wish to consider establishing mechanisms such as National Inter-Agency Access and Benefit-Sharing Committees or National Multi-Stakeholder Committees involving representatives from relevant government ministries and other authorities, indigenous local communities, and other relevant stakeholders to foster internal coordination, communication, and dialogue regarding regulation of access and benefit-sharing at the national level and streamlining institutional/administrative and decision-making arrangements and procedures.

Out of the 54 African countries, 47 are Parties to the Nagoya Protocol (CBD 2023b) (Table 30.7). Among the countries which have established National Focal Points for Access and Benefit-Sharing, some are Party States, others are not. In addition, many African governments lack regulations on bioprospecting, resulting in the unregulated exploitation of their biological and genetic resources, including livestock. Fortunately, as

evidenced by their engagement in international negotiations of these instruments, African governments are increasingly recognizing the role legal frameworks play in providing controlled and legally secure access to potential users of locally available biological and genetic resources. However, as is the case with the Cartagena Protocol, operationalization of the Nagoya Protocol has been highly variable across countries. Unfortunately, no systematic quantification has been done to determine if and how countries are meeting their obligations under the CBD and the Nagoya Protocol. This is also true with regard to the extent of use of the AU Guidelines and what benefits have accrued to them so far. Also similar to the status of the Cartagena Protocol, a major concern regarding the operationalization of the Nagoya Protocol is the lack of capacity, including institutions and systems, to implement it effectively in developing regions of the world. African governments are reporting little progress and pointing out that reluctance by genetic resources user countries (mostly in the Global North) to share benefits, by paying for the true value of AnGR from the South, remains a challenge.

30.2.4 The Global Plan of Action for Animal Genetic Resources

Globally, it is estimated (FAO 2015) that more than 8800 domestic animal breeds or populations (of mammals and birds) within 38 species have been developed by farmers and pastoralists in diverse environments in the 12,000 years since the first livestock species were domesticated. These breeds and populations now represent unique combinations of genes conferring numerous characteristics, including adaptability. Today, faced with the needs of a growing population, changes in consumer demand, and the challenge posed by climate change and emerging diseases, we need to recognize and utilize these adaptive attributes and potentials to face an uncertain future.

The State of the World's Animal Genetic Resources for Food and Agriculture (SoW-AnGR) published in 2007 (FAO 2007) provided the first global assessment and analysis of the status and trends in animal genetic resources. It raised global awareness and understanding of their ongoing erosion. It also identified significant gaps in capacities of countries to manage animal genetic resources, particularly in the developing world. The Sow-AnGR report formed an important cornerstone in the creation of global awareness. As part of this process, the international community, in September 2007, adopted the first ever *Global Plan of Action (GPA) for Animal Genetic Resources*, comprising 23 *Strategic Priorities* which fall under *four Strategic Priority Areas* aimed at combating the erosion of animal genetic diversity and using animal genetic resources sustainably. It was considered that the implementation of the *Global Plan of Action* would contribute significantly to achieving the Millennium Development Goals (MDG 1, to eradicate extreme poverty and hunger; and MDG 7 to ensure environmental sustainability).

Managing AnGR involves considerations of complex interrelated issues and questions—those specific to the resources themselves (e.g. selective breeding, use, and conservation) and those which are cross-sectorial (e.g. animal health, trade standards, and environmental management). Moreover, responsibilities are invariably shared across sectors and institutions, nationally and internationally. Further, policymakers in many countries, and internationally, are seldom aware of the diverse and significant contributions of animal genetic resources to food and agriculture and of traditional rights of livestock keepers. Consequently, the sustainable use and conservation of animal genetic resources has remained a low priority in the development of agricultural, environmental, trade, and human and animal health policies. The effect has been a failure to invest adequately and appropriately in essential institutional development and associated human and infrastructural capacity.

The GPA provides a framework that countries can use to develop and operationalize policies for characterization, conservation, and use of AnGR. It aims to promote a pragmatic, systematic, and

efficient overall approach, which harmoniously addresses the development of institutions, human resources, cooperative frameworks, and resource mobilization.

The aims of the GPA (FAO 2007) are to:

- Promote the sustainable use and development of animal genetic resources, for food security, sustainable agriculture, and human well-being in all countries.
- Ensure the conservation of the important animal genetic resource diversity, for present and future generations, and to halt the random loss of these crucial resources.
- Promote, as per Nagoya Protocol, a fair and equitable sharing of the benefits arising from the use of animal genetic resources for food and agriculture and recognize the role of traditional knowledge, innovations, and practices relevant to the conservation of animal genetic resources and their sustainable use, and, where appropriate, put in place effective policies and legislative measures.
- Meet the needs of pastoralists and farmers, individually and collectively, within the framework of national law, to have non-discriminatory access to genetic material, information, technologies, financial resources, research results, marketing systems, and natural resources, so that they may continue to manage and improve animal genetic resources and benefit from economic development.
- Promote agro-ecosystems approaches for the sustainable use, development, and conservation of animal genetic resources.
- Assist countries and institutions responsible for the management of animal genetic resources to establish, implement, and regularly review national priorities for the sustainable use, development, and conservation of animal genetic resources.
- Strengthen national programmes and enhance institutional capacity—in particular, in developing countries and countries with economies in transition—and develop relevant regional and international programmes. Such programmes should include education, research and training to address the characterization, inventory, monitoring, conservation, development, and sustainable use of animal genetic resources.
- Promote activities aimed at raising public awareness and bringing the needs of sustainable use and conservation of animal genetic resources to the attention of concerned governments and international organizations.

The *Strategic Priorities for Action* cover the four Strategic Priority Areas, namely:

Strategic Priority Area 1: *Characterization, Inventory, and Monitoring of Trends and Associated Risks*. The actions provide a consistent, efficient, and effective approach to the classification of AnGR and to assess trends in, and risks to, the AnGR.

Strategic Priority Area 2: *Sustainable Use and Development*. Focus is on ensuring sustainability in animal production systems, especially on food security and rural development.

Strategic Priority Area 3: *Conservation*. That is, steps needed to preserve genetic diversity and integrity, for the benefit of current and future generations.

Strategic Priority Area 4: *Policies, Institutions, and Capacity-building*. Focus is on actions which address the key questions of practical implementation, through coherent and synergistic development of the necessary institutions and capacities.

The complete list of the 23 strategic priorities of the GPA is summarized in Table 30.3 by Strategic Priority Area.

Institutional Framework for Operationalizing the Global Plan of Action (GPA)

Among instruments for operationalizing the GPA is an institutional framework (FAO 2011) which provides a basis for effective management of animal genetic resources, both nationally and internationally, and guidelines which present an overview of the components of the global network for the management of animal genetic resources and how they can be strengthened at national and regional levels. Guidance is provided on the role of National Coordinators for the

Table 30.3 Strategic Priority Areas (SPA) and Strategic Priorities (SP) of the Global Plan of Action for AnGR

Geographical target	SPA1 Characterization, inventory, and regularity of monitoring	SPA2 Sustainable use and development	SPA3 Conservation	SPA4 Policies, institutions, and capacity-building
National	*SP1*: Inventory and characterize AnGR, monitor trends and risks associated with them, and establish country-based early-warning and response systems	*SP3*: Establish and strengthen national sustainable use policies *SP4*: Establish national species and breed development strategies and programmes *SP5*: Promote agro-ecosystem approaches to the management of AnGR *SP6*: Support indigenous and local production systems and knowledge systems	*SP7*: Establish national conservation policies *SP8*: Establish or strengthen in situ conservation programmes *SP9*: Establish or strengthen ex-situ conservation programmes	*SP12*: Establish or strengthen national institutions, including national focal points *SP13*: Establish or strengthen national educational and research facilities *SP14*: Strengthen national human capacity for characterization, inventory, and monitoring of trends and associated risks *SP18*: Raise national awareness of the roles and values of AnGR *SP20*: Review and develop national policies and legal frameworks for AnGR
Regional			*SP10*: Develop and implement regional and global long-term conservation strategies	*SP17*: Establish regional focal points and strengthen international network
International	*SP2*: Develop international technical standards and protocols for characterization, inventory, and monitoring of trends and associated risks		*SP11*: Develop approaches and technical standards for conservation	*SP15*: Establish or strengthen international information sharing, research, and education *SP16*: Strengthen international cooperation to build capacities *SP19*: Raise regional and international awareness of the roles and values of AnGR *SP21*: Review and develop international policies and regulatory frameworks relevant to AnGR *SP22*: Coordinate the Commission's efforts on AnGR policy with other international forums *SP23*: Strengthen efforts to mobilize resources, including financial, for the conservation, sustainable use, and development of AnGR

Source: FAO (2007)

Management of Animal Genetic Resources and the development and operation of National Focal Points for the Management of Animal Genetic Resources supported by National Advisory Committees, working groups, and country stakeholder networks.

National Focal Points are supposed to initiate, lead, facilitate, and coordinate country activities related to the implementation of National Strategies and Action Plans (NSAPs) for AnGR and to interface with AnGR stakeholders within the country and cooperate with the *Regional Focal Point* (where available) and with the *Global Focal Point*, to plan and develop regional and global initiatives as appropriate. The Global Focal Point is located at FAO headquarters in Rome, while the Regional Focal Points are established within the respective regions (Regional Economic Communities or other Sub-Regional Organizations) as a means of facilitating regional communications, providing technical assistance and leadership in AnGR management and coordinating activities that can best be implemented at regional level or will benefit from coordination among countries within the region.

The National Coordinator is expected to work within the country's National Focal Point and lead national efforts to implement the Global Plan of Action. The National Coordinator is defined as: "*the government nominated person who coordinates national implementation of the Global Plan of Action for Animal Genetic Resources and leads the development and operation of a national network on animal genetic resources. He or she is the contact person for communication with FAO on matters relating to the implementation of the Global Plan of Action for Animal Genetic Resources and with global and regional animal genetic resources networks.*"

The Global Plan of Action and African States

Cao et al. (2021) have undertaken an analysis of progress with implementation of the GPA and observed clear differences in the implementation across countries and regions. Results from the 2019 round of the SoW-AnGR show that, in general, countries with higher GDP per capita report higher scores regarding Global Plan implementation. Countries reporting high scores but relatively low GDP per capita were almost systematically BRICS countries (specifically Brazil, China, India, and South Africa) having made significant investment in livestock production in recent years to meet rising consumer demand. By contrast, some Near and Middle East countries with relatively high GDP per capita (Qatar and Saudi Arabia) reported very low scores in Global Plan implementation, which is possibly in relation to their relatively small livestock sectors and thus lack of emphasis on livestock production in country policies.

For African countries, greater progress was reported for SPA4 (Policies, Institutions, and Capacity-Building). This was considered to be related to the implementation of donor-funded projects dedicated to the management of AnGR at regional level (mainly the interventions by AU-IBAR) or to the development of national strategies considering AnGR issues, such as the Livestock Master Plans—supported by the International Livestock Research Institute (ILRI)—developed by Ethiopia, Rwanda, and Tanzania. The lack of progress regarding SPA3 was observed in all regions except Africa where, building on existing facilities, AU-IBAR has engaged some RECs and countries to facilitate establishment of regional gene banks for AnGR as part of the support being given to countries to establish National Strategies and Action Plans. To date, 15 countries have established NSAPs and 12 are in the process of doing so (Sect. 30.5.1).

30.3 The African Union Inter-African Bureau for Animal Resources

Originally established as the Inter-African Bureau of Epizootic Diseases (IBED) in 1951 to study the epidemiological situation of, and lead the fight against, rinderpest in Africa, the organization was renamed African Union–Inter-African Bureau for Animal Resources (AU-IBAR), to reflect its broadened mandate which is to support

and coordinate the improved utilization of animals (livestock, fish, and wildlife) as a resource for human well-being in the Member States of the African Union (AU) and to contribute to economic development, particularly in rural areas. An examination of the role of AU-IBAR in animal resources policy is best done by looking at the specific areas of its mandate (referred to as niche in its 2018–2023 Strategy (AU-IBAR 2018)), which are:

(a) Formulation, validation, and dissemination of animal resources continental strategic frameworks.
(b) Coordination of Africa's contribution to the development of relevant standards and regulations and enhancement of compliance by Member States.
(c) Strengthening institutional capacity and support of policy coherence and harmonization at national, regional, and continental levels.
(d) Packaging and dissemination of information and knowledge on animal resources to Member States, Regional Economic Communities, and other continental and regional institutions.
(e) Coordination of the African Voice (and common positions) in Animal resources development.
(f) Enhancing the pan-African coordination, networking, and partnerships in Animal Resources.
(g) Providing technical support and associated tools to Member States for effective implementation of their policies and strategies.

AU-IBAR's main clients are the African Union (AU) Member States and the Regional Economic Communities (RECs) to which the Member States belong. Over the years, AU-IBAR has developed a track record across domains of animal production and health, including in pastoral systems, and is recognized in the development community as providing leadership on animal resources issues at the continental level.

AU-IBAR's strategic positioning and approach to the delivery on its mandate is guided by the recognition that the productive use of animal resources is only sustainable when clear national livestock development policies, adequate institutional frameworks, relevant scientific research activities, and sustained technical and financial resourcing are in place.

30.3.1 The African Animal Genetic Resources Project (2013–2018)

Recognizing that Africa was lagging in the implementation of the Global Plan of Action (GPA) for sustainable use of AnGR, the AU-IBAR implemented a project in the period 2013–2018 (AU-IBAR 2014), funded by the European Union (EU), titled "Animal Genetic Resources Project" which sought to fast-track the implementation of the GPA in the continent. With a theme *Strengthening the Capacity of African Countries to Conserve and Sustainably Use African Animal Genetic Resources*, the project focused on building capacity for effective formulation and implementation of policies and strategies for the management of AnGR and creating awareness for its inclusion into national and regional agricultural investment priorities. The initiative also aimed to develop a suite of biodiversity indicators suitable for the African context to assess and report on progress towards the set targets. Project interventions were at two levels:

- *Regional Economic Community (REC) level*: The focus here was on harmonization of national policies and regional policies for transboundary breeds. The project envisaged to leverage on regional complementarity and pools of resources for the establishment of regional gene banks (see below) and creation of the institutional environment for the implementation of the GPA at regional levels.
- *National level*: The focus was on building capacity for formulation of national policies and strategies as well as national action plans for the implementation of the GPA, ensuring the mainstreaming of the AnGR issues in national sectoral and inter-sectoral policies, strategies, and plans.

The Project also aimed to build consensus on the methodology and tools for the characterization and inventory of AnGR. Communication of outputs and outcomes included policy briefs, specialized dissemination, and training sessions on the use of data tailored to specific target groups and use of community radios and local publications in local languages. The major deliverables of the Project are summarized in Table 30.4 by objective.

30.3.2 The State of Farm Animal Genetic Resources in Africa

An important rationale for the AU-IBAR programme was the fact that African AnGR are undervalued, and the awareness about their economic potential among policy makers and the general public is limited, and the recognition that this state of affairs had resulted in a lack of appropriate infrastructure, institutions, capacity, and technologies to harness the inherent potential of these genetic resources. It was also recognized that, since the adoption of the Global Plan of Action (GPA), only a few countries in Africa had formulated National Strategies and Action Plans (NSAPs) for implementation. Moreover, in countries where the NSAPs had been developed, low technical and financial capacity as well as a lack of information on the current population status and trends of Farm AnGR was constraining their implementation. In addition, the absence of harmonized characterization, inventory, and monitoring approaches had resulted in lack of credible evidence to inform policy making.

It was therefore imperative that the "baseline" situation be established to inform scope of work going forward. As part of its objective to catalogue information and knowledge gaps, the initiative sought to identify the most significant gaps and needs for conservation and utilization of AnGR, to provide the basis for designing strategic national, regional, and international policies to underpin the implementation of priority activities.

The assessment of the current situation leading to the publication, in 2019, of *the State of Farm Animal Genetic Resources in Africa* (AU-IBAR 2019) (in 2019) identified the state of countries in regard to livestock polices and strategies relevant for AnGR. Although livestock policies and/or strategies of many countries include at least some reference to AnGR, implementation is limited—almost in all countries. Indeed, many countries have had livestock policies over decades, but these have never been implemented.

The assessment report proposes the following priority areas for the development of Farm AnGR in Africa:

(a) Strengthening national and regional efforts in characterization and inventories of indigenous breeds.
(b) Establishment of sustainable breeding and conservation strategies for native and transboundary breeds.
(c) Establishment of regional and continental programmes to understand existing crossbred populations and creation of productive and resilient synthetic breeds.
(d) Establishment and strengthening of information systems—linked to development of monitoring tools.
(e) Creation of AnGR monitoring committees at country and regional levels.
(f) Coordination mechanisms: Mapping of key actors and development of networks, partnership arrangements, and collaboration around activities underpinned by AnGR Focal Points in each country.
(g) Harmonization of policies and legislation, and monitoring tools.
(h) Ex-situ conservation: Strengthening existing or facilitating establishment of new national and regional gene banks, and a continental backup facility to serve all regions and countries.
(i) Strengthening the capacity of value chain actors—individuals and institutions.
(j) Advocacy and awareness raising of Farm AnGR issues and needed actions.

30.3.3 Policy Framework for Sustainable Use of AnGR

As can be seen from the summary of strategic areas in Table 30.4 (Sect. 30.3.1), a major output of the AU-IBAR AnGR work has been the devel-

Table 30.4 Summary of achievements of AU-IBAR's Animal Genetic Resources Project

Result area	Objective	Achievements
1. The Status and trends of AnGR in Africa	1. Identify threatened and at-risk breeds	Forty-four Member States were supported to compile their AnGR status reports as part of the FAO-led second State of the World AnGR Report Publication of the State of Animal Genetic Resources in Africa (Sect. 30.3.2)
	2. Take stock of existing policies and regulations on the use of AnGR	Inventory of Policies and Strategies related to AnGR was completed and validated by stakeholders in East, Central, West, North, and Southern Africa. This showed that: Only a few countries had policies and legislation specific to the management of AnGR (Sect. 30.5.1) Most policies and regulations relate to control of animal movement—focusing on disease control, particularly transboundary diseases Policies and legislation in many countries are outdated There are no policies and legislation addressing crossbreeding or transboundary breed issues
	3. Assess the genetic impact of livestock production systems	The assessment of the impact of livestock mobility (nomadism) was initiated in Central and East Africa. It highlighted impacts through interbreeding and identified lessons and good practices
	4. Assess impact of breeding programs on genetic diversity and socio-economic status	An assessment was initiated to identify the key selection and breeding programmes in the regions, focusing on transboundary breeds
2. Policy frameworks for sustainable use of AnGR	1. Develop guidelines for crossbreeding policies	Issues paper on crossbreeding and conservation and management of transboundary AnGR in Africa has been developed—and will be a basis for consultations to identify key issues to be covered in the regional policy and legislative frameworks on crossbreeding
	2. Develop technical standards and protocols for exchange and use of genetic materials	The African Union Strategic Guidelines for the Coordinated Implementation of the Nagoya Protocol—and analysis of the legal environment for the exchange and movement of animal genetic material in the continent. This will culminate in the development of technical standards, legislation, or regulatory requirements for the exchange and movement of animal genetic materials

(continued)

Table 30.4 (continued)

Result area	Objective	Achievements
3. Conservation and improvement strategies and initiatives	1. Support countries to develop and implement National Strategies and Action Plans (NSAPs) for AnGR	Work has been initiated on strengthening capacity of countries to develop NSAPs and mainstream AnGR in the national ag. investment plans (NAIPs) through the CAADP country processes
	2. Support countries to develop or strengthen breeding and conservation strategies as part of their NSAPs	A total of 15 countries completed the development of their NSAPs, and 12 were underway at the close of the project (Sect. 30.5.1)
	3. Support development of regional conservation policy and strategic frameworks for trans-boundary livestock breeds at risk	Inventory of policies and legislation conducted in Southern (SADC) and Eastern Africa (EAC and IGAD) countries to be used to guide the approach for other regions
	4. Support development of regional facilities for ex-situ conservation	Regional gene banks proposed or initiated (Sect. 30.5.1)
	5. Support development and/or strengthening of Livestock Breeders' Associations	Explored different models for advisory and financial support to existing Livestock Breeders' Associations
4. Knowledge, attitude, and practice regarding contribution of livestock to economic growth, food security, and poverty reduction	1. Develop harmonized tools and protocols for characterization and inventory of AnGR	An AnGR Taxonomy Advisory Group (AnGR-TAG) has been established to develop and/or improve tools and guidelines for characterization, inventory, and monitoring
	2. Establish AnGR databases	A module on AnGR, *the African Animal Genetic Resources Information System* (AAGRIS), has been created in *Animal Resources Information System* 2 (ARIS2) *ARIS* addresses data and information gaps to underpin assessment of capacities and to facilitate effective responses to animal health and broader animal resources challenges; the software will support better policy and decision-making by enhancing information and knowledge management to improve planning of interventions The provision of ICT equipment to 31 Member States to facilitate capture and analysis of data on AnGR
	3. Establish and strengthen systems for monitoring of trends of breeds and associated risks	Tools for characterization, inventory, and monitoring of trends and risks have been developed, validated, and piloting done in a few countries
	4. Develop regional networks for information sharing	Regional Domestic Animal Diversity Networks (DAD-Nets) have been established. To-date, DAD-Net West Africa, DAD-Net for Central Eastern Africa, Northern, Southern Africa regions are operational under the Sub-Regional Focal Points and AU-IBAR
	5. Establish or strengthen regional focal points for AnGR	Sub-Regional Focal Points (S-RFPs) for AnGR established and are at different levels of operation
	6. Document and disseminate best practices and lessons on AnGR conservation and improvement	Dissemination of AnGR information through the AU-IBAR and partners' websites, African DAD-Nets, and international workshops Publication of AnGR characterization, conservation, and use issues through the Bulletin of Animal Health and Production in Africa (BAHPA)

opment of a policy framework, consisting of a range of initiatives at national and regional (REC) levels, for the sustainable use of AnGR. The policy framework provides, inter alia, guidelines for the formulation and harmonization of cross-breeding, protocols and tools for characterization and inventory of AnGR, in situ and ex-situ conservation, technical standards, protocols for the exchange and use of genetic materials, and establishment and implementation of action plans on AnGR. As part of these efforts, AU-IBAR has organized and facilitated capacity building support to countries and RECs around sustainable use and conservation of AnGR through institutionalizing national and regional policy and legal and technical instruments. These efforts have also included catalyzing and facilitating the formation or strengthening of regional and national livestock breeders' associations.

30.3.4 AnGR Gene Banking Strategy

AU-IBAR is developing a strategy for the use of AnGR gene banks (AU-IBAR 2019, 2020). A regional approach that is driven and owned by Member States but ensures efficiency and effectiveness through sharing of facilities hosted at designated regional locations has been proposed in this regard. Potential advantages of regional gene banking include: providing access to cryopreservation facilities for countries lacking national gene banks; acting as a back-up storage for national gene banks; providing storage of material from trans-boundary breeds; and providing uniform tools and protocols for identification and evaluation of breeds to be preserved.

However, although regional animal gene banks have these advantages which make them potentially cost-effective, several issues still require attention. One of these is the fact that Member States who are signatories to the Convention on Biological Diversity need to ensure that international transfer of animal genetic resources is consistent with the terms of the Nagoya Protocol on Access and Benefit-Sharing (Sect. 30.2.3). The FAO Guidelines for cryo-conservation of animal genetic resources will inform the development of common technical standards for operation of the animal gene banks. The analysis undertaken by AU-IBAR suggests that regional animal gene banks should be located in national facilities and, to ensure they are functional, must be supported with the necessary equipment, training, and supplies. Special attention has to be given to animal health to prevent the spread of animal diseases through the movement of genetic material. This includes accurate records of the health status of sampled animals. Legal protocols must be in place to ensure that the samples in a regional animal gene bank remain in the ownership of the country of origin with provision made for appropriate access by interested parties presenting valid claims for the use of such material. Users will also be expected to replenish the gene bank, as needed, with samples (e.g. of semen or embryos) from the regenerated animals. Development and harmonization of legal instruments have been initiated, i.e. Material Acquisition Agreements (MAAs) and Material Transfer Agreements (MTA).

Regional gene banks proposed or initiated to date are:

- West Africa: Bobo Dioulasso, Burkina Faso, hosted by CIRDES
- Southern Africa: Gaborone, Botswana, Department of Agricultural Research (DAR)
- Eastern Africa: Entebbe, Uganda, National Animal Genetic Resource Centre and Data Bank (NAGRIC & DB)
- Central Africa: Bambui, Cameroun, Centre Régional de Recherche Agricole de Bambui-Mankon
- North Africa: To be determined
- Continental backup: Debre Zeit, Ethiopia, The African Union Pan-African Veterinary Vaccine Centre (AU-PANVAC)

30.3.5 The 2015–2035 Livestock Development Strategy for Africa (LiDeSA)

African Heads of State and Governments endorsed the first ever 20-year Livestock

Development Strategy for Africa (LiDeSA) (AU-IBAR 2015) in 2017. The strategy calls for an agricultural sector transformation agenda and underscores the importance of utilizing animal genetic resources to address the continent's pressing needs for food and nutritional security. It was framed as the continent blueprint for the transformation of the livestock sector through energizing its under-utilized potentials. The strategy identified the insufficient attention paid by Member States to the merits of exploiting the resilience and adaptive capacity of local animal breeds. It noted that Member States have tended to go for perceived quick fixes through importation of exotic germplasm, and in the process putting indigenous breeds at risk. The strategy identified the following six pathways for sustainable use of AnGR in African livestock transformation:

(a) Accelerate genetic improvement and access to appropriate, productive, and resilient breeds that best match the production contexts, informed by research and development, innovation (including use of ICT), and appropriate partnerships.
(b) Formulate and promote supportive, inclusive, and integrated institutional and policy frameworks for the sustainable management of animal genetic resources.
(c) Conduct inventory and characterization and innovatively utilize indigenous bio-resources (e.g. rumen and milk microbes, genes) with potential industrial and business application in African production systems
(d) Design and implement innovative and sustainable breeding and conservation programmes at national and regional levels.
(e) Develop appropriate and more effective delivery systems of appropriate and superior genetic material.
(f) Develop and support inclusive community-public-private partnerships and business models 1for generation, implementation, and delivery of appropriate genetic resources.

It was envisaged that the implementation of the LiDeSA as planned would dramatically transform the African livestock sector, towards its potential as a major contributor to the continent's socio-economic development.

30.4 Africa's Regional Economic Communities (RECs)

The Regional Economic Communities (RECs) are regional groupings of African states. Their creation was proposed by the 1980 Lagos Plan of Action for the Development of Africa and the 1991 Abuja Treaty as the basis for wider African integration. Each with their own role and structure, the RECs aim to facilitate regional economic integration between members of the region and through the wider African Economic Community (AEC), established under the Abuja Treaty. The RECs are closely integrated with work of the African Union (AU). Increasingly, RECs are involved in coordinating the interests of African Union Member States in broad areas such as peace and security, development, and governance. Figure 30.1 (map) shows which RECs each African country belongs to and indicates the various combinations of overlapping memberships to the regional economic communities in the continent. The AU recognizes eight RECs, namely the Arab Maghreb Union (UMA), the Common Market for Eastern and Southern Africa (COMESA), the Community of Sahel–Saharan States (CEN–SAD), the East African Community (EAC), the Economic Community of Central African States (ECCAS), the Economic Community of West African States (ECOWAS), the Intergovernmental Authority on Development (IGAD), and the Southern African Development Community (SADC). This section presents engagements by the different RECs in the development and operationalization of policies and strategies relevant for AnGR. The section has benefited from a 2016 review of agricultural and livestock policies undertaken by AU-IBAR (in

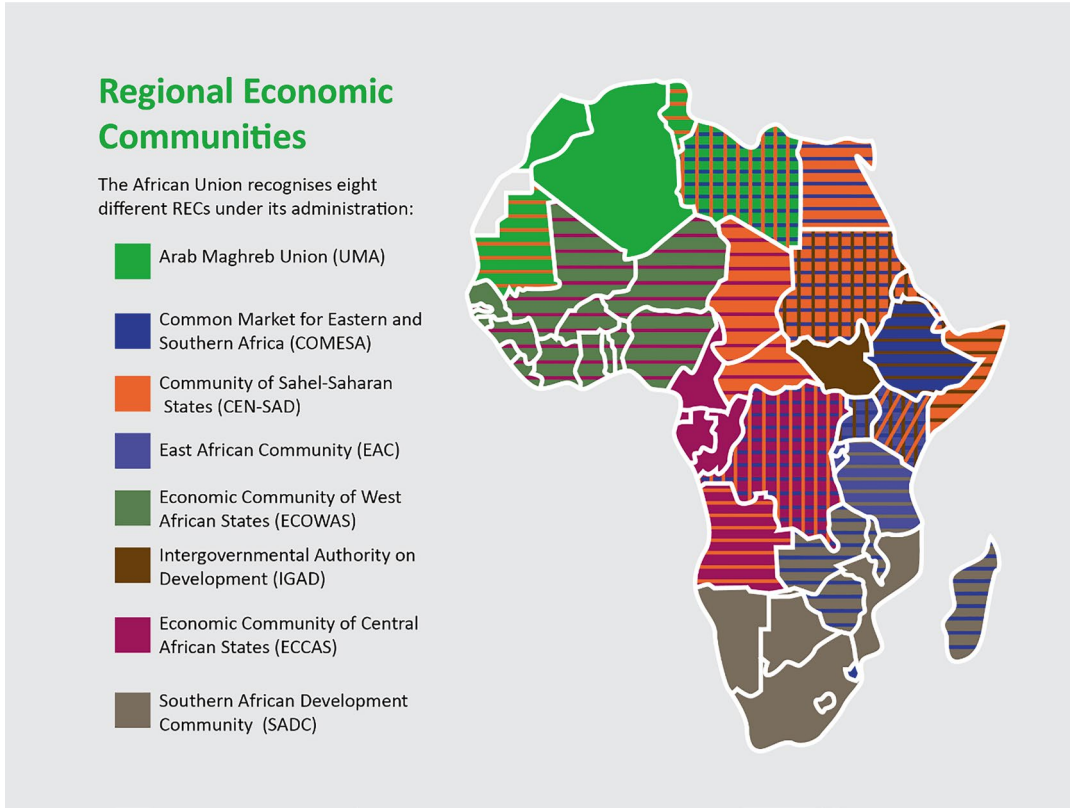

Fig. 30.1 The Regional Economic Communities in Africa

collaboration with RECs) as part of its Reinforcing Veterinary Governance in Africa (AU-IBAR 2016).

30.4.1 Common Market for Eastern and Southern Africa (COMESA)

Informed by, and significantly aligned to, the AU-IBAR's "*Livestock Development Strategy for Africa*" (LiDeSA), the COMESA Regional Livestock Policy Framework (COMESA 2015) includes "*Policies to enhance Livestock Production and Animal Health to increase Productivity and Resilience of livestock production systems*."

Specifically, policies to *improve the genetic potential and performance of animals include*:

- Support Member States to accelerate genetic improvement and access to appropriate, productive, and resilient breeds that best match the production systems/environments mediated by innovative research and development, business, public-private partnerships, and ICT.
- Formulate and promote supportive, inclusive, and integrated institutional and policy frameworks for the sustainable management of animal genetic resource.
- Support Member States to conduct inventory and characterization and innovatively utilize indigenous bio-resources (e.g. rumen and milk microbes, genes) with potential industrial and business applications in African production system.
- Support Member States to design and implement innovative and sustainable breeding and conservation programmes at national and regional levels.
- Support Member States to develop appropriate and more effective delivery systems of appropriate and superior genetic material.

- Support Member States to develop and implement inclusive community-public-private partnerships and business models for generation, implementation, and delivery of appropriate genetic resources.

While not specific to AnGR, two other relevant policy areas are: policies to enhance innovation, generation, and utilization of technologies, capacities, and entrepreneurship skills of livestock value chain actors; and policies to enhance access to markets, services, and value addition.

30.4.2 East African Community (EAC)

The EAC was established with a vision to set up a prosperous, competitive, secure, stable, and politically united East Africa and provide a platform to widen and deepen Economic, Political, Social, and Culture integration to improve the quality of life of the people of East Africa. It is a regional intergovernmental organization of eight Partner States: The Republic of Burundi, the Democratic Republic of the Congo, the Federal Republic of Somalia, the Republic of Kenya, the Republic of Rwanda, the Republic of South Sudan, the Republic of Uganda, and the United Republic of Tanzania, with its headquarters in Arusha, Tanzania. The work of the EAC is guided by its Treaty which established the Community. It was signed on 30 November 1999 and entered into force on 7 July, 2000 following its ratification by the original three Partner States—Kenya, Tanzania, and Uganda.

The EAC Council of Ministers adopted the EAC Livestock Policy in 2016. The policy (EAC 2016) envisions a "*vibrant livestock industry contributing significantly to improved living standards of EAC citizens, economic growth and sustainable natural resources management by 2025*." The six strategic pillars which explicitly cover AnGR are:

1. *Policy instruments and* strategies *to enhance conservation and sustainable utilization of livestock resources:*
   - Strengthen institutional capacities and engagements for strategic partnerships in implementation of the Global Plan of Action (GPA) for animal genetic resources.
   - Promote sustainable utilization of indigenous breeds with high priority to rare breeds with unique attributes through branding, incentives, and protection frameworks.
   - Support investments in regional conservation facilities.
   - Strengthen institutional capacities and engagement with strategic partners for effective and successful implementation of the GPA for animal genetic resources.
2. *Policy instruments and* strategies *to enhance access to quality breeding stock*:
   - Support public investment in infrastructure for animal breed improvement and multiplication of high-quality breeding stock.
   - Promote sustainable utilization and conservation of indigenous breeds with unique attributes.
   - Facilitate regional trade and investment in animal semen, embryos, and biotechnology research for production of quality breeding stock.
   - Support public-private partnerships in livestock improvement and multiplication of quality breeding stock.
   - Advice on, and support, sustainable livestock breeding programmes in Partner States.
   - Support Partner States to establish animal conservation and breeding centres
   - Domesticate and implement the GPA on AnGR conservation and utilization.
3. *Policy instruments and* strategies *to enhance wider application and benefits of biotechnology*:
   - Increase investment in establishment of regional advanced biotechnology research facilities and centres of excellence.
   - Prioritize biotechnology research in diagnostics product development and vaccines for diseases of economic importance.
   - Prioritize biotechnology research in genetic and product improvement technologies, animal feeds, and nutrition.
4. Policy instruments and strategies to enhance access to financial services and products:

- Advocate for implementation of fiscal and monetary policies that include livestock recording, registration, and transactions as collateral for securing loans.
- Promote strengthening and capacity building of cooperatives, village banks, and Self-Help Groups to provide financial services and products to livestock producers, traders, and SMEs.

5. Policy instruments and strategies to strengthen research in livestock subsector:
   - Advocate for Partner States commitment to allocating at least 5% of the annual research budget to livestock research.
   - Mobilize resources for establishment and administration of competitive livestock research funds.
   - Invest in capacity building, laws, and programmes strengthening intellectual property rights.
   - Prioritize research support to animal-based mechanization and integrated nutrient management research.
   - Support collaborative public-private research agendas in priority concerns to livestock value chain actors.
6. Policy instruments and strategies to enhance contribution of livestock to ecosystem productivity:
   - Support and promote implementation of payment for environmental services schemes in livestock systems.
   - Support actions for enhancing marketing of livestock-related environmental goods and services from carbon trade, biogas, and ecotourism.
   - Support actions for implementation of rules and regulations and pricing regimes to control access and use of fragile ecosystems
   - Support participatory processes and actions for implementation of community management of common pastures and water and other fragile ecosystems in each Partner state.

The EAC Livestock Policy proposes that a regional Animal Resources Committee (ARC) be formed to advise the EAC Agriculture and Food Security Council of ministers on technical matters of animal resources development. The EAC Secretariat commits to working with Member States to prepare a national master plan of action and implementation strategy of rolling out the policy in their national livestock programmes, and that the national master plans will facilitate prioritization of actions by each Member State to reflect its context, and it will detail implementation timeframe, specific actions, investments, responsible actors, and the indicators of progress for Monitoring and Evaluation towards achieving the policy objectives and targets.

30.4.3 Economic Community of Central African States (ECCAS)

The Economic Community of Central African States (ECCAS) was established in 1983 through a Constitutive Treaty, which was revised and adopted and entered into force in 2019. ECCAS is made up of 11 Member States—Angola, Burundi, Cameroon, the Central African Republic, Congo, Gabon, Equatorial Guinea, the Democratic Republic of Congo, Rwanda, Sao Tome and Principe, and Chad.

The ECCAS region prides itself in possessing significant agricultural and forestry potential. It hosts the Congo Basin Forest, Africa's largest rainforest, and also known as "*the Green Heartland of Africa*". Relevant policy and strategy instruments in the field of Agriculture and food security include the development and adoption, in 2015, of the Common Agricultural Policy of ECCAS (CAP-ECCAS) and the Regional Programme for Agricultural Investment, Food Safety, and Nutrition (PRIASAN). In addition, Ministers of ECCAS Member States in charge of Agriculture, Livestock, and Fisheries made a Declaration in support of the transformation of Agriculture in Central Africa in accordance with the commitments of the 2014 AU Malabo Declaration.

In 2022, AU-IBAR convened a high-level technical Regional Workshop on Capacity

Building on the Guidelines to Strengthen the inclusion of Livestock in the Regional and National Agricultural Investment Plans (RAIPs and NAIPs) as part of the initial Livestock Sector Review of the ECCAS CAP and PRIASAN. AU-IBAR is partnering with ECCAS, FAO, and other partners to reformulate the ECCAS CAP and the PRIASAN. The formulation of the CAP and PRIASAN is considered as critical strategic initiative. However, to date, there is no regional livestock stand-alone policy document in the ECCAS Region, and individual Member States do not have specific national livestock development policies. At the same time, there are no national animal health/veterinary policies and strategies.

With funding from the European Union, the AU-IBAR is supporting the development of the livestock for livelihood in Africa (Live2Africa (AU-IBAR 2023)) project. Live2Africa is implementing the continental aspects of the Livestock Development Strategy (LiDeSA) (Sect. 30.3.5). One of the result areas is "To enhance the implementation of breeding and conservation programmes for sustainable utilization and management of African livestock." Part of this funding is being used to establish a regional chicken Layer-parent stock farm in ECCAS, at a location in Cameroon. The establishment of the farm will support other parts of the chicken value chain, including small and medium layers' commercial producers.

30.4.4 Economic Community of West African States (ECOWAS)

The Economic Community of West African States (ECOWAS—also known as CEDEAO in French and Portuguese) is a regional political and economic union of 15 countries of West Africa. It was established on 28 May 1975, with the signing of the Treaty of Lagos, with a mission to promote economic integration across the region. The stated goal of ECOWAS is to achieve "*collective self-sufficiency*" for its Member States by creating a single large trade bloc—building a full economic and trading union. ECOWAS aims to raise living standards and to promote economic development. A revised version of the treaty was agreed and signed on 24 July 1993 in Cotonou, Benin.

While ECOWAS does not have a livestock-specific policy document, the ECOWAS Agricultural Policy (ECOWAP) seeks broadly to ensure food sovereignty by reducing dependence on imports for food security and to reduce poverty, and the previous ECOWAP included a Livestock Action Plan (LAP 2011–2020). The goals of LAP cover: (1) promotion of livestock sector, specifically meat and dairy; (2) provision of security for cross-border movement of livestock and reduction of conflicts; (3) restructuring of the livestock production sector; and (4) creating a favourable environment for the development of livestock, meat, and dairy products (ECOWAS Commission 2010). In addition, ECOWAS has established an International Transhumance Certificate (ITC) which seeks to facilitate cross-border transhumance among ECOWAS member countries to assure free seasonal movement of livestock in search of water and pasture.

The operationalization of ECOWAP was done through action programs targeting six themes, namely (ECOWAS Commission 2009): (1) Water management; (2) Management of other shared natural resources; (3) Sustainable development of farms; (4) Markets and supply chains; (5) Prevention and management of food crises and other natural disasters; and (6) Institutional strengthening. In addition, there was a cross-cutting programme focused on the development of an Agricultural Information System (AGRIS).

While ECOWAP, through the LAP, addresses issues critical for livestock keepers in the region, it does not explicitly cover policies and strategies aimed at characterization, conservation, and sustainable use of indigenous AnGR. An examination of the policy landscape of individual ECOWAS member countries reveals that a large proportion of Member States have overarching visions and agriculture sector development policies and strategies, but more than half of them do not have specific livestock development policies

or strategies. Similarly, most of the Member States have not developed animal health/veterinary policies or strategies, and the existing animal health legislations were enacted decades ago and are generally out of tune with current needs.

30.4.5 The Intergovernmental Authority on Development (IGAD)

The Intergovernmental Authority on Development (IGAD) in Eastern Africa was created in 1996. It succeeded the Intergovernmental Authority on Drought and Development (IGADD) which was founded in 1986 to mitigate the effects of the recurring droughts and other natural disasters that resulted in widespread famine, ecological degradation, and economic hardships in the region. The founding members were Djibouti, Ethiopia, Kenya, Somalia, Sudan, and Uganda. Eritrea joined in 1993 and South Sudan joined in 2011. During the launching of IGAD, members decided to enhance regional cooperation in three priority areas, namely, food security and environmental protection; economic cooperation, regional integration and social development; and peace and security.

Approximately 70% of the IGAD region is arid and semi-arid and is home to about 75% of the livestock population of the IGAD region. It is, therefore, not surprising that IGAD has developed many initiatives and programmes that address issues germane to animal resources. IGAD Drought Disaster Resilience and Sustainability Initiative (IDDRSI) was established following the severe drought that devastated the region in 2010/2011 period. IDDRSI aims at addressing the effects of drought and related shocks in the IGAD region in a sustainable and holistic manner. It has seven priority intervention areas, namely, (1) Natural Resources and Environment Management; (2) Market Access, Trade, and Financial Services; (3) Livelihood support and Basic Social services; (4) Disaster Risk Management, Preparedness, and Effective Response; (5) Research, Knowledge Management, and Technology Transfer; (6) Conflict Prevention, Resolution, and Peace Building; and (7) Coordination, Institutional Strengthening, and Partnerships.

The IGAD Centre for Pastoral Areas and Livestock Development (ICPALD) was established in 2012 as a specialized institution to "*promote and facilitate sustainable and equitable drylands and livestock development in the IGAD region*". ICPALD is expected to provide a platform for regional cooperation and coordination in drylands, and livestock development, including animal health, production and marketing, enhanced dryland agriculture, and value-added alternative livelihood products.

In 2022, IGAD developed a Strategy (2022–2037) for Sustainable and Resilient Livestock Development in View of Climate Change (IGAD 2022). The goal and purpose of the Strategy is to provide a framework to support the identification and prioritization of policies and actions to increase the resilience and sustainability of the livestock sector to climate change impact in the IGAD region. One of the priority intervention areas is on natural resource base and ecosystem services for livestock production, and one of its aims is to facilitate preservation of regional biodiversity.

IGAD has also collaborated with the AU-IBAR (IGAD and AU-IBAR 2018), to develop a model policy framework to guide IGAD Member Countries as they develop policy and legal instruments to support characterization, conservation, and sustainable use, including access to, and benefit-sharing of, animal genetic resources. The model policy framework is expected to contribute to the development of the National Action Plans on AnGR as provided for in the Global Plan of Action. The framework has five policy objectives, namely:

Policy Objective 1: Ensure the conservation of indigenous farm animal genetic resources and significantly improve their contribution to the livelihood of livestock keepers and the national economy.

Policy Objective 2: Ensure the national actions and multi-national collaboration of countries in the conservation and use of trans-boundary indigenous farm animal genetic resources.

Policy Objective 3: Develop a mechanism for sustainable utilization and development of indigenous animal genetic resources in tandem with the larger global community.

Policy Objective 4: Ensure mainstreaming of conservation and sustainable utilization of animal genetic resources in the various sectors and within and without the continent's borders.

Policy Objective 5: Ensure that global commitments are met, and agreements are kept in the implementation of indigenous farm animal genetic resources conservation, sustainable use and access, and equitable benefit-sharing.

It is envisaged that lessons from this process and its eventual rollout in IGAD Member States will inform approaches to be applied to support other African regions and countries towards development and operationalization of policies and strategies on animal genetic resources.

The policy landscape in IGAD Member States remains diverse. While some countries (e.g. Djibouti, Ethiopia, and Eritrea) have developed and operationalized national livestock policies and strategies, previously unstable countries such as South Sudan and breakaway Somalia republics have not. However, other than Ethiopia (Sect. 30.5.2), IGAD Member States, like the majority of African countries, still do not have operational policies that specifically address characterization, conservation, and sustainable use of animal resources.

30.4.6 The Southern African Development Community (SADC)

The Southern African Development Coordination Conference, SADCC, the forerunner of the Southern African Development Community (SADC), was established in April 1980 by governments of nine Southern African countries. Today's SADC comprises 16 Member States: Angola, Botswana, Comoros, Democratic Republic of Congo, Eswatini, Lesotho, Madagascar, Malawi, Mauritius, Mozambique, Namibia, Seychelles, South Africa, United Republic Tanzania, Zambia, and Zimbabwe. The mission of SADC is to promote sustainable and equitable economic growth and socio-economic development through efficient, productive systems, deeper cooperation and integration, good governance, and durable peace and security so as to be a competitive and effective player in international relations and the world economy.

The SADC has developed a Regional Agricultural Policy (SADC-RAP) which defines agreed objectives and measures to guide, promote, and support actions at regional and national levels in the agricultural sector of the SADC Member States in contribution to regional integration and the attainment of the SADC Common Agenda (SADC 2013). Observing that few farmers are able to access improved and adequate levels of supply of technologically improved plant and animal genetic material, and that this seriously impedes agricultural production and productivity, the policy commits SADC to complement national interventions by promoting and supporting measures to improve farmer access to improved plant and animal genetic material and the adoption of biotechnology in crop and livestock development. The policy also identifies the lack of capacity to regulate GMOs as a potential deterrent to embracing and adequately harnessing biotechnology. In this regard, interventions proposed include (1) Facilitating private-public sector initiatives that promote economies of scale in production and distribution of improved seeds, as well as other plant and animal genetic materials; (2) Promoting forage research and the establishment of viable forage seed industry; (3) Promoting regional value-chain partnerships in stock-feed production; (4) Facilitating agreement on a harmonized approach to the safe use of modern biotechnology and clarifying how to deal with GMOs; (5) Promoting national capacity and regional collaboration for research in biotechnology and biosafety; and (6) Facilitating the implementation of the SADC Harmonized Seed Regulatory System.

Of more direct relevance to animal genetic resources, the policy recognizes that *the SADC region is endowed with a wealth of plant and animal genetic resources and indigenous innova-*

tions with the potential to contribute significantly to economic growth and people's well-being, but that these genetic resources are rapidly being lost. To address this, *SADC shall complement national interventions by promoting and supporting measures for conservation and* sustainable use *of plant and animal genetic resources for food and agriculture*. Like in the EAC livestock policy, the SADC agricultural policy proposes specific interventions that speak to conservation and sustainable use of animal resources. These include:

- Promoting ex-situ and in situ (on-farm) conservation of genetic resources for food and agriculture.
- Strengthening national and regional capacity to conserve genetic resources.
- Promoting the development of crop varieties and animal breeds that are adaptable to climate change and variability.
- Promoting the access and benefit-sharing of plant and animal genetic resources for food and agriculture.
- Promoting collection and dissemination of information on genetic resources to enhance utilization of conserved material.

In the R&D domain, the regional policy states that SADC shall complement and support measures by Member States to promote agricultural research and development in crops, livestock, fisheries, and forestry, with specific intervention areas being: Providing policy guidance for the region's agricultural R&D; Promoting innovation for strategic and demand-driven R&D; Promoting private, public, and international partnerships in R&D; Harmonizing policy frameworks on protection of intellectual and property rights including indigenous knowledge systems; and Informing strategies and instruments to effectively promote increased adoption rates of appropriate technologies by farmers, such as through research, capacity building, and exchanges and dissemination of experiences.

In addition to the uniqueness of the SADC livestock policy in its explicit attention to animal (and plant) genetic resources, it is also unique in the way it was developed and the ownership this has created among its Member States and other crucial stakeholders. Member States acknowledge the key success factors in the implementation of the Regional Agricultural Policy as: (1) Recognition of the high potential of SADC region to be a leading agricultural producer and commitment to unleashing this potential; (2) Member States agree to focus on a few actions with the most rapid impact on agricultural growth, and within those specific objectives, focus on a few selected strategic interventions and commodities at a time; (3) Strong political will and commitment to the Policy by all Member States and key stakeholders through its alignment with, and domestication into, national policies, strategies, and programmes; (4) Establishment of an Agricultural Development Fund (ADF) as an in-built financial instrument under the Policy's Regional Agricultural Investment Plan (RAIP) that corresponds to interventions under Member States' own CAADP National Agricultural Investment Plans (NAIPs); (5) Establishment of a strong monitoring and evaluation system involving SADC Secretariat, Member States, and key stakeholders; (6) Creation, partly through adaptation of existing arrangements, of a mechanism for full engagement of private sector organizations, e.g. through public, private partnerships (PPP), in the implementation of accelerated agricultural development programmes promoted under the Policy; (7) Confidence built among financial partners regarding the effectiveness of the policy agenda and its governance; (8) Progressive elimination of barriers to trade and investment in compliance with the SADC Trade Protocol and Annexes; (9) Establishment of the requisite infrastructure to support agricultural development; and (10) Intentional mainstreaming of gender, youth, HIV/AIDS, environment, climate change and variability, and other cross-cutting issues into the Policy interventions at both regional and national levels. This Policy is implemented in 5-year reviewable cycles. This is to ensure responsiveness to change and progressivity, including recognition that capacity and systems will be developed and strengthened over time.

At the national level, the SADC livestock policy landscape is quite variable. Although Member States have demonstrated ownership of the regional policy, its translation, specifically the livestock dimensions relevant for animal genetic resources, into national policies remains limited. Indeed, only a few SADC countries (see Sect. 30.5.1) have developed livestock policies and strategies, although the situation is beginning to change. For example, Zambia has had no specific Policy to guide livestock development since independence and, until 2020, the livestock sector operated under a legal framework with a multiplicity of laws that governed specific areas of livestock development. National stakeholders recognize that the lack of a policy and legal framework has constrained effective development of the Zambian livestock sector. An example of an outcome of the AU-IBAR engagement with countries through SADC is the development of the Zambia National Livestock Development Policy (2020) (Zambia-MoFL 2020) which specifically addresses the promotion of sustainable Farm Animal Genetic Resources through, among other things, evaluation and conservation of indigenous breeds and the creation of animal genetic resources management database—a Livestock Information Management System (LIMS). Malawi has also recently developed a National Livestock Development Policy (2021–2026) (Malawi-MoA 2021). However, the policy does not articulate specific interventions that touch on indigenous animal resources, especially with regard to conservation and sustainable use.

On the positive side, all SADC Member States have elaborate animal health legislations, although some are decades old and could benefit from revision.

30.5 National Livestock Policy Instruments, Strategies, and Actions

As is clear from Sect. 31.4, progress made by the different Regional Economic Community blocks in regard to policies, strategies, and actions on AnGR differ substantially. But even more important, the differences among countries within and between these blocks are so substantial that the location of a country in a REC block is not a good indicator of status of progress. In addition, while most national livestock development policy and strategy documents recognize the importance of AnGR in transforming the livestock sector and provide recommendations for action, implementation is quite limited and varied among countries.

30.5.1 Overview of Country Situations

This section provides an overview of country situations in regard to the development and implementation of AnGR-relevant policies and strategies. As has been alluded to in earlier sections, only a small number of countries have stand-alone livestock policies, and AnGR is covered to varying extents in livestock sector policies and strategies. In most countries AnGR policy coverage is embedded in broader agricultural policies, strategies, and plans. Table 30.5 summarizes the current status of African countries in terms of policies and strategies specific to AnGR and associated implementation instruments. The latter include National Strategies and Action Plans (NSAPs) as per the Global Plan of Action (GPA) and Animal Performance Recording Schemes. Only six countries have policies which explicitly address AnGR. This compares to 15 countries which have established NSAPs and 14 which have Animal Recording Systems in place. This speaks to the fact that, while intentions expressed in policies are important, operational systems can be, and has been in some countries, put in place in the absence of policies.

Table 30.5 also indicates which countries have gene banks for AnGR, as well as countries with private sector-driven breed societies—which are crucial vehicles for sustainable management of AnGR. The institutional contexts and governance mechanisms of these gene banks are quite varied. The range includes those that were originally

Table 30.5 Summary of status of policies and implementation instruments by African countries

Policy, strategy, framework of plans	Established or planned	No. of countries
1. Specific policies and strategies for AnGR	Ghana, Kenya, Uganda, South Africa, Tanzania, Zambia	6
1.1.2. National strategies and action plans for AnGR	• *Developed and implementation underway (at differing stages and paces):* Mali, Mauritania, Guinea, Sierra Leone, Liberia, Sudan, DRC, Uganda, Kenya, Zambia, Zimbabwe, Namibia, Lesotho, Eswatini, Madagascar	15
	• *Development is in progress:* Algeria, Niger, Nigeria, Burkina Faso, Benin, Ghana, Ethiopia, Rwanda, Tanzania, Mozambique, Botswana, and South Africa	12
	• *Development is planned (and resources allocated)*: Senegal, The Gambia, Cameroon, Gabon, and Burundi	5
3. National animal performance recording schemes or breeding centres	Algeria, Botswana, Burundi, Cameroon, Egypt, Ethiopia, Kenya, Lesotho, Namibia, South Africa, Swaziland, Tunisia, Zambia, Zimbabwe	14
4. Livestock breeders' associations	Algeria, Mauritania, Mali, Burkina Faso, Cote d'Ivoire, Guinea, Niger, Nigeria, Cameroon, Egypt, Uganda, Kenya, Tanzania, Rwanda, DRC, Zimbabwe, Mozambique, Namibia, South Africa	19
5. Gene banks for AnGR	Botswana: *FAnGR Gene Bank*, *DAR*[a] Burkina Faso: *CIRDES*[b], *Bobo-Dioulasso* Cameroon: *The University of Dschang* Egypt: *National Gene Bank*, *Cairo* Ethiopia: *Biodiversity Institute*, *Addis Ababa* Kenya: *Kenya AnGR Centre*, *Kabete* Nigeria: *NACGRAB*[c], *Ibadan* Rwanda: *National Gene Bank*, *Huye* South Africa: *GCRB*[d], *Irene*; and *ARC*[e], *Irene* Tunisia: *Banque Nationale de Genes*, *Tunis* Uganda: *NAGRC&DB*[f], *Entebbe* Zimbabwe: *CUT Bank*[g], *Chinhoyi*	12

[a]Farm Animal Genetic Resource gene bank, Department of Agricultural Research (DAR)
[b]Centre International de Recherche-Développement sur l'Élevage en zone Sub-humide (CIRDES)
[c]National Centre for Genetic Resources and Biotechnology (NACGRAB)
[d]Germplasm Conservation and Reproductive Biotechnologies (GCRB)
[e]Agricultural Research Council (ARC) Loskop Conservation Centre
[f]National Animal Genetic Resource Centre and Data Bank (NAGRC&DB) in Entebbe, Uganda, in East Africa
[g]Chinhoyi University of Technology Semen Station and Cryobank (CUT Bank)

established as Artificial Insemination (AI) Centres under government ministries or departments responsible for livestock development (e.g. Kenya AnGR Centre came out of what used to be the Central Artificial Insemination Station, CAIS), to those established specifically to facilitate AnGR conservation (e.g. Ethiopia's

Biodiversity Institute—originally focused on crops, before expansion to cover livestock), to one initiated independently by a University (e.g. Chinhoyi University of Technology Semen Station and Cryobank, the CUT Bank, in Zimbabwe), and one established by a regional livestock centre, but now serving as a national facility (the CIRDES Gene Bank in Burkina Faso). The case of the National Animal Genetic Resources Centre and Data Bank (NAGRC and DB) in Uganda is quite unique. It was established through an Act of Parliament, the *Uganda Animal Breeding Act of 2001*, to provide for the promotion, regulation and control, marketing, import and export, and quality assurance of animal and fish genetic materials and to provide for the implementation of the national breeding policy in Uganda.

30.5.2 Selected Country Case Studies

As alluded to above, countries differ substantially in terms of where they are on policy, strategies, and action plans relevant for conservation and use of AnGR (Sect. 30.5.1). This section provides case studies of six countries (Ethiopia, Ghana, Kenya, Nigeria, South Africa, and Tanzania) to illustrate the diversity of country contexts and current situation, including specific interventions that different countries are pursuing. The case studies illustrate the many dimensions of differences: the role of the private sector, especially breed societies and Stud Book; the role of public sector beyond development of policy and legislation—e.g. actions catalyzing industry practice; the role civil society can play; and the strong links that can be leveraged among characterization, conservation, and use.

30.5.2.1 Ethiopia

Ethiopia has a well-established Biodiversity Institute (originally focused on plant genetic resources) and has fully mainstreamed and institutionalized biodiversity conservation and sustainable use. The country has developed several policies and legal frameworks in this regard. The Biodiversity Institute is mandated to undertake conservation and promote development and sustainable utilization of the country's biological resources, namely: plants, animals, and microbial genetic resources as well as associated traditional knowledge and the ecosystems. The institute has the responsibility to implement international conventions, agreements, and obligations on biodiversity to which Ethiopia is a party. These include the proclamation on Access and Benefit-Sharing, the establishment of animal genetic resources directorate within the Biodiversity Institute, and the enactment of animal breeding policy. The breeding policy emphasizes on indigenous genetic resources through selection, improvement, and conservation.

Ethiopia's National Biodiversity Conservation and Research Policy (1998) and, subsequently, the National Biodiversity Strategy and Action Plan (2005) (IBC 2005) provide guidelines for conservation, development, and sustainable use of biodiversity. The policy objective is to ensure that genetic resources and essential ecosystems of the country are conserved, developed, and sustainably used, asserting national sovereignty over genetic resources, enriching the country's biological resources through restoration, integrating biodiversity conservation with sectoral and cross-sectoral strategies and programs, recognizing and protecting traditional knowledge, ensuring that the local communities obtain shares of benefits arising from the use of genetic resources and indigenous knowledge, and promoting regional and international cooperation.

In 2012, Ethiopia developed a draft National Strategy and Plan of Action for Conservation and Sustainable Utilization of AnGR in line with the Global Plan of Action (IBC 2012). The vision of the Strategy is conserving *animal genetic resources for food and agriculture and promoting its use in support of national* food security *and sustainable development for present and future generations*. Its goals are: Promotion of sustainable use and development of animal genetic resources for food security, sustainable agriculture, and human well-being; Ensuring conservation of animal genetic resources diversity for present and future generations, and halting loss and erosion of these resources; Recognizing and

promoting the role of indigenous knowledge, innovations, and practices relevant to the conservation of animal genetic resources and their sustainable use; Ensuring fair and equitable sharing of the benefits arising from access to, and use of, animal genetic resources and associated indigenous knowledge; Putting in place effective policies and legislative measures to ensure use, sustainable development, and conservation of animal genetic resources for food and agriculture; Meeting the needs of pastoralists and farmers, individually and collectively, within the framework of national law, to have non-discriminatory access to genetic material, information, technologies, financial resources, research results, marketing systems, and natural resources, so that they may continue to manage and improve animal genetic resources and benefit from economic development; Promotion of agro-ecosystems approaches for the sustainable use, development, and conservation of animal genetic resources; Assisting national regional states and institutions to establish, implement, and regularly review national and regional priorities for the sustainable use, development, and conservation of animal genetic resources; Strengthening Federal and national regional states' programs and enhancing institutional capacity, namely education, research, and training to address the characterization, inventory, monitoring, conservation, development, and sustainable use of animal genetic resources; and Promotion of activities aimed at raising public awareness and bringing the needs of sustainable use, development, and conservation of animal genetic resources to the attention of concerned stakeholders.

Other policies and strategies that address AnGR issues directly or indirectly include Ethiopia's Education Policy, Conservation Strategies of Regional States, Agricultural Growth Program, Livestock Growth Program, and regulations and control on the introduction and export of domestic animal genetic materials.

While the Strategy and Action Plan is quite ambitious in its coverage, its operationalization has been slow. A workshop held in November 2018 to evaluate implementation Strategy and Action Plan concluded that there is a need for capacity building in farm AnGR use, development, and conservation as well resourcing of implementation programmes, with breed characterization being a top priority.

30.5.2.2 Ghana

A number of policies and strategies have been put in place to improve the performance of the livestock sector in Ghana over the years. Some of these policies and strategies have been implemented in projects such as the National Livestock Services Project, Agriculture Sub-Sector Investment Project, and Livestock Development Project. In addition, several studies addressing the development of the livestock sector have been carried out since 1995. Those relevant for AnGR include: the National Animal Breeding Plans for the Republic of Ghana (1995); the State of Ghana's Animal Genetic Resources (2003); the role of Livestock in Rural Livelihoods in Ghana (2002); and Livestock Sector Review 2010 and 2012.

Although implementation has been limited, Ghana's livestock policies (those that have been stand-alone as well as those part of overall agricultural policy) have historically consistently recognized the importance of the country's wealth of indigenous AnGR and recommended interventions on their genetic improvement and conservation. The 2004 Livestock Development in Ghana—Policies and Strategies (MOFA 2004), for example, includes a policy guideline on *improvement of* indigenous breeds *through selection of local breeds to build on the existing desired traits and conservation of local breeds to maintain the desirable resistant attributes of such breeds for future exploitation*.

Ghana's Livestock Development Policy and Strategy (LDPS) (MOFA 2016) of 2016 is underpinned by a vision of a livestock sector that is modernized, competitive, and sustainable, contributing to food and nutritional security, employment generation, equity and poverty reduction while preserving the environment. The policy document recognizes that "*previous policies have largely been ineffective as a result of non-implementation or inadequate implementation of various* strategies *as well as lack of effec-*

tive monitoring and evaluation mechanisms". The stated objective of the Policy and Strategy is to develop a competitive and more efficient livestock industry that increases domestic production, reduces importation of meat and livestock products, and contributes to the improvement of the livelihoods of all livestock value chain actors and the national economy, while protecting the environment, *preserving livestock biodiversity*, and ensuring bio-security.

The specific objectives of the LDPS are (1) to support the existing livestock production systems for improving production, productivity, and income of livestock producers; (2) to strengthen overall animal health; (3) to support training, research, and development for improving livestock production, productivity, and health as well as profitability; (4) to improve the production and productivity of livestock by promoting and disseminating technologies developed by the research system; (5) to *promote conservation and genetic improvement of* indigenous breeds *of livestock*; (6) to increase availability of feed and fodder resources to meet the requirement of various species of livestock; (7) to encourage value addition of livestock products; and (8) To create an enabling environment to attract investment and finance for improving livestock infrastructure, production, processing, value addition, and marketing.

Strategic interventions covering objective 5—promotion, conservation, and genetic improvement of indigenous breeds of livestock—include the following:

(a) Conservation of indigenous genetic material through the establishment of gene banks.
(b) Improvement of existing livestock breeding stations.
(c) Establishment of open nucleus breeding schemes.

The LDPS envisages that these interventions will be driven by the Council for Scientific and Industrial Research—Animal Research Institute (CSIR-ARI), Universities and Colleges, Ministry of Food and Agriculture (Animal Production Department), Livestock Breeders, and Farmer-Based Organizations (FBOs).

The commitment by the government to implement these policy recommendations is evident through their inclusion in the "Rearing for Food and Jobs" (RFJ) which is one of the five models of the government's flagship 5-year (2019–2023) agricultural improvement programme under the theme "Planting for Food and Jobs" (PFJ). The objective of the RFJ is to develop a competitive and more efficient livestock industry that increases domestic production, reduces importation of livestock products, and contributes to employment generation and to the improvement of livelihoods of livestock value chain actors and the national economy. Priority areas under this programme include:

- Characterization, conservation, genetic improvement, and commercialization of local chicken and guinea fowl ecotypes.
- Genetic improvement of the local Ashanti Black/Dwarf pig.
- Genetic improvement of the local sheep and goat breeds.
- Genetic improvement of Ghana Shorthorn, Sanga, N'Dama cattle breeds, and their crosses.

In its 2014 State of the World's AnGR report (to FAO), Ghana reported that the country had not done an inventory of its AnGR and that the country lacked an early warning system for AnGR. In 2015/2016 period, with AU-IBAR support, the Ghana National Animal Resources Data Management Platform (ARDMP) was developed and officially launched in August 2016. In this connection, stakeholders suggested that, to facilitate implementation, a memorandum of understanding (MOU) be developed between the Veterinary Services Directorate, the Ghana Statistical Service, School of Veterinary Medicines, Ghana Private Veterinarians Association, and other partners that will be involved in the platform, and an annual workplan be developed to guide the implementation of the National ARDMP.

30.5.2.3 Kenya

Session Paper Number 2 of 2008 on National Livestock Policy (Kenya-MoLD 2008) addresses the challenges in the livestock sub-sector, covering livestock breeding, nutrition and feeding, disease control, value-addition and marketing, and research and extension. It includes an objective on improvement and conservation of animal genetic resources, with plans to:

- Undertake a survey of livestock species, breeds, and types and evaluate them to identify potential candidates for further conservation or improvement.
- Establish nucleus herds of indigenous animal genetic resources for breeding, characterization, conservation, and utilization. Linked to this, a national gene bank for storage of AnGR germplasm would be set up and livestock registration and recording schemes will be strengthened.
- Put in place appropriate regulations to guide management and exploitation and use of animal genetic resources and establish breeding programmes with long-term selection of indigenous breeds for high productivity and local adaptive traits, especially in the arid and semi-arid areas.
- Establish a central authority—a National Focal Point—to facilitate coordination of Animal Genetic Resources activities in the country and as a link to similar regional or global focal points; and that this should be done recognizing the multiplicity of institutions involved in provision of animal breeding services in Kenya (the Kenya Stud Book, the Livestock Recording Centre, the Central Artificial Insemination Station, the Kenya National Artificial Insemination Service, the Breed Associations, individual farmers, etc.).
- Develop appropriate guidelines on breeds and production systems for various ecological zones of the country.
- Set up mechanisms to strengthen the management of breeding services and regulate breeding service providers, improve delivery of extension services, and institute export and import controls of semen, embryos, and live animals, and modernization of quality control laboratories in the Central Artificial Insemination Station (CAIS) to meet required international standards. In addition, expand mandate of CAIS to serve as a gene bank for all species of livestock.

In 2018, a draft National Action Plan on Animal Genetic Resources of Kenya (Kenya – Ministry of Agriculture and Irrigation 2018), an adoption of the Global Plan of Action, was drafted and is still under discussion. Subsequently, Kenya has embarked on the formulation of policies that guide the management of AnGR in the form of the national livestock policy, dairy development policy, poultry development policy, and the feeds policy.

The Establishment of the Kenya Animal Genetic Resources Centre (Kagrc)

Established in 2011, the Kenya Animal Genetic Resources Centre (KAGRC) succeeded the Central Artificial Insemination Station (CAIS) which was established back in 1946 with the objective of controlling reproductive diseases and genetic improvement of exotic dairy cattle.

KAGRC has the mandate to produce, preserve, and conserve animal genetic materials (semen embryo, tissues, and live animals) and to produce breeding sires to produce high-quality disease-free semen to meet the national demand and for export. To meet its mandate, KAGRC works in close collaboration with other breeding organizations such as the Kenya Stud Book, the Dairy Recording Services of Kenya, and the Livestock Recording Centre. Together, these organizations implement the Contract Mating and Progeny Testing Programmes. KAGRC works closely with the breed societies as well as individual and institutional farms which provide herds for the breeding programme.

A draft National Livestock Policy (Kenya-MoLD 2019) was developed in 2019 but has not been operationalized. However, Sessional Paper Number 3 of 2020 (Kenya-MoLD 2020) on National Livestock Policy amplifies and seeks to operationalize the content of the 2019 draft policy. Both instruments emphasize intentions of

Sessional Paper Number 2 (2008). However, having been developed after the creation of devolved County governments, both the draft policy of 2019 and Sessional Paper Number 3 propose roles of national (national infrastructure, legislation, national animal identification system, import and export procedures) and sub-national (County) governments (mostly focused on characterization, animal performance recording, and conservation through use). The livestock dimensions of the 2021 Agricultural Policy (Kenya-MoALC 2021) also express commitment to biodiversity conservation, including attention to indigenous crops and livestock as critical components to ensure adaptable and resilient agriculture.

30.5.2.4 Nigeria

The Nigerian National Centre for Genetic Resources and Biotechnology (NACGRAB) is a Federal Government Parastatal institution which was established in 1987 under the Federal Ministry of Science and Technology with a mandate to collect and conserve valuable genetic resources for food and agriculture and ensure that they are used sustainably. The Federal Government of Nigeria promulgated Decree No. 33 of 1987 (Federal Government of Nigeria 2016) (now amended as Act of Parliament, 2016). The Act establishes the National Crop Varieties and Livestock Breeds Register and provides for the insertion in the Register of the names of old and new crop varieties and livestock breeds. The Act also establishes the National Crop Varieties and Livestock Breeds Registration and Release Committee (the National Varietal Release Committee, NVRC), which has responsibility for crop varieties and livestock breed validation, registration, naming, and release in the country.

One of the activities of NACGRAB is the coordination of the National Committee on Naming, Registration, and Release of new Crop Varieties and Livestock/Fisheries breeds through various Technical Sub-Committees. The Centre maintains gene banks for both Plant and Animal Genetic Resources. The stored materials are registered and subsequently evaluated for performance characteristics. The Technical Sub-Committee of Livestock/Fisheries of the NVRC has compiled descriptors for registration of both the existing and new livestock/fisheries breeds or strains into a database—the National Register or Catalogue.

The NACGRAB gene bank for crops is located in Ibadan in south-west Nigeria. The AnGR unit was established in 2004 as one of the core units of the Centre and currently has ex situ conservation activities on poultry, fishery, snails, small ruminants, cane rats, and rabbits. The functions of the unit include:

- Exploration, collection, and conservation of indigenous animal genetic resources.
- Preservation of endangered animal genetic resources.
- Genetic characterization and evaluation of animal genetic resources.
- Conduct of research in conservation and utilization of animal genetic resources, including the use biotechnology tools.
- Assisting National Varietal Release Committee (NVRC) in the naming of livestock breeds and fisheries strains, as well as registration, and release activities.

The coordination of AnGR activities in Nigeria is the remit of the Federal Department of Animal Husbandry Services (DAHS) of the Federal Ministry of Agriculture and Rural Development (FMARD) which is also the FAO representative for the AnGR management for Nigeria. One of the activities of the DAHS is to document and regularly update information on AnGR. Nigeria's National Advisory Committee (NAC) on Animal Genetic Resources was inaugurated in 2018. Nigeria has also developed a draft National Animal Breeding Policy. This document was developed by FMARD in collaboration with Animal Breeders' and Geneticists' Network of Nigeria (ABGeN-NG), which is a network of animal breeding and genetics experts drawn from the Nigeria Institute of Animal Science (NIAS), Genetics Society of Nigeria (GSN), and the Nigerian Society for Animal Production (NSAP).

Nigeria's Progress Report for the 2014–2019 period on the National Strategy and Action Plans

on AnGR states that the NSAP was due to be completed in 2020. However, it has stalled "due to lack of funding". Indeed, while institutional roles for AnGR are well laid out in various documents, not much has happened in the last decade, mostly due to inadequate budget allocation. Consequently, information on status of breeds in Nigeria remains limited. Most of the figures cited on breed sizes and characteristics are from old and limited data.

30.5.2.5 South Africa

The *Animal Improvement Act* of South Africa was passed in 1998 (Act No. 62) (Republic of South Africa 1998) and its associated regulations were finalized in 2002. Its purpose is to provide for the breeding, identification, and utilization of genetically superior animals in order to improve the production and performance of animals in the interest of the Republic. The Act focuses on the implementation and documentation of breeding animals and addresses the type and scope of performance testing and recording in compulsory breeding programmes. In addition, the Act has provisions on the implementation and use of biotechnology in artificial insemination and embryo transfer, the approval of breeding associations, breeding companies, insemination centres, embryo transfer institutes and their breeding programmes, herd-book regulations (herd-book recording) and their areas of activity, conditions for import and export of animal genetic material, and the roles of breed companies and the stud book in these processes. The responsibility for the implementation of the Act lies with the Registrar of the Animal Improvement Act who is appointed by the Minister responsible for Livestock.

To support legislation and regulation of the Animal Improvement Act, and to guide implementation, an Animal Improvement Policy (Republic of South Africa 2007) was developed and gazetted in November 2007. The objectives of the policy include promoting the sustainable use of Animal Genetic Resources as major contributor to national food security and facilitating the conservation of Animal Genetic Resources for Food and Agriculture. The policy explicitly recognizes the importance of indigenous livestock breeds, the threats they face, the need for action to conserve and commercialize them as a means of ensuring their sustainable use, and the role of indigenous knowledge and the rights of owners and breeders.

In addition to the Animal Improvement Act, other instruments which underpin the Animal Improvement Policy include: the Animal Identification Act of 2002; National Animal Improvement Schemes; and a National Advisory Committee for AnGR conservation and improvement.

South Africa and the Global Plan of Action

South Africa has submitted to FAO its report on The First and Second State of the World's Animal Genetic Resources for Food and Agriculture. In addition, the AU-IBAR has engaged the Department of Agriculture, Forestry and Fisheries (DAFF) of South Africa through the Directorate of Genetic Resources to initiate the formulation of the National Strategy and Action Plan for AnGR (NSAP) as provided for in the FAO-led Global Plan of Action (GPA), and a draft of the NSAP has been prepared in form of a comprehensive report of the NSAP process (Republic of South Africa 2016). The emerging NSAP has three strategic priority areas, namely, (a) characterization and inventory of farm AnGR; (b) sustainable use and development of farm AnGR; and (c) conservation of farm AnGR.

A validation stakeholder workshop was held in 2019. However, the NSAP has not been operationalized in South Africa to date.

The South Africa Stud Book

South Africa presents one of the best examples of commercializing local breeds as a means for ensuring their sustained use. The South Africa Stud Book, an association of 63 livestock and animal breeders' societies, is a crucial instrument for development and commercialization of livestock breeds. Current breeders' societies include 26 cattle, 15 small ruminants (sheep and goats), 16 horse breeders' societies, and six breeders' societies for other species. These societies cover 77 different animal breeds. The Stud Book also

handles the registrations of 29 other breeds—minor breeds that do not have breed societies.

The vision of the Stud Book (The South Africa Stud Book 2023) is to develop exceptional domestic animals and establish them as a sustainable resource and treasure for all South Africans. Its mission is to be a significant role player in the genetic improvement of animals in South Africa. Its aims are to:

- Promote the breeding, conservation, and genetic improvement of the production potential of animals under its jurisdiction
- Facilitate pedigree and performance recording of animals and issue certificates of registration for recorded animals
- Safeguard and advance the collective interests of stud breeders and their breeders' societies and act as a mouthpiece for the stud-breeding industry
- Represent the collective interest of animal breeders and their societies on various national and international bodies and forums
- Provide technical and advisory services to breeders' societies, their members, and participants in the Integrated Registration and Genetic Information System (INTERGIS)
- Promote the export of animals with pedigrees registered or recorded with the association and of semen, ova or embryos from animals thus registered or recorded.

While the SA Stud Book covers exotic breeds (dairy cattle, beef cattle, and sheep), it is actively involved with several indigenous breed societies, namely: Nguni, Afrikaner, Bonsmara, and Drakensberger cattle breeds; Dohne, Dorper, Persian, Pedi, Damara sheep breeds; and Savannah, and Boer Goat breeds. This list also demonstrates the extent to which South Africa has been involved in developing and commercializing local composite breeds—Bonsmara and Drakensberger cattle, and Dohne Merino and Dorper sheep.

The extent of commercial orientation of South Africa's livestock industry is also reflected in the number of registered breeds and those with breed societies (Table 30.6). Unfortunately, as is the case in most African countries, stud-breeding has not made much inroad into the traditional smallholder (or communal) livestock sector of South Africa. Institutionalizing the integration of stud breeding in the smallholder sector and accompanying increase in numbers of pure stock (of indigenous breeds preferred by certain communities)—to the benefit of both the communal and stud cattle breeders—can potentially significantly improve management of AnGR in this historically marginalized sector of South Africa.

Table 30.6 Number of livestock breeds and breed societies in South Africa

Species	No. of breeds	No. of breed societies
Cattle	42	25
Dog	2	2
Goat	11	3
Horse	28	17
Ostrich	1	1
Pig	5	1
Sheep	26	12
Total	*115*	*61*

Source: The South Africa Stud Book (2023)

In some cases, where no formal breed society exists, breeder clubs undertake these roles, especially the promotion and marketing.

The Farm Animal Conservation Trust (FACT)

South Africa is effectively engaging Farm Animal Conservation Trust (FACT), an NGO, in the conservation of farm AnGR. FACT is modelled on the Rare Breeds International (RBI) and the Rare Breeds Survival Trust (RBST) in the United Kingdom. FACT has been involved as a partner in a national initiative that involves public sector institutions to create awareness and promote hitherto endangered indigenous livestock breeds. The other partners involved are the Department of Agriculture, Land Reform and Rural Development, the Agricultural Research Council, some public universities, and the Department of Sport, and Arts and Culture (responsible for identification, assessment, management, protection, and promotion of heritage resources in South Africa). As part of promotion of endangered indigenous breeds, FACT activities include the

preparation and dissemination of information on them and facilitating conservation through commercial use. In this regard, FACT has facilitated the publication of a booklet on South Africa's landrace breeds. In the meantime, South Africa has made significant progress in collecting, cataloguing, and storing available literature on the origins, domestication, and historical usage and evolution of its indigenous breeds and their production environments. The database is based at the Irene Animal Improvement Institute. It is considered that availability of this information will spur interest in these neglected breeds, including by smallholder farmers in traditionally marginalized communities.

30.5.2.6 Tanzania

Tanzania is an excellent case study of challenges African countries face in the *Policy-to-Practice* connection. In the last three decades, the country has had a good track record of consistently developing livestock policy frameworks and strategies—either as stand-alone documents or as part of overall agricultural policies. However, there has been limited translation of these policies to actions on the ground. Moreover, attention to indigenous animal genetic resources has been flip-flopping and, as in many African countries, there is little evidence that the intentions expressed in these past policy and strategy instruments have made a difference in improving the state of indigenous animal genetic resources. The National Livestock Policy (NLP) of 2006 (Tanzania-MoLD 2006) document states that its aim is to streamline livestock areas which were previously neglected (in the *1997 Agricultural and Livestock Policy* (Tanzania-MoAC 1997)) combined with crop-related services such as regulatory, technical, and cross-sectoral services. The 1997 policy statements on livestock emphasized crossbreeding or upgrading with high-performance exotic breeds to improve productivity. The 2006 policy expresses the intention to promote livestock breed inventory, characterization, evaluation, and genetic improvement, as well as to strengthen technical support services in animal breeding. It also recognizes the need to promote Breeders Associations to ensure sustainable conservation, breeding, and use.

The Tanzania Livestock Modernization Initiative (TLMI) (Tanzania-MoLFD 2015) of 2015 aimed to implement the National Livestock Policy (NLP) of 2006 in the context of the National Five-Year Development Plan and other national and sectoral plans and programmes. One of the strategic priorities was the improvement of the quality and performance of Tanzanian livestock populations, the preservation of the resiliency of indigenous breeds while optimizing performance gains, underpinned by conservation interventions. The TLMI calls out selection of desired characteristics of resilient and productive improved breeds, paying attention both to genetic and production environment, including feed and health, improvement. It recognizes that genetic heterogeneity of Tanzania's indigenous livestock can be exploited to develop adaptability to climate change, refers to the existence of a Livestock Identification, Registration and Traceability Act (Tanzania-MoLD 2010), and calls for "*Swift enactment of an Animal Breeding Act, that incorporates and facilitates the major tenets of the Tanzanian livestock breed improvement programme*".

In 2017, Tanzania developed a Livestock Master Plan (TLMP) (Tanzania-MoLF 2017). The TLMP recognized that better coordination of the development and protection of animal genetic resources in Tanzania should include the establishment of reliable and sustainable germplasm delivery systems and the involvement of the private sector in animal genetic improvement. It proposed the establishment and enforcement of a legal framework, including the development of an animal breeding policy and the implementation of the animal breeding bill (under development then). It recognized that livestock selection for genetic improvement needed to focus on: (1) Ensuring effective breeding, selection, and conservation programmes are in place, including open nucleus breeding schemes and the renovation of public livestock farms and artificial insemination centres; (2) the establishment of performance recording systems for on-station and on-farm breed evaluation programmes for

both locally adapted and exotic breeds and their crosses; and (3) training and support to strengthen animal breeding infrastructure, such as artificial insemination and laboratories. Unfortunately, like the previous ambitious instruments, the intentions espoused in the TLMP are not supported in the more recent Livestock Sector Transformation Plan (LSTP, 2022) (Tanzania-MoLF 2022) which, while recognizing that the country has a large population of indigenous livestock breeds, decries their low productivity, and proposes strengthening of artificial insemination to upgrade them. The LSTP focuses heavily on productivity improvements and does not make any explicit plans for improvement and/or conservation of the well-adapted indigenous animal genetic resources, which could be put at risk by the proposed emphasis on crossbreeding with exotic breeds. Of note is that Tanzania is credited with the development of a highly promising composite cattle breed, the Mpwapa (see Chap. 4). Unfortunately, lack of policy to underpin sustained investment in this initiative has led to the neglect of this breed. Today the Mpwapwa breed is disappearing fast, and will be extinct soon, unless intentional conservation and further development are undertaken urgently.

In 2019, supported by AU-IBAR, Tanzania developed a *National Compact Strategies and Action Plan to implement Global Plan of Action for Animal Genetic Resources* (Tanzania-MoLF 2019). The goal of the Action Plan was to guide conservation and sustainable utilization of AnGR and its contribution to the livelihoods of the people in Tanzania and the national economy. The stated objectives are to: Carry out a comprehensive inventory, characterization, and monitoring of trends and associated risks of livestock breeds for all species existing in the country, including their production systems; promote sustainable use of AnGR through adoption of modern technologies and indigenous knowledge; develop a comprehensive framework and ensure conservation of AnGR; and influence policy and strengthen institutional capacity in terms of technical and infrastructure. Not only has the Action Plan not been implemented, but key livestock stakeholders, including those active in AnGR work in the country, do not even know of its existence and/or status of implementation.

In an analysis of food production and supply in Tanzania during the period 1961–2001, Isinika et al. (2003) observed frequent policy changes and remarked that despite good intentions of the government, some of the policies failed to deliver intended results due to market and institutional distortions which were introduced. The government has tended to overreact to emerging problems that affect agricultural production and other development plans (and policies and strategies are often developed without accompanying implementation instruments, especially resourcing). The analysis alludes to limited capacity for policy analysis in order to determine their broad ramifications before they were adopted for implementation and that the frequent policy changes brought uncertainty and increased risk for producers and traders (investors) with consequent detrimental effects to the nation. It is estimated that during the period in question, Tanzania had a policy change or a government directive that affected the agricultural sector every 2–3 years.

30.6 Summary and Conclusions

African livestock keepers are encountering challenges in their efforts to achieve food security and improve their livelihoods. Sustainable intensification of livestock production systems is essential to successfully address these challenges, and indigenous AnGR have a critical role to play in this. While awareness about needed actions, including the role of policies, legislation, strategies, and plans, has increased in Africa substantially, especially since development of the Global Plan of Action (GPA), and many initiatives have been initiated in Africa to catalyse action, indigenous AnGR continue to decline. Promotion of a limited number of supposedly more productive breeds is a major driver of the continuing decline of local breeds, a crucial resource for low-input livestock systems of poor smallholder farmers.

Taken together, the analysis of efforts by AU-IBAR and its partnership with RECs suggest that the development of policies on conservation

and sustainable use in Africa has, by and large, not translated into improvements in the state of indigenous AnGR in Africa. Only a limited number of countries have developed policies and strategies targeting indigenous AnGR. Even for these countries, a major challenge has been the absence of effective operational modalities that translate intentions articulated in the policies and strategies into practice. As stipulated in the GPA, establishment of AnGR National Focal Point and appointment of National Coordinators are critical underpinnings of effective management of AnGR at national levels. Unfortunately, where these have been established, the majority have remained ceremonial, occasionally being requested by FAO to prepare country reports on AnGR—the contents of which have generally remained static, reflecting limited progress. Indeed, the status of AnGR in most countries has deteriorated significantly over the last two decades. Establishment and resourcing of functioning National Focal Points, with dynamic Coordinators and Steering (or Advisory) Committees, is clearly a priority for the continent. In addition, it is critical that the institutional frameworks put in place under the leadership of the Focal Point institution facilitate coordination/collaboration mechanisms with agencies responsible for livestock extension, research, trade, foreign affairs, pastoral development, natural resources, and environment to ensure that these agencies work synergistically to design and implement effective programmes that deliver the desired conservation and sustainable use outcomes. In addition, the policy function of government ministries responsible for livestock should explicitly include conservation and sustainable use of indigenous AnGR.

31 Resourcing and Institutional Arrangements to Deliver Sustainable Animal Genetic Improvement in Africa

Eveline M. Ibeagha-Awemu, Victor Olori, Ismail Muritala, Olubunmi I. Duduyemi, Mizeck G. G. Chagunda, and John E. O. Rege

Abstract

The contents of the chapters of this book attest to the fact that sustainable livestock production is imperative to meeting the food needs and the economic development of Africa. To achieve this, all stakeholders involved must understand their roles and also be willing to pull together resources through sustainable cooperations, guided by clear local, regional, and continent-wide policies to achieve the common objective of sustainable livestock improvement. This chapter presents the roles of various institutions—within countries, between countries, and multinationals engaged in supporting animal improvement in Africa. It discusses the importance of functional linkages and needed cooperations between the various stakeholders. It concludes that the crucial elements necessary for the effective utilization of the factors presented in this book to deliver resilient and sustainable animal genetic improvement for the transformation of the African livestock industry are enabling policies, functioning institutional arrangements, access to appropriate technologies, funding and information, and adequate infrastructure and trained personnel.

31.1 Introduction

Improving the animal genetic resources (AnGR), and in particular livestock genetic resources, in Africa is an important element of feeding the growing African population, solving malnutrition, and driving sustainable development of the continent. The various components, drivers, and challenges of successfully putting in place sustainable livestock genetic improvement programs in Africa have been discussed in Chapters 1 to 30. A well-planned and implemented sustainable livestock genetic improvement process leads to increased genetic gain in traits under selection which translates to increased productivity, better health of animals, and increased profitability which benefits the producer, consumers, the livestock industry, and everyone or group or institution along the livestock-value-chain. Collectively, they form the stakeholders in the livestock-value-chain process. Therefore, stakeholders in livestock genetic improvement generally refer to those individuals or groups or organizations that have an interest in or benefit from the improvement of farm animals. In this regard, livestock will refer to animals (cattle, chicken, sheep, goats, pigs, etc., see Chapters 1 to 12) that are farmed for the provision of meat, milk, eggs, wool, and other animals' products. Generally for livestock, it involves the primary keepers of livestock animals (generally associated with small-scale livestock farmers), breeders (farmers involved in more sophisticated breeding programs, who supply the animal seed stock and could work individually or in groups/associations), regulatory bodies (those that regulate the quality and supply of animal breeding stock and the activities of the livestock industry, e.g. governments), livestock companies (those that use the improved animal seed stock to produce animals and products to meet consumer preferences), consumers (utilize animal products for food, sports, and farming), processors (those that process the primary animal products into secondary value-added products), marketers (those involved in every aspect of marketing animals and animal products), associations or cooperatives, service industries (make products for the livestock industry), funding bodies, civil society organizations, training and research institutions, and governments. Collectively, these stakeholders resource the animal genetic improvement process either directly or indirectly, requiring functioning institutional arrangements for the gainful involvement of all stakeholders.

Thus, it has been severally emphasized that the successful implementation and sustainability of AnGR management activities, including livestock genetic improvement, depend on the many key factors discussed in previous chapters of this book and the participations of the diverse stakeholders in the livestock-value-chain listed above (Wurzinger et al. 2011; Zonabend et al. 2013; Mueller et al. 2015; Leroy et al. 2017; Ibeagha-Awemu et al. 2019). The importance of clear arrangements and policy-guiding stakeholder participation is underscored by the past failed years of the lack of recognition of the common

interest in sustainable improvement of livestock production. Increased livestock productivity does not benefit the primary producer only, but everyone along the livestock-value-chain, the populace and governments. Stakeholder involvement includes participation in every aspect of sustainable livestock production such as direct animal management activities (feeding, healthcare, reproduction management such as artificial insemination services, animal identification, data collection and recording programs, genetic evaluation, breeding, training, infrastructure, etc.), marketing (market access, processors, transportation, etc.), services (feed, drugs, processors, transportation, etc.), clear policies (favourable policies, implementation, provision of services, decision making, etc.), and funding (direct cash provision in the form of grants, access to loans, etc.). It should be noted that the involvement and level of participation between stakeholders may differ between regions of the same country, between countries, and continental regions as defined by the specie, the stakeholder parties, their relationships, and level of engagement in livestock production and related matters.

A sustainable and successful animal genetic improvement process requires a long-term perspective of production, inputs (funding), and market requirements, for achieving a positive genetic improvement outcome, which is cumulative over time. Thus, the collaborative effort through various functional institutional arrangements with stakeholders will strengthen partnerships within countries, between countries, continental, and multicontinental bodies/organizations engaged in resourcing animal improvement in Africa and will (1) sustainably support animal genetic improvement; (2) boost overall productivity and profitability ; (3) fulfil market demands; (4) boost livestock health, growth rate, carcass output, fleece weight, fibre diameter, and birth weight variance, among other attributes; (5) boost activities and profitability of the livestock-value-chain; (6) support economic development, and (7) boost GDP growth, among others.

The key components that drive successful (Chapteranimal genetic improvement programs include breed characterization, clearly defined breeding goals, infrastructure (genetic evaluation, data maintenance, information dissemination), human capacity/training, marketing channels, and the necessary policy guidelines. The animals whose genetic makeup and environmental influences determine the specific breeds and medium for the dissemination of genetic improvement are the most important component. Chapters 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13 and 14 of this book present a description of the breed characteristics, the production systems, and the effects of raising livestock on climate change. The livestock specie in turn determine the structure of the breeding program (Chapters 15, 16, 17, 18 and 19), which is the organization of people and the infrastructure dedicated to the genetic improvement processes (Chapters 20, 21, 22, 23 and 24), the technology, techniques, and procedures (Chapters 20, 21, 22, 23 and 24) deployed to achieve livestock genetic improvement and the standards or key regulatory roles and the institutional arrangements (Chapters 25, 26, 27, 28, 29, 30 and 31) guiding effective implementation of the livestock genetic improvement processes. A plethora of individuals, institutions, and organizations work hand in hand to resource animal improvement programs in Africa.

This chapter examines the critical stakeholders resourcing animal genetic improvement, the necessary institutional arrangements and the mitigating factors, and the key elements in achieving sustainable genetic improvement in the African continent.

31.2 Stakeholders Resourcing Animal Genetic Improvement

31.2.1 Role of the Private Sector in Animal Genetic Improvement

The private sector's contribution in African animal genetic improvement is of utmost importance and if properly harnessed, it will sustainably balance different policy objectives such as maintaining animal genetic diversity and environmen-

tal integrity, meeting the increasing demand for livestock products, responding to changing consumer requirements, ensuring food safety, and contributing to rural development and the alleviation of hunger and poverty.

31.2.1.1 Custodians of the Animals: Individual Farmers/Keepers

The most essential stakeholder group in the improvement of livestock comprises the owners of the livestock. This includes the individual farmers, farmer associations/cooperatives, and breed associations. The individual farmer, in this regard, also refers to the farm where it is a corporate entity owned by more than one individual.

The farmer is an important stakeholder because they are the primary keepers of livestock and the primary user of the end product of all genetic improvement efforts. In this regard, their demand for a specific breed or breeds is the most important motivation for investment in the development and distribution of improved animal seed stock. Furthermore, as custodians of the animals, they are also the most important source of the data required for genetic improvement of livestock. Recording the performance and pedigree of individual animals in their care is the most important contribution of the farmers to the genetic improvement of a breed. For example, in order to facilitate application of molecular methods for animal improvement, the farmers supply samples from their animals (e.g. tissue, blood, hair, etc.) from which DNA is extracted for the genotyping of individual animals.

Individual farmers play key roles in the conservation of animal genetic resources and hence the available variation in breeds used for production. They do this through the choice of the breed of animals they keep and the production practices. By keeping indigenous breeds based purely on interest or regional availability, they ensure the survival of marginalized breeds that would otherwise have gone extinct. By practicing random breeding with no directional breeding, they help maintain variation at the molecular level. This practise also, unfortunately, results in high gene flow between breeds and the dilution of breed specific characteristics. This could explain the wide array of breeds of cattle, sheep, goats, and chicken found in Africa.

There is the risk that as farmers adopt modern production practices and decide to keep only a few highly improved breeds for the main production objective, there will be a narrowing of genetic variation of the population. While this risk is real, it depends on how much other less productive breeds are neglected. This is why the Food and Agriculture Organization (FAO) of the United Nations has taken up the leadership in providing a framework for national governments to help in the conservation of AnGR (FAO 2011). The conservation of genetic variation within and across breeds and support for the creation of awareness in this key aspect of our livestock is perhaps the most important contribution of the FAO to genetic improvement of livestock. This is because future improvement depends on today's variation and today's variation also ensures we can change to alternatives in the future if the production environment or consumer preferences changes. In all of these, the choices of the individual farmers play a key role.

31.2.1.2 Farmer Organizations or Cooperatives

The impact that each individual farmer can have on overall genetic improvement is limited. This is because genetic improvement relies on expression of variation which can only be accurately estimated when information on performance is recorded on many animals across many different production environments and farms. Farmer organizations are formed on the basis of geographical location and/or the rearing of the same species. Formal or informal membership-based, farmer groups are collective action institutions with the purpose of assembling and possessing established organizational structure to support members in pursuing their individual and collective interests. One essential function is to organize relations with independent parties to mediate between members and others who act in their economic, institutional, and political environment. This definition includes farmer associations, farmer cooperatives, farmer clubs, farmer groups, producer organizations, and women's

groups. These are usually farmer-based formed at regional and/or national levels.

Farmer groups assist individual farmers by consolidating the outputs of multiple producers, procure large quantities of inputs at reduced prices, and provide members with access to agricultural support services. Given their significant scale, cooperatives possess sufficient market influence to increase/determine price of products and provide a more stable and secure income for its members. Several agricultural associations also incorporate savings and loan programs for their members. These programs assist farmers in managing finances, maintaining records, and acquiring crucial financial skills to enhance their productivity. Therefore, farmer organization services are actions, strategies, or activities undertaken to help members generate more income and have better access to raw materials, inputs, training, marketing outlets, agricultural extension services, and veterinarian services, among others. Farmer organizations are found in many countries in Africa. Examples are shown in Table 31.1.

The Northwest Pig Farmers Cooperative (NOWEPIFAC) is composed of enthusiastic pig farming groups in Cameroon. The main motivation of NOWEPIFAC is to collectively fight the challenges (e.g. limited feed resources, limited market channels/access, high disease burden, and high cost of conventional drugs, among others) limiting pig farming in Cameroon. Founded in April 2004 in Bamenda (headquarters) by Mr. Atomba Titus Tegwi, the cooperative has its own building for offices and meetings in Bawock, and a slaughter house where pigs are slaughtered, inspected, and sold. NOWEPIFAC is principally made-up of different groups of mixed crop-livestock producers, pig producers (e.g. Netap Mixed Farming group, Tchi-Ncha Mixed Farming group, Baform Mixed Farming group, Fumjoh Mixed Farming group, Matter Horn Farming group, Cui-Cui Mixed Farming group, Struggling Women Mulang group, Feshang Women Group Baba 1 Ndop and Living Together Pig Farmers Nitop 1, etc.), and service providers (e.g. Mobile consultancy livestock service). These groups are composed of individual small crop-livestock farm families that have decided to work their way out of poverty through pig production.

In Cameroon, livestock including pig are kept as a way of savings and are sold for cash to cater for needs like school fees and supplies (when schools re-open in September of every year), medical bills and celebrations, among others. The farmers in the North West Region of Cameroon are principally crop farmers (maize, beans, cassava, plantains, banana, groundnuts, yams and coco-yam of different varieties, etc.) from which food for human and animal consumption are formulated. Problems like underdeveloped infrastructure (roads, housing, equipment, market, etc.) and language barrier (the North West and South West rRegions constitute the minority anglophone populations of Cameroon) hamper the sale of crops produced, so pig farming is seen as a way of solving these issues. With the main aim of fighting against vulnerability (poor crop harvest, limited market access, animal diseases, etc.) and helping cooperative members and their children sustainably support their livelihoods, membership in the cooperative is growing with members drawn from six divisions of the North West Region. NOWEPIFAC therefore seeks to achieve the following: (1) share pig farming facilities and equipment; (2) training and knowledge/wisdom sharing to develop and maintain quality pig farming, pork production, and marketing; (3) manage the pig production value-chain business (pig production, feed milling, pig slaughter, and sale of pork and other products); (3) financial independence for its members; (4) support the education of their children through the sale of pigs; (5) see beneficiaries become leaders of their communities and support the growth of their communities; (6) participate in the growth of Cameroon as a leader in the Central African region, and (7) encourage sharing and collaboration to end poverty and conflict between communities.

NOWEPIFAC receives support from many local and foreign donors which helps to grow the cooperative and keep farmers' hopes alive. The capacity of NOWEPIFAC was enhanced through its first project that started in 2006 (with the sup-

port by Mr. Arie Peter Wingelaar and Mr. Hanneke Mertens, both of the Netherlands) with the provision of working materials (such as office supplies like cupboards, computers, microscope, tables, and chairs), feed mill, cooperative truck, a pig demonstration farm (for the training of members), training of its coordinator (international diploma in animal feed production) in the Netherlands and maintenance of vehicle and equipment, through funding by the Dutch Ministry of Development Cooperation. The second project of the cooperative came through a Dutch girl named Djouke (introduced to cooperative by Mr. Wingler) who started the project named, "A Pig Van Djouke" (which means a pig from Djouke) in 2007. As a way of alleviating poverty in Cameroon, Djouke sends regular small cash (Euros) donations to promote pig production, and by November 2014, more than 100 farm families have benefited. The project now renamed "The Pig Van Djouke POG Project" consists of donating pig feed and female piglets to farmers to breed and then pass on the gift to other deserving farmers in a process known as "Passing on the Gift: POG" (Fig. 31.1). Since the initial donation, Djouke has been able to assist hundreds of farmers, working with village communities of the North West Region through its founder, Mr Atomba Titus Tegwi, who is a veterinarian and vision bearer of NOWEPIFAC.

A slaughter house project founded by PUM (www.pum.nl) of the Netherlands enabled the cooperative to participate in the slaughter and marketing of pigs produced by members. Funding by the Foundation DIO of the Netherlands supported training in livestock farming (pig, poultry, and rabbit) of over 200 farmers in various areas of livestock production, especially pig farming. Eight training sessions over a period of 2 years were given by the local project coordinators and Dutch experts from PUM (www.pum.nl). Over the years, proper functioning of the cooperative has been achieved through collaboration with other civil society organizations (e.g. North West Farmer's Organization, North West Association of Development Organizations, etc.) and

Fig. 31.1 Recipients of piglets and feed through The Pig Van Djouke POG (Pass on the Gift) Project. (Photo by NOWEPIFAC)

non-governmental organizations (NGOs) (local and international NGOs).

Kenya Livestock Producers' Association (KALPA) is an apex body of livestock producers in Kenya. One of its objectives is strengthening the market linkages of its farmers and other members. This objective became a reality when the Djibouti Agro-Pastoral Association set out to implement a pilot project importing 45 dairy goats bred by Kenyan dairy goat farmers. The project, which was funded by the FAO and facilitated by the Eastern Africa Farmers Federation, together with other stakeholders, aimed to find out whether these dairy goats could be productive in Djibouti.

In the 1990s, Kenyan farmers came together to form groups for the purpose of breeding and marketing of dairy goats. This led to the formation of the Dairy Goats Association of Kenya (DGAK). The DGAK is an active member of KLPA. It ensures that its 16,000 members, who rear between 3 and 50 dairy goats, produce and rear the best dairy goat breeds. The association has been upgrading local breeds with bucks sourced from Germany since 1992. And because of the mix of indigenous and exotic characteristics, survival and high yields are achievable with improved animal husbandry. Government and donor funding encouraged DGAK members to rear dairy goats as a source of income for families that could not afford the land space or money to maintain a cow. In early 2000, the farmers established group nurseries of fodder shrubs for the purpose of providing quality feeds to dairy goats and cows in addition to other benefits accrued from fodder shrubs. They also ventured into production of improved fruit trees. DGAK is mainly involved in managing the breeding and marketing of improved dairy goats. The association has put in place a complex system of buck rotation between the groups as a mechanism of controlling inbreeding in their flocks. It has elaborate training programmes that precede the distribution of improved goats to new areas. The training programme has a feeding component where the use of fodder shrubs as goat feeds is highly recommended. The association has thus helped in scaling up the adoption of fodder shrubs in the East African region and its impacts are well perceived in the region. One of the challenges faced by DGAK farmers is lack of quality breeds due to inbreeding which slowed down the production of pedigree goats, leading to decline milk production and importation of semen from German and French Alpine goat breeds.

The Meru Goat Breeders Association and the Kitui-Mwingi Goat Breeders Association, both in Kenya, evolved from a Farm-Africa Goat improvement initiative (Peacock et al. 2011). These Associations have facilitated the successful development of a high yielding synthetic goat breed based on ¾ genes of an imported Toggenburg breed and ¼ genes of a local indigenous meat goat breed found to be most acceptable in terms of productivity and adaptation to local production environments (Ahuya et al. 2002). The maintenance of the pure line Toggenburgh breed as well as the planned selection and mating to produce the optimum synthetic breed is facilitated by the collaborative efforts of the members of the groups who provide the data to facilitate selection and share in the beneficial use of the identified superior bucks and does.

The Malawi Milk Producers Association (MMPA), an umbrella organization made up of three Regional dairy associations: Mpoto Dairy Farmers Association in the North, Shire Highland Milk Producers Association in the South, and the Central Region Milk Producers Association, has a membership of about 17,000 smallholder Dairy Farmers with herd sizes of one to two dairy cows each. The MMPA operates 121 Milk Collection Centres (or Bulking Groups) where milk produced by farmers is cooled and collected daily by one of five Dairy processors in Malawi for processing and sale to consumers.

The South African Beef (Becker 2016) and Dairy Genomics (Joubert 2016, 2018) programs established in 2015/16 and composed of diverse breed societies, technology innovation agencies, industry players, and international participants, has played a vital role in livestock improvement. The foremost activity of the consortia was the discovery of single nucleotide polymorphisms, establishment of DNA sequencing initiative for South African indigenous cattle breeds, and establishment of genomic selection in South African dairy cattle breeds. This led to the setting up of an accelerated long-term, sustainable programme for genomics and genetic improvement of South African breeds including establishment of a data bank for storing and managing genotypes generated, a bio-bank for biological samples, and development of a reliable methodology to derive and estimate genomic estimated breeding values for use in the beef and dairy industries.

These examples show that the collaboration of a group of farmers in recording performance information, sharing genetic resources to create genetic links across farms and production environments, and desiring to use improved stock is a strong driver for genetic improvement, or collectively collating their products for sale is a strong driver of profitable livestock farming. Facilitating the coming together of farmers for common purposes is an essential aspect in the development of sustainable livestock breeding programs.

31.2.1.3 Breed Associations

A breed association is a special kind of farmer group comprised of members with common interest in the promotion of a single breed. The main interest is usually for the promotion of the breed for commercial production or for aesthetics of the breed as often seen in companion animals. Different breed societies have been founded across the globe, addressing issues bordering on genetic improvement of livestock species. Examples include the Boran cattle societies of Kenya and South Africa, the pig breeders society of South Africa, among others (See Table 31.2 for more African examples). These associations like many others have a keen interest in the development, preservation, and promotion of their breed and its use for the production of the product for which the breed is best suitable. To do this, accurate records of animals and their location are kept, which facilitate traceability. They facilitate the registration of new births and keep meticulous record of parentage, thus allowing to have a good indication of numbers and demography of the breed. The records of births and parentage certification are very useful in generating the pedigree records on which accurate genetic evaluation relies. Members are encouraged to keep records of performance which constitutes the data for genetic evaluation and play a key role in facilitating progressive competition through the organization and participation in "shows" during

Horse	Arab Horse Society	http://arabhorse.co.za	South Africa

which animals on show are judged on key features of the breed and winners given awards and honours. This act contributes a lot to the hunger of These awards or prizes serve as motivation to individual farmers to improve their stock and hence the desire for genetic improvement. This desire is a key element in the compliance of individual members of the association to registrater the births of animals and record performance. The desire of the breed associations to promote their breed among farmers is the reason why they cooperate readily in the formation of independent genetic evaluation centres which compare different breeds. Such centres constitute a key resource in animal genetic improvement programs facilitating within- and across-countries comparison of animals and breeds.

In 1950, for example, the Kenyan Boran Cattle Breeders' Society (BCBS) was established, after the registration of the first Boran with the Kenya stud book. Thereafter, the Borans started moving out of Kenya. The late 1950s saw the arrival of the first Borons in Northern Zimbabwe, followed by heifers and bulls. Throughout the 1960s and 1970s, the Kenyan Boran breeders prospered from export of their stock to Zambia, Uganda, and Zaire. The Society sets and maintains standards, which are used to approve the registration of individual animals in the Kenya Stud Book. Animals showing constitutional defects such as excessively pendulous sheaths, lack of pigment, faulty feet and legs, wildness, and abnormalities of any kind are not registered. Borans registered in the Kenya Stud Book are eligible (under Society rules) for live exports and as parent stock for embryo and semen sales. The Society handles export protocol and holds an annual show and sale in Nairobi where the top bulls are on offer.

The BCBS was the first breed society in East Africa to create guidelines for improving indigenous cattle. In so doing, it established a strain of the East African Shorthorn Zebu as a recognized breed—the Boran. An important objective of the BCBS is to retain the efficiency and adaptation of the breed to harsh conditions. Hardiness and fertility in the Boran have made it the premier breed for crossbreeding and rangeland beef production in Kenya. The Society guards against losing these qualities.

The South African Boer Goat Breeders' Association, founded in 1959, has established the standards followed by breeders around the world. The primary aim of the society is to promote the breeding of quality and functional Milk Goats by providing relevant information to breeders on goat breeding and keeping.

31.2.1.4 Livestock Breeding Companies

Historically, private breeding companies have facilitated breed genetic improvement in Africa through the development and supply of seed stock from elite animals to livestock farmers. While notable cattle breeding companies facilitate the development of elite bulls and supply of semen through Artificial Insemination (AI) companies, poultry breeding companies supply fertile eggs, day old chicks, or parent stock which are used to generate the production population with superior performance in broiler meat and egg production. The major companies that have impacted the African livestock industry include but are not limited to the following.

ABS Global https://www.absglobal.com/: Apart from the supply of semen for AI, ABS also develops and makes available the Genetic Management System® (GMS) which is a mating program that allows farmers to make a good choice of bulls and replacement cows based on their genetic merit for various traits. This allows farmers to maximize productivity and profit in their flocks while managing inbreeding and preventing the introduction of deleterious recessive genes into their flock.

Genus plc https://www.genusplc.com/ is a global player in cattle and pig breeding. It is the parent company of ABS through which it supplies improved cattle seed stock and PIC® through which it supplies elite sows and boars as well as boar semen for pig breeding. Its impact on dairy production in Africa is mostly through Genus Breeding India and ABS South Africa. The availability of sexed semen through the cattle breeding companies allows farmers in Africa and elsewhere to breed their replacement animals from their own good cows much quickly, resulting in faster herd improvement. De Novo Genetics https://www.absglobal.com/uk/services/de-novo-genetics/ is a collaboration between Genus ABS Global and De-Su which specializes in producing superior Holstein Friesian cows for milk production. These are marketed in Africa through ABS Global.

Poultry breeding is currently undertaken by a handful of companies, most of which have market shares in Africa. These include Cobb Vantress https://cobbgenetics.com/ which focusses on broiler chicken production and Hendrix Genetics https://www.hendrix-genetics.com/en/ which is involved with multiple species breeding such as chicken, turkeys, pigs, fish, and shrimps. One poultry breeding company that is a key player in Africa supplying the well-known brands such as Ross, Arbor-Acre (AA), and Lohman India River (LIR) is Aviagen® https://aviagen.com//. Other companies that supply layer chickens include Hy-Line Genetics based in the US https://www.hyline.co.uk/about-us/history/ and Lohmann Breeders based in Germany https://lohmann-breeders.com/. In addition to these big players, there are a handful of poultry breeding organizations in Africa which specialize mostly on indigenous chicken improvement and supply locally.

Sustainable Supply

Poultry breeding companies like Aviagen play an important role in livestock genetic improvement and sustainable production in Africa. They fund research and development activities to bring about sustainable genetic improvement in traits of economic, biological, and welfare importance. However, the most important impact they have in Africa is the sustainable supply of high genetic merit poultry seed stock in the form of parent stock, fertile egg, or day old chicks on which commercial poultry production relies. The distribution network of the breeding company includes fully and co-owned grandparent stock companies located in Africa such as Aviagen East Africa based in Tanzania, Aviagen South Africa based in South Africa, and Ross Central Africa based in Zambia, as well as clients that rear parent stock for producing day old chicks. By setting up these subsidiaries closer to their clients and farmers, Aviagen ensures security of supply and minimizes the environmental footprint of the supply chain. Reducing the supply distance between hatchery and farmers also improves the welfare of day old chicks.

Technical Support

Another key contribution is the provision of technical services to farmer and hatcheries. Highly

knowledgeable technical staff regularly visit farmers and hatcheries to help producers identify problems and proffer solutions to ensure they get the benefit of the full potential of their high genetic merit birds. This service, provided free of charge, supports the distributors by providing client support in the areas of nutrition and feeding, veterinary care and animal welfare, and a host of other issues. The visits to these farms also allow the technicians to hear directly from the farmers, product trends, and client requirements which are fed back to the breeding program to determine the direction of genetic improvement.

Education, Training, and Capacity Development

Another important role played by the primary breeding companies is the provision of educational materials, hands-on training of poultry production staff, and overall capacity development. For example, Aviagen runs the Aviagen production management school https://aviagen.com/en/about-us/school-overview/ which celebrated its 60 years anniversary in 2023. Its comprehensive approach to poultry training is provided through a 1-month long in-person training annually. A dedicated course for customers in Europe, Middle East, Africa, and Asia was established in 2012 offering similar experience to Africans. To date, about 1100 students from over 74 countries in these regions have benefited from the training, gaining practical skills in poultry house ventilation, hatchery management, and broiler and breeder management. In addition to the training, Aviagen also develops and maintains a repository of education materials in their "info centre" https://aviagen.com/eu/tech-center/ which can be searched to quickly access expert technical documents on a search topic. These materials which are freely available represent excellent teaching materials for academics for use in training the next generation of poultry farmers in various formal educational institutions. These examples are some of the various ways poultry primary breeders impact the availability of high genetic merit chicken and turkey birds to African poultry farmers and how best to manage them for improved productivity, bird welfare, and farmer profitability.

31.2.1.5 Animal Production Supply Chain

The animal production supply chain or livestock value chain can be regarded as the compendium of activities by different individuals involved in the transformation or processing of livestock products or engaged in different phases of the production process (e.g. live animal, chicks, egg, meat, feed, medication, fibre, manure, leather, etc.) and delivery of finished products to the consumer. The livestock value chain is also regarded as a market-focused partnership among different interested parties who produce and market value-added livestock products.

A simple livestock value chain could include the primary producers, intermediates and processors, packaging houses, wholesalers, and retailers of finished products. Individuals with similar interests along the livestock value chain and for the purpose of streamlining processes (e.g. sharing cost and knowledge sharing, etc.) form associations. Supply chain management which bothers on monitoring the flow of products and services from raw materials to finished goods (Lysons and Farrington 2012) supports the smooth function of the livestock-value-chain. In Africa, many actors are responsible for these activities. These supply chain actors and the complementary services they provide help small-scale producers upgrade their practices, raise their productivity, and subsequently improve their welfare. They include agro-dealers, processors, traders, and cooperatives who purchase livestock products from small-scale producers and process for sale to consumers.

Each participant (actor) in a value chain contributes value as the product progresses from the start of the chain to the end consumer. By contributing this value, all players are rewarded with an economic benefit—the primary advantage or motivation for engaging in a value chain. Livestock producers must possess efficient organizational abilities to thrive in an increasingly competitive market. Membership of a farmer association is an essential step for small-scale

farmers aspiring to enhance their income and gain a greater share of value in the value chain. Farmer groups possess the necessary resources to effectively engage and establish connections with many stakeholders in the value chain, both at the local and international levels, which individual farmers may lack.

The poultry production supply chain starts with the primary breeder who keeps several pure lines from which current and future products are created. At the breeding nucleus, animals are kept and data are collected at various stages of the bird's life cycle for relevant traits. These data are analysed to determine the genetic merit of individuals in different cohorts of birds from which parents of future generations are selected. The bulk of the birds from the breeding nucleus are multiplied and crossed at the next stage in the supply line. The birds at this stage are the great grandparents (GGP) of the broilers that will be sold to consumers. GGP operations are managed by different companies in collaboration with the primary breeder. They add value by crossing different lines to create the parents of the desired product as well as multiplying the bird's numbers to ensure sufficient products can be supplied to the next level on demand. Their products constitute the grandparents of the desired broiler product and they sell these to the Grandparent (GP) operators. These GP operators are located in various regions including Africa and are privately owned operations that produce and distribute the parent stock (PS). They add value by crossing various male and female grandparent lines to produce the parents of the broiler product. GP operators multiply the grandparents of the broiler birds depending on the number of clients they have and their holdings. The PS operators are closer to the farmers who rear broilers, hence they are even more decentralized and more in number within most African countries. They often produce fertile eggs and run large hatcheries to produce broiler day old chicks for distribution to various broiler farmers. The broiler farmers buy the exact number of birds they can rear to market weight from the hatcheries and finish these to the desired market weight several times in a year. They add value by feeding the birds according to specification so that they can make the birds achieve the desired market weight or the weight desired by processors on time.

In many countries where the market is dominated by live bird sales, the broiler birds from the farms go directly to the market through a number of wholesaler or off takers. In other cases, the birds go to a process plant where value is added by dressing the birds with or without cutting into chicken parts. These then are transported to be sold fresh in supermarkets and butcher stalls or by cold room merchants who are thus able to store large quantity of processed birds over a longer period. More recently in Africa, the increase in number of fast food operations has necessitated further processing of dressed broilers into chicken parts like wings, thighs, and breast fillets which are sold to restaurants and specialized chicken fast food vendors. Cold room operators also stock cut-up chicken parts. The processing and cutting up of chicken into parts make the meat accessible to people of various means who otherwise could not afford to purchase whole chickens or have the willingness, skill, or resources to process live birds in their homes.

31.2.2 The Role of Training and Research Institutions

Education and training and knowledge generation are vital components of sustainable agricultural productivity and livestock improvement. These can be achieved through formal educational institutions, research institutions, professional networks, professional meetings and farmer focused meetings among others.

31.2.2.1 Academic and Research Institutions

Academic and research institutions (universities, colleges, specialized schools, research centres, research farms, etc.) play vital roles in building capacity and generating knowledge for all aspects of livestock genetic improvement. Livestock and agriculture in general are vital components of human survival and are major contributors to the economic development of all African countries.

Recognizing the important place of agriculture, national governments of African countries created public-funded agricultural centred universities, departments, colleges, and specialized institutions with the important task of capacity development to support the growth and development of the agricultural sector. The training and research activities at these institutions are the bedrock of technological developments and scientific innovations in sustaining the livestock industry and the agriculture sector in general. The academic institutions and research organizations train the students (future capacity), producers, and other value-chain players and generate and document knowledge on all aspects of the livestock-value-chain. All levels of capacity development are offered by the agricultural-centred institutions in Africa and internationally.

The top agricultural universities and colleges' building capacity in all areas of livestock production are discussed in Chapter 27, while Chapter 28 presents an overview of human capacity building in livestock genetic improvement and the limitations of current curricular as well as the opportunities for adopting training options that are suitable for the African environment. To increase effective programs delivery by these institutions, greater cooperation with primary producer groups, non-governmental organizations, and governments and other players in the livestock-value-chain will ensure the flow and sharing of knowledge, innovations, and information. International institutions (like the International Livestock Research Institute (ILRI)), national and international initiatives, and donors have played significant roles in resourcing livestock genetic improvement in Africa through funding and training.

31.2.2.2 Livestock or Breed Improvement Networks

Livestock or breed improvement networks are a grouping of researchers, farmers, and persons interested in the improvement of livestock or specific breeds. The African Goat Improvement Network (AGIN), established in 2011, is a collaborative group of scientists interested in the genetic improvement of goats in smallholder communities in Africa (Van Tassell et al. 2023). The goals of the AGIN are to: improve the productivity of indigenous goat breeds; characterize existing goat populations; facilitate germplasm preservation; apply genomic approaches to better understand adaptation; develop cost-effective strategies to implement genomic strategies to improve goat productivity without sacrificing adaptation; perform genome-wide genetic variation-enabled genetic diversity studies; facilitate improved germplasm preservation decisions; and take necessary steps to initiate large-scale genetic improvement programs. These propositions were partly executed via a sequence of community-level breeding schemes that actively involved and empowered local small-scale farmers, particularly women, to foster the sustainability of the production system. One of AGIN's goals is to facilitate concurrent, multi-faceted capacity development for researchers, students, farmers, communities, as well as local and regional government officials.

The African Animal Breeders Network (AABNet) (Djikeng et al. 2025) is another initiative that brings together animal breeding/scientist professionals and concerned stakeholders with the common goal of the sustainable development of the African livestock sector.

31.2.2.3 Professional Animal Production Societies

Professional animal production societies are a grouping of individuals (professionals, students, farmers and industry personnel) with interest to advance the improvement (genetics, health, management, reproduction, welfare, etc.) of livestock and promote viable and sustainable production systems in the face of changing environmental conditions. Membership in professional animal production societies is drawn from agricultural institutions (animal, plant, and veterinary medicine) of learning, producers, government departments, support institutions, and service industries. The societies could be national, continent-wide, or international. Sample animal science societies are listed in Table 31.3, and through their listed website addresses, specific information about each society can be seen. Their main goals are

Table 31.3 Sample professional animal production-based societies in Africa and internationally

Name of society	Acronym	Website

European Association for Animal Production	EAAP	https://www.eaap.org/
World Association of Animal Production	WAAP	https://waap.it/

similar and include the following: advance all aspects of the husbandry of livestock species and the products derived from them; advance the nutrition, genetics, physiology, reproduction, health, and breeding of livestock animals; ensure the humane care of livestock; ensure that animal sourced food is produced ethically and economically; provide networking opportunities among members; share knowledge and practices through regular meetings; share knowledge on scientific innovations through publications like journals, magazines, and books, among other goals specific to each society.

The Animal Science Association of Nigeria (ASAN), for example, focuses to improve understanding of the animal sciences and the ways food is produced ethically and economically. The ASAN supports the career advancement of scientists and animal producers and serves as a platform to encourage the younger generation into pursuing animal science careers. It also advances the discovery, sharing, and application of scientific knowledge for sustainable livestock production and for the responsible use of animals to enhance human well-being and environment sustainability. The ASAN draws membership from individuals, firms, and organizations with interest in instruction, research and application, and extension services in animal science, or individuals involved in livestock production, processing, distribution, and marketing of livestock and its products. The ASAN holds regular scientific meetings and workshops for its members and other interested parties; an avenue where the latest scientific innovations in the animal sciences are shared and networking opportunities established. The ASAN publishes the Nigerian Journal of Animal Science, which covers diverse topics within the framework of sustainable livestock production including animal products, biotechnology, health, production, nutrition, management, physiology, feeds/feedstuff, genetics and breeding, reproduction, socio-economics, farming systems, crop/livestock interactions and extension, among others.

The Nigerian Society for Animal Production (NSAP) has contributed immensely to livestock improvement. Inaugurated during the First International Symposium on Animal Production in the Tropics at the University of Ibadan in Nigeria in March 1973, the NSAP mission is to promote the study and practice of all facets of animal production; provide a platform for discussions on scientific and industrial policies and educational and social issues of relevance to the development of animal production in Nigeria;

engage in the dissemination of scientific and educational information related to animal production; interact with organizations with similar ideologies within Nigeria and internationally. The membership of NSAP includes individuals and corporate bodies that are interested in all aspects of animal production such as animal scientists, livestock economists, farmers, feed millers, livestock sociologists, pasture agronomists, veterinarians, and students of animal science and related disciplines. The NSAP holds annual meetings where its members meet to share the latest scientific innovations in the animal sciences, network, and form linkages. The Nigerian Journal for Animal Production is the flagship journal of the NSAP. It has maintained consistent publication since its first issue in 1974 and has over 50 volumes to date. The Nigerian Society for Animal Production is a member of the World Association for Animal Production.

The All Africa Society for Animal Production (AASAP) brings together individuals, groups, organizations, and institutions interested in the art, science, and practice of animal sciences relevant for animal agriculture such as genetics and breeding, animal nutrition and feeding, health, welfare, reproduction, and all other aspects of animal husbandry. The AASAP main goal is to facilitate the use of technical, policy, institutional, and scientific innovations to address current and emerging challenges of animal agriculture in Africa through engagement of animal-related communities of practitioners in Africa and beyond. Every 4 years, the AASAP organizes an international meeting titled "The All Africa Conference on Animal Agriculture" (AACAA) in collaboration with other Animal Production Societies, drawing participants from the African continent and internationally. Each meeting addresses specific themes of relevance to the African continent. In 2023, the AASAP organized its 8th meeting (AACAA8) which was cohosted by Botswana University of Agriculture and Natural Resources and in association with two Livestock Production Societies (Botswana Society of Livestock Science and Production and South African Society of Animal Science) and the National Agricultural Research and Development Institute. The AACAA8 addressed the following eight themes: (1) enhancing youth engagement in animal agriculture in Africa; (2) towards sustainable resolution of farmer-herder conflicts in Africa; (3) climate change adaptation and mitigation: the role of animal scientists; (4) the One Health Concept—managing zoonotic disease transmission through controlled contacts between domestic livestock and wildlife; (5) animal food safety and consumer health: current status in Africa and required interventions; (6) animal science, ecological goods, and rangeland services in Africa; (7) information and communication technology and data science: opportunities for utilization of innovative technologies in sustainable animal agriculture in Africa; and (8) appropriate animal genetics, feeds, and health inputs: towards solutions for access and last mile delivery. The AASAP is a member of the World Association of Animal Production (with its secretariat in Rome).

The International Poultry Council (IPC), a member-driven organization, is composed of national sector associations, poultry businesses, and other key industry stakeholders. Members of the IPC are responsible for over 88% of the world poultry meat production and 95% of the global poultry meat trade. The IPC is proactive in promoting science-based solutions and information-sharing for regulatory authorities and poultry producers worldwide and is uniquely positioned to provide a holistic view of the global poultry sector. The IPC is therefore regarded as the voice of the global poultry meat industry as it brings together global poultry industry stakeholders, represents the whole value chain (from farm to fork, and from genetics to consumption), and leverages the resources and strengths of national organizations.

International dairy federation (IDF) is a recognized international authority in the development of science-based standards for the dairy sector. IDF ensures that the right policies, standards, practices, and regulations are in place to ensure the world's dairy products are safe and sustainable.

31.2.3 The Role of National and Regional Governments

National and regional governments are vital stakeholders in resourcing animal genetic improvement because of their interest to ensure national food security, minimize carbon footprint, protect the environment, create jobs, empower youths, support rural development, and grow their Gross Domestic Product (GDP). More importantly, agriculture is a major contributor to the GDP of African countries and hence a key sector of national economies. In practical terms, government's role in resourcing animal genetic improvement involves: (a) supporting the development of the concept and setup of agencies responsible for genetic improvement; (b) support the development and availability of human capacity to man the agencies, i.e. people with the right training, knowledge, and skills to man various positions in the organization; (c) create and support education and training institutions for manpower development; (d) facilitate the operation of agencies, in terms of policy framework, regulation, standardization, and funding; and (e) provide the enabling environment for seed stock development, dissemination, and utilization which includes the support for and sensitization of farmers as to the value of utilising high genetic merit animals in farming and providing the required environments for these to thrive in order to attain sustainable improvement in livestock production.

In some African countries like South Africa, agencies dedicated to livestock genetic improvement exist and are operating routinely. In others like Nigeria, agencies such as the Centre for Genomic Research and Innovation, embedded within the National Biotechnology Development Agency https://nabda.gov.ng/, are in the development phase with a vision to set up the key infrastructure for livestock genetic improvement (Olori and Nash 2021). The task of resourcing animal genetic improvement in Africa is particularly daunting and may require initial government involvement. This is because the livestock production sector is less evolved compared to the crop production sector. Most livestock are reared under traditional production systems characterized by small and highly dispersed farms, and, for large ruminants, migratory or nomadic in nature. These make the task of animal identification and data collection difficult, requiring a new approach in breeding program design and operation. Evolving and resourcing new production systems that facilitate efficient livestock production may require government policy and intervention. These include land use, water resource and energy resource development and supply, road networks, and market development. It will also require government intervention in allocating resources to human capacity development by way of formal education as well as training of various supporting personnel and farmers. To fulfil its role in agriculture and hence livestock production, many African countries have a ministry dedicated to agriculture and livestock production. Depending on the country and government of the day, the portfolio of the ministry could include rural development and/or fisheries.

31.2.3.1 Development of Policy Framework

The primary role of national governments in livestock genetic improvement revolves around policy development, facilitation, regulation and funding. In this regard, agencies of governments have a responsibility to provide the policy framework that facilitates and promotes livestock farming, conservation of animal genetic resources, generation and dissemination of animals' seed stock, and safe utilization of products of genetic improvement for the maintenance of human health, human and animal welfare, as well as protection of the environment. Government support for livestock genetic improvement programs fulfils the multifaceted role of facilitating conservation and utilization of available animal genetic resources as well as generation and dissemination of animal seed stock to support sustainable livestock production. This indirectly reflects government interest in rural development, job creation, food security, protection of the environment, and minimization of carbon footprint of the agricultural industry. In many western countries like the UK, the government also has interest in

protecting the rural landscape and hence the utilization of the available land for agriculture and especially livestock production.

Governments develop the policy framework that governs sustainable livestock production, animal welfare and health as well as the protection of human health from health risks emanating from livestock production and consumption. These policies therefore directly affect livestock producers, production environment, productivity, and hence genetic improvement. The development of policy framework implies that governments will have a clear indication of capacity requirement (including human capacity, land, and stock), principles of practice (including ethics, welfare, and health considerations), and funding requirement (level, allocation, and accounting). A good policy framework will give clarity on who can undertake livestock genetic improvement, where it can be undertaken based on environmental and health considerations, and the standard of the products that can be disseminated to farmers to improve productivity. It is pertinent to note that government regulations must be matched by government funding to enhance compliance. Such funding can sometimes be in the form of public-private partnerships or wholly private with appropriate regulation of source. For example, if for the purpose of protecting human health a farmer is asked to slaugther and appropriately dispose of all their stock, compliance will depend on how well the farmer is compensated for the loss of stock and revenue, and how well the government can monitor and supervise implementation of the directive.

31.2.3.2 Standards and Operational Regulations

One aspect of policy is the development of standards. For the purpose of protecting human health, animal health and welfare, or protecting the environment, government or their agencies sometime define the standards for the use of various biotechnologies in livestock production and genetic improvement. Examples include the use of antibiotics in livestock, the level of slurry spreading on agricultural land, or nitrogen fertilizer application to the soil where nitrogen leaching to the water table is a problem. This is another key role of government in livestock farming and hence genetic improvement. Governments also play a key role in creating bilateral agreements with different countries or group of countries to facilitate cooperation in livestock production matters. This could include the sale of livestock or animal seed stock across borders, the standard of imported inputs and bilateral export certification for biosecurity, and confidence in the health status of imported stock.

31.2.3.3 Development of Infrastructure

The most important direct role of the government is the resourcing of agencies that provide the key infrastructure that supports livestock production and genetic improvement. These include general infrastructure such as roads and other transport facilities, power/electricity, piped water supply, telecommunication facility as well as market outlets. More importantly, government mostly has the responsibility to provide infrastructure for education and training to develop the needed human capacity for livestock production and genetic improvement. A good road and transportation network is important to facilitate humane animal transportation which supports trade in animals, especially the improved genetic seed stock. For example, the transportation of day old chicks from the hatchery to the farmer's farm must happen quickly under good transportation conditions in order to minimize early mortality. In Africa where temperatures and humidity are generally high, poor transport facilities mean birds will spend more time on the road in very poor conditions which could reduce the viability of the chicks (Yerpes et al. 2021).

In terms of specific infrastructure for genetic improvement, the most important use of public funding will be in setting up an independent organization with responsibility for all aspects of livestock genetic improvement. This takes the burden from government and allows a specialized organization to take the responsibility with government support. In this regard, the government initially acts as the convener urging and facilitating all stakeholders to work with the

specialist organization in all aspects of livestock improvement. For example, genetic improvement relies heavily on the presence of a unique animal identification system, the recording of livestock performance from different farms, and the condition under which they perform. The organization also needs to maintain the identity, pedigree, genomic, and performance data generated from farms and analyse the data to provide selection information to farmers.

Setting up such an organization in many countries requires national and/or regional government grants. Such expenditure can be justified for many reasons. First, such an organization can support the maintenance of genomic database of livestock and the estimation of population parameters,as well as the conservation of animal genetic resources. It can also facilitates the selection of genetically superior animals for breeding the next generation which brings about genetic improvement and hence efficient production and consequent minimization of national carbon footprint from agriculture. Furthermore, a good animal identification system is not only important for genetic improvement, but it is also critical for government to have accurate information on livestock populations and demography which is needed for accurate planning and siting of key infrastructure. The ability to track the movement of animals is critical in disease prevention and control. Identification also facilitates traceability which helps consumer confidence and is critical for livestock security. For example, the ability to trace the owner and origin of cattle will discourage large-scale cattle rustling which is a key security issue among migratory pastoral cattle farmers.

The key infrastructure required to support an efficient animal identification system is an institution with computing facilities and human capacity for safe storage and processing of animal identification records. Such institution will need to devise a process of issuing unique animal IDs as well as capturing and verifying such IDs. This requires an adequate livestock database to facilitate the capturing and storage of associated information. Many countries have a system where every animal born is immediately registered. For example, in many European Union (EU) countries, it is a government requirement for every animal born to be registered with the appropriate government department or designated organization. In the EU, the incentive for this is cash payments to qualifying farmers through various national schemes under the European common agricultural policy. An example of a national scheme is the Beef data and genomics program of the Republic of Ireland https://www.gov.ie/en/service/5b44a8-beef-data-and-genomics-programme-20152020/#.

In many countries, these roles may be consolidated in one or shared between a few organizations. For example, the Irish Cattle Breeding Federation (ICBF) (www.icbf.com), the South Africa Stud Book and Animal Improvement Association (http://studbook.co.za) and Lactanet (www.lactanet.ca) in the Republic of Ireland, South Africa, and Canada, respectively, combine the responsibility of data collection, storage, and management of farmers' data with the provision of a genetic evaluation service. The development of a central database in Ireland (Olori et al. 2005) allowed the ICBF to consolidate the functions of many different organizations, thereby avoiding duplication and minimizing costs. In other countries, these responsibilities are shared between two or more organizations, for example, in the USA, The Council on Dairy Cattle Breeding in the USA (www.uscdcb.com) is responsible for the genetic evaluation, while data collection, storage, and management are undertaken by a group of public-private state or regional Dairy Record Providers and Dairy Record Processing Centres.

31.2.3.4 Research and Livestock Development

Many countries in Africa have agricultural research councils expected to provide farmers and government with direction and leadership regarding livestock research and development. In addition to these direct agencies of governments, many Universities, other education institutions, and dedicated livestock research institutions supported with government funds play key roles in conducting research to support genetic improve-

ment efforts. These include basic research as well as socio-cultural research to support estimation of population parameters, to improve the understanding of the biological basis of observed variation, especially with genomic information, development of livestock inputs, improvement in health care and biosecurity as well as supporting the uptake and utilization of animals of high genetic merit by farmers. Starting from the 1960s, many countries with the cooperation of universities and agricultural research departments undertook livestock improvement programs. The examples of Nigeria and Gambia are highlighted below.

Highlight of Livestock Development Programs by the Government of Nigeria

Efforts by the Nigerian government to improve livestock productivity started in the 1960s with the importation of Holstein Friesian (improved cattle breed) and distribution to farms (Agege Dairy Farm, Iwo Road Dairy, Ibadan) and universities (University of Ibadan and Ahmadu Bello University, Zaria) and again in the 1990s to develop crossbreds with the White Fulani cattle breed by the Nigerian Veterinary Research Station in Vom and use for higher milk production by West African Milk Company (Adebambo 2013). Poor management practices, lack of adequate funding, and political instability contributed to the failure of these programs.

Efforts to develop sheep and goat meat production by the government of Nigeria started in 1978 at three sites, Tuma in Katsina state (sheep), Ladanawa in Kaduna state (sheep), and Zugu in Sokoto state (goat). The objectives of the small ruminant program were to: (1) maintain pure breed herds of Sokoto goat and Balami sheep, (2) develop suitable management practices for sheep and goat production such as supplementary feeding ingredients, optimum pasture utilization, controlled mating programs, 3) establish within breed genetic selection strategies, and 4) develop sound animal health management regimes, among others. This was followed by the set up of sheep and goat multiplication centres by individual states such as at Kaltungo in Bauchi State, Marguba in Borno State, Pampegua in Kaduna State, Rano in Kano State, and Fasola in Oyo State. The main objective of these programs was to develop and distribute breeding animals to local farmers. Thus, the various livestock species were kept and managed in Breeding and Multiplication Centres in geographical zones where they are best adapted.

The federal government of Nigeria furthered efforts to genetically improve indigenous breeds of livestock in the country by establishing different research centres with specific mandates, including: (1) The National Centre for Genetic Resources (with main functions being to develop animal genetic resources - cattle, poultry, goat, sheep, etc.) and the naming, registration, and release of livestock breeds. (2) The National Animal Production Research Institute (with a mandate to genetically improve the indigenous livestock resources). (3) The Nigerian Conservation Foundation (responsible for the conservation of the animal genetic resources of Nigeria to ensure their sustainable use through research and development). All centres collaborated on sharing data on indigenous animals, especially those of economic and conservation importance.

The Federal government of Nigeria also established many departments of agriculture and veterinary medicine at major Nigerian universities as well as technical agricultural institutions for the purpose of training and research. The training and research activities on agricultural matters were tied to the National breeding policy in the implementation of the road map in Animal genetic resource development, among others. The goal of the policy is to increase the productivity of indigenous livestock and poultry and the number of officially registered livestock breeds and to popularize the use of registered species. Research activities have led to great stripes in the genetic improvement of Nigerian indigenous livestock breeds. Glaring examples are the development of improved breeds of chicken in Nigeria-FUNAAB ALPHA (sponsored by Bill and Melinda Gates Foundation) and NOILER. A recent livestock productivity and resilience project (L-PRES) of the Federal Ministry of Agriculture and rural development has as devel-

opment objectives to improve livestock productivity and resilience, promote the commercialization of selected value chains, and strengthen the capacity of Nigeria to respond to crisis situations or emergencies. The L-Press project seen as a strategic step in Nigeria's long-term approach to sustainable transformation of the livestock sector seeks to (1) strengthen national livestock institutions for improved environment and service delivery; (2) enhance value chain performance; and (3) prepare for crisis prevention and management (conflict mitigation, peace building, and project coordination). The project considers modern breeding facilities, increased research efforts, and application of in situ, in vivo, and in vitro conservation methods as vital aspects for the improvement of livestock productivity and conservation. Within the goat-value-chain of the L-PRES project, clusters of goat farmers received pure-bred Boer goats in fulfilment of the program's goal to genetically improve indigenous goat productivity. The program faced many challenges such as: (1) low or non-existing animal genetic conservation; (2) more emphasis placed on crop than livestock; (3) high hybridization of indigenous livestock species; (4) very low infrastructural and personnel capacities for conservation; (5) low and inconsistent power supply to power storage and research facilities; (6) weak linkages between research institutions, universities, and the ministry of agriculture; and (7) moribund breeding and multiplication centres. As mitigation strategies, the L-PRES project (1) supported functional centres for the conservations of genetic resources along ecosystems with comparative advantages for some livestock breeds; such as Sokoto Gudali cattle, uda and sahel sheep at the North West; Rahaji cattle, Balami and Sahel sheep at the North East; and -Muturu, Ndama, Keteku cattle, West African Dwarf goat and sheep at the South West; (2) undertook concurrent conservation and crossbreeding to address food security; (3) promoted collaboration with research centres and foreign breeding companies to set up semen and embryo collection centres to serve the needs of Nigeria and the surplus for export.

To maintain pedigree details of animals, the government of Nigeria plans to implement genetic improvement programmes for which performance recording is a prerequisite, as well as animal identification and traceability recording systems, by livestock improvement organizations. The goal is to assist farmers in the management of their herds. A further goal of the Nigerial government is to establish veterinary health institutions and organizations to manage the health and vaccination of herds or individual animals (FRN 2019).

Highlight of Livestock Development Programs by the Government of Ghana

Genetic Improvement Programme in Ghana

Up until 1990, there was no livestock genetics improvement program in existence in Ghana (Okantah 2009) that addressed the multifunctional roles played by various livestock species. The Ministry of Food and Agriculture, university faculties of Agriculture, and the Animal Research Institute were the major organizations that showed interest in breed evaluation and genetic improvement of cattle in Ghana. The programs included the use of Zebu crossed with Taurine (e.g. White Fulani × West African Shorthorn), exotic × local (e. g. Friesian × Sanga), or pure-bred exotics (e.g. Friesian). According to Okantah (2009), the exotics and their crosses had better growth rates and milk yields than indigenous breeds. However, the exotic breeds also had poorer adaptation to the local environment. It was concluded that the very elaborate breed evaluation and genetic improvement experiments conducted by the universities were limited to stations, resulting in little or no impact on the livestock production systems. The experiments by the Ministry of Food and Agriculture were the most successful, as the Sanga progeny from the Zebu × Taurine crossbreeding projects was adopted by farmers in all cattle-rearing regions in the country (Okantah 2009), but the genetic improvement efforts were largely uncoordinated at the time.

In recent years, Ghana Ministry of Food and Agriculture attempted the modification of the existing livestock development policies and strat-

egies in the country with the overall objective to develop a competitive and more efficient livestock industry with capacity to increase domestic production, reduce importation of meat and livestock products, and contribute to the improvement of the livelihoods of all livestock value chain actors and the national economy while protecting the environment, preserving livestock biodiversity, and ensuring bio-security. The strategies put in place were (1) to promote conservation and genetic improvement of indigenous breeds of livestock with a rich diversity of animal genetic resources that have over the years survived the existing harsh environments and disease challenges and (2) to improve the production and productivity of livestock by promoting and disseminating improved technologies, among others (GMFA 2016).

The necessity for all stakeholders to contribute to the genetic improvement of indigenous livestock genetic resources to ensure sustained food and nutrition security, particularly for rural households, was recognized. Within this recognition, the following categories of poultry and livestock species were areas of particular importance and focus: domestication and improvement of Grasscutter farming; characterization, conservation, genetic improvement, and commercialization of local chicken and guinea fowl ecotypes; genetic improvement of the local Ashanti Black/Dwarf pig, indigenous sheep and goat breeds, and indigenous cattle breeds and their crosses (Ghana Shorthorn, Sanga, N'Dama and their crosses).

Different livestock breeding programs that have been implemented in Ghana so far are: traditional livestock breeding system which involves the use of supposedly good males, often selected by visual assessment for upgrading flocks in the extensive (characterized by uncontrolled mating) and semi-intensive systems; and open nucleus breeding scheme which is based on individual animal performance. The open nucleus breeding scheme was undertaken by Animal Production Directorate in its genetic improvement program in conjunction with participating breeders. This scheme covered Djallonke sheep and goat, the Ashanti Black Forest pigs, and the West African Shorthorn cattle. There were on-farm selection of breeding animals (male and female) and on-station at Animal Production Directorate breeding farms. The aftermath of the selection and breeding was distribution of selected males to participating breeders for multiplication and sale of selected male offspring to other farmers for the genetic improvement of their flocks. However, the increasing use of exotic livestock and lack of conservation of indigenous breeds has been implicated in the decrease in the relative abundance of the West African shorthorn from 65% to 47% of Ghana national cattle hard in 2001 which later declined to 39.3% in 2011 (GMFA 2016).

To accomplish successful growth in the near futur, comprehensive policy and strategy instruments are required that will enable the country's livestock resources and the many actors in the livestock value chain to express their potential. A road map for the efficient application of suitable policies and strategies will need to be implemented on time, and closely monitored and evaluated.

31.3 Role of Non-governmental Organizations and Other Charities

According to the Britannica dictionary, non-governmental organizations (NGO) are a voluntary gathering of persons or organizations, not affiliated to any government, with common interests to provide a service or advocate on common topics. While majority are not-for-profit organizations, a small number of them are for-profit organizations. NGOs are involved in a wide variety of activities including trade unions, religious organizations, community groups, agriculturally based organizations, among others. The 1970s onwards saw an explosion of international NGOs in Africa focusing on different areas of development and relieve activities including livestock improvement (Thomas-Slayer 1992). In Africa, NGOs have thus been instrumental in advancing livestock improvement with the main goal of helping local communities out of poverty. Many international NGOs have contributed signifi-

cantly in advancing the livestock sector in Africa including Catholic Committee against Hunger and for Development (CCFD) (French Catholic founded NGO), German Agro Action (GAA), Heifer International (HI) (USA founded NGO), OXFAM (British-founded confederation of 21 NGOs), Nederlandse organisatie voor internationale ontwikkelingssamenwerking (Netherlands Organization for International Development Cooperation) (NOVIB), Services d'Appui aux Initiatives Locales de Développement (SAILD) (local NGO in Cameroon), and Vétérinaires Sans Frontières (Veterinarians Without Borders) (VSF) (France, Belgium, and Switzerland), among others. These NGOs work with many stakeholders to drive their specific agendas in areas of focus.

Responding to achieving the United Nation's sustainable development goals (SDGs) (FAO 2015), a multistakeholder partnership of governments, organizations, civil society, research/academia, private sector, donors, NGOs, inter-governmental and multi-lateral organizations committed to the sustainable development of the livestock sector developed a common Global Agenda for Sustainable Livestock (www.livestockdialogue.org) development. The NGO cluster (The Donkey Sanctuary, HI, Kyeema Foundation, the LIFE network, and VSF) is committed to working with smallholder livestock farmers and pastorals in low- and middle-income countries to meet set targets. The NGOs are specialized in different aspects of relevance to pastoralism and smallholder livestock farming, animal health and welfare, environment, resilient livestock-based livelihoods, and integrated service delivery for poverty reduction. A recent policy brief by the NGO cluster examined smallholder and pastoral systems and highlighted the role of sustainability and innovation, and the impact that modern technologies (e.g. mobile phones), scientific research (e.g. new immunization methods), and favourable policies have on sustainable development (GASL 2019). The role of HI or Heifer Project International (HPI) is further highlighted as a case study to give better insights into the activities and functioning of an NGO in resourcing livestock genetic improvement in Africa and Cameroon in particular.

31.3.1 Case Study: Four Decades of HPI Role in Driving Livestock Genetic Improvement in Cameroon

Heifer International (HI) or Heifer Project International (HPI) (www.heifer.org) is a development not-for-profit organization (NGO) working to end hunger, poverty, and care for the earth by using sustainable practices and engaging smallholder farmers in agricultural development. Heifer International is founded on the simple belief that ending hunger begins with giving people the means to feed themselves, generate income, and achieve sustainable livelihoods. With this strong foundation, Heifer focuses her pro-poor work by creating wealth through viable value chains that harness the social capital of communities to drive market development. Heifer International works in about 21 countries across the World, and these countries are located in Africa, Asia, and the Americas, and USA. Notably, HPI has worked with over 46 million people worldwide. The activities of HPI in Cameroon will be further highlighted as an example of its achievements in many countries.

The HPI has been involved in dairy development in Cameroon since 1974. Prior to this period, Cameroon was a typical tropical developing country with relatively little or no dairy tradition apart from milking of cattle under an extensive traditional system of management by Fulani pastoralist and a small dairy farm established in Buea (Upper Farms) in the 1930s with the introduction of the German Brown Cattle by colonialists (Atekwana and Maximuangu 1981). HPI's first attempt to jumpstart the development of the dairy industry in Cameroon began in 1974 with the introduction of 22 Holstein–Friesian and Jersey (Fig. 31.2) cattle imported from the United States of America (USA). This was followed by subsequent importations of live cattle (Holstein and Jersey) and semen, dairy goats, pigs, and chicks (chicken), equipment, and supplies in sub-

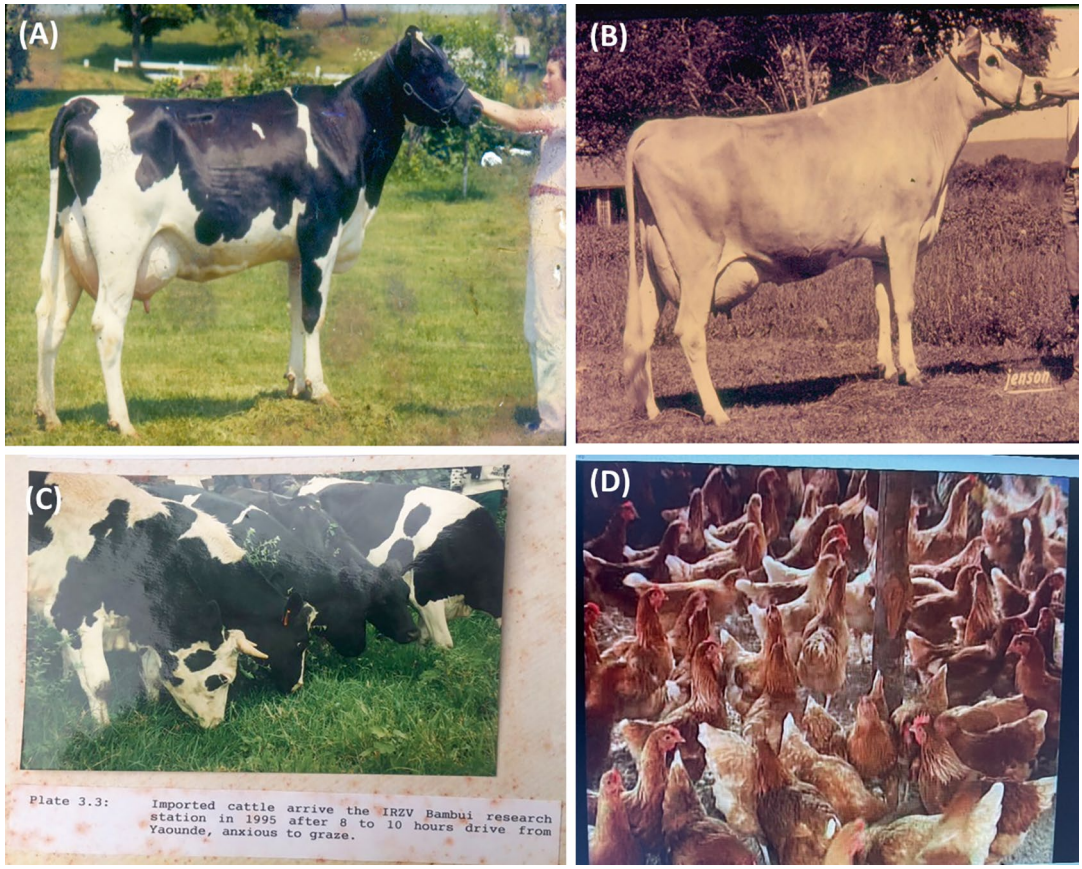

Fig. 31.2 Imported Holstein (**a**) and Jersey (**b**) and Holstein (1995 batch) (**c**) at IRZV Bambui centre, as well as imported hens (**d**). (Photos by HPI, extracted from HPI Cameroon archives and provided by Emmanuel Bassam (HPI Director of Program))

sequent years. The aim of these importations was to improve the genetic make-up of indigenous cattle (Gudali, Red Mbororo (or Red Fulani), and White Fulani), sheep, goat, pig, and chicken populations through crossbreeding for improved milk, meat, and egg production. The imported animals and supplies were used for research and development purposes at the Institut des Recherches Zootechniques et Vètèrinaires -IRZ (Institute of Animal and Veterinary Research) (presently IRAD - Institut de Recherche Agricole pour le Dévéloppement (Agricultural Research Institute for Development)) centres at Bambui, Mankon, and Wakwa. Crossbreds (progenies) of exotic cattle and indigenous cattle (same for other livestock species) developed at these research centres were distributed to local farmers via extension services. This marked the official beginning of HPI agricultural development activities in Cameroon.

Following HPI's initial activities in 1974, the next 10-year period of operations (1975–1984) was regarded as the decade of implantation and experimentation. A HPI and the National Office for Scientific and Technical Research (ONAREST) of Cameroon (ONAREST—HPI) cooperation started in 1976 with objective "to make animal protein more readily available, and cheaply too, to the population of Cameroon". The specific objectives of the program were to (1) build a genetic base on which the Cameroon livestock industry will expand; (2) improve the economic and nutritional status of rural people and increase the supply of livestock products to urban centres; (3) reduce foreign exchange on the importation of animal products and by-products;

(4) provide employment opportunities to curb rural exodus; (5) provide good quality breeding stock to smallholders at subsidized prices; and (6) provide training and management opportunities to livestock farmers. The IRZV Bambui centre was focused on dairy cattle development, while the IRZV Mankon centre was focused on dairy goat development. A 1978 evaluation of the IRZV Bambui dairy program indicated that the exotic dairy breeds adapted well, reproduced, and produced normally under the prevailing climatic and environmental conditions of Bambui, which facilitated the extension of the dairy program to local farmers. To join the program, training sessions were organized and farmers who completed the training as well as demonstrated capacities (had pastures of sufficient quality and quantity) and well-constructed milking sheds were offered dairy animals.

Working jointly with the Institute of Animal Research (IAR), HPI began distributing crossbred dairy cows to smallholder farmers in 1978. By 1981, a semi-intensive dairy production system based on the South-South Workshop on Contributions of HPI to small-scale dairy development in Cameroon was instituted in the North West Province of Cameroon (Fig. 31.3a–c). HPI also engaged in pasture and forage development (Fig. 31.3d) and in using local knowledge, herbs, and practices (ethnoveterinary medicine) to treat sick animals.

The HPI-Farmer activities resulted in the establishment of the Bamenda Dairy Cooperative Society (BDCS), which functioned by distributing feed to farmers on a monthly basis, collected and sold farmers' milk on a daily basis, and held monthly appraisal meetings with farmers. Farmers needed 5–6 years of technical advice, encouragement, and support to fully establish as smallholder dairy farmers.

During this period, the productivity of the Holstein as expected was higher (3500–4000 L) compared to crossbred animals (Holstein × zebu) (2700–3300 L) and zebus (300–800 L) in a 270–300-day lactation period. HPI also initiated collaborative work with several local institutions, including the Presbyterian Rural Training Centre (PRTC) at Mfonta, the Saint Joseph's Children and Adult Homes (SAJOCAH), and the Sisterhood of Emmanuel in Bafut in 1981. HPI also worked with many smallholder farmers, gave practical training courses, and distributed animals on PASSING On the Gift (POG) basis, thus initiating the shift in focus from research to working directly with farmers. The initial decade of operation helped define HPI-specific objectives in Cameroon (Box 31.1).

Box 31.1 HPI-Specific Objectives in Cameroon

1. Respond to requests for development assistance such as provide livestock and related training and technical assistance, to enable families attain self-reliance in food production and income generation on a sustainable basis.
2. Encourage farmers who receive in-kind loans of livestock from HPI to pay back by passing on the gift to other farmers in a manner that enhances dignity and accord an opportunity to everyone to make a difference in the fight to alleviate hunger and poverty.
3. Support project leadership development at the local level, farm-family unity, and cultural unification.
4. Work with farmers to develop appropriate techniques for year-round on-farm feed production, integrated agriculture, and better farm management, thereby ensuring reduced livestock mortality rates and increased animal and crop production.
5. Provide extension services to HPI-assisted farmers in collaboration with farmer leaders and collaborating agencies.
6. Actively support the formation and management of viable small-scale farmer cooperatives and other self-help activities, mostly those by women groups, and encourage project sustainability, farm-family self-reliance, and savings in credit unions.

7. Exploit the potentials of agroforestry in enhancing sustainable livestock production and agricultural production in general, and environmental protection.
8. Promote parity between men and women by (i) consulting development partners at the various stages of project plan implementation, accomplishment, and evaluation; (ii) accompany development partners through exchange; (iiil) develop, test, and apply effective gender balance practices and also share same; (iv) gather and disseminate gender assessment tools, methodologies, and practices; and (v) collaborate with agencies that prioritize gender.
9. Conduct nutrition studies and education, public awareness programs, and market studies to promote the sale and consumption of crops and livestock.
10. Make HPI-assisted livestock and integrated projects profitable through family employment, human nutrition improvement, and income-generating activities.
11. Apply indigenous veterinary medicine practices to control and treat economically important livestock diseases and other complications.
12. Set up and operate para-veterinary associations and use well-trained and experienced Fulani grazers and other capacity building activities for staff (HPI and local), volunteers, and student interns.
13. Conduct training and other capacity-building activities for staff (HPI and local), volunteers, and student interns.
14. Collaborate with other organizations in co-financing and facilitation of technical and other networking arrangements that enhance the progress of projects.
15. Cost-effectively use human and material resources to achieve project goals.

Between 1980 and 1983, HPI extended its training initiatives by sponsoring 14 persons for short- (8 persons) and long- (6 persons) term courses in the USA, as well as provided infrastructural support to the IRZV Mankon station and purebred Holsteins (imported from USA and supported by the United State Department for Agriculture (USDA)) to IRZV Wakwa station. In 1982, HPI distributed Jerseys and Holstein Friesians to individual farmers and several institutions like Mambu Health Centre (Bafut), Emmanuel Sisterhood of Bafut, PRTC Fonta, Mbengwi Monastery, Catholic Mission Njinikom, Mbingo Hospital, Ndu Baptist College, and Shisong hospital. Following an evaluation of the productivity of animals, HPI determined that crossbred (exotic × zebu) dairy cattle had superior adaptability to the prevailing environmental conditions and local management practices and lower mortality than exotic purebreds.

A cooperation between IRZV, HPI, and USAID which started in 1976 and renewable every 5 years established a "*HPI Small Farmer Livestock and Poultry Program*". The program ended in 1985 with an end-of-project evaluation report that strongly recommended among others that: (1) the "crossbreeding *program between Holstein Friesians and white Fulani be continued in IRZV Bambui station*; (2) *the* crossbreeding *program between Holstein Friesian and Gudali be discontinued in Bambui but continued in Wakwa*; and (3) *artificial insemination with frozen semen be encouraged at Bambui and Wakwa Stations*".

A dairy goat program with goal to "improve the management of dairy goats" was instituted at the IRZV Mankon centre. Animals under the program performed poorly due mainly to poor management resulting from the lack of experience in goat management and training in livestock production by the staff of the Centre, most of whom were hired at entry level with no formal training in livestock management. To solve the problem, four persons were trained on different aspects of animal production in the USA to supplement the lack of experience by IRZV staff in

Fig. 31.3 Farmers receive Holstein-Friesian cattle at Nseh Mbabu village (**a**), Holstein-Friesian under semi-intensive system of management at Bamendakwe (**b**, **c**); and HPI staff at a pasture and forage development site at Fonta, Bambui (**d**). (Photos by HPI, culled from HPI Cameroon archives and provided by Emmanuel Bassam (HPI Director of Program))

goat production management. The goat herd which included 42 dairy goats from the HPI shipment of 1976 and 50 local goats bought with funding support by the International Foundation for Science of Sweden was not sustainable due to poor management. The management failures included (1) lack of training and supervision of livestock attendants; (2) overgrazed paddocks; (3) disease, theft, lack of adequate nutrition and disease management, and poor housing conditions; (4) inadequate grass/forage production for confinement feeding and supplemental feeding in the dry season; (5) lack of water for dry season cleaning of the goat and sheep barns and for filling dipping vats; (6) underfeeding of kids; (7) irregular feed supply; (8) incompetent veterinary personnel; (9) failure to treat sick animals; (10) lack of a breeding program; and (11) neglect of routine management practices.

In the face of many challenges of maintaining exotic animals, HPI in 1983 discontinued the importation of exotic animals and concentrated on crossbreeding (natural service and artificial insemination) programs. To ensure an adequate supply of dairy cattle to participating farmers, HPI instituted crossbreed "multiplier herd" farms in collaboration with local institutions like Mambu Health Centre (Bafut), Emmanuel Sisterhood of Bafut, PRTC Fonta, Mbengwi Monastery, Catholic Mission Njinikom, Mbingo Hospital, Ndu Baptist College and Shisong hospital, and colonel Valentine's centre in Ndop.

In the third decade (1985–1994) of operation in Cameroon, HPI focused more on direct grassroot assistance and support. While USAID and MESRES (Ministry of Higher Education and Scientific Research) in collaboration with MINEPIA were willing to participate in exten-

Fig. 31.4 A ram from HPI Project in the far North Region of Cameroon (**a**); Sheep placement in the Mbam Upper Sanaga Valley Integrated Sheep/Goat Project in the Center Region of Cameroon by HPI (**b**); and Sheep placement in the Bui Donga Small Holder Integrated Sheep & Goat Project in the Northwest Region of Cameroon by HPI (**c**). (Photos by HI, extracted from HPI Cameroon archives and provided by Emmanuel Bassam (HPI Director of Program))

sion and on-farm research with HPI, Cameroon through ONAREST laid more emphasis on research, while on-farm extension services were neglected. This disagreement in direction of focus caused a fracas in the IRZ/HPI/USAID cooperation causing HPI to downsize on its activities, withdraw most of its staff from Cameroon in 1985, and hand over most of its assets to IRZV. Now operating at a limited scale, HPI focused on its traditional on-farm/extension approach with farmer training and direct placement of animals on small-scale farms (Fig. 31.4).

Following the Lake Nyos gas disaster in Cameroon in 1986 (Kling et al. 1987), HPI responded by providing much needed relieve to livestock farmers. Under a 1987 HPI project tagged "*Lake Nyos Livestock Restocking Project*" (sponsored by HPI and Equatorial Foundation), livestock (pregnant Zebu cows, Holstein Friesians, Boran and cross-bred Boran × Holstein Friesians) (Fig. 31.5) were imported from Kenya and distributed to Fulani livestock farmers who lost their cattle during the Lake Nyos disaster for resilience building in the gas-affected communities of Nyos. Furthermore, HPI participated actively by providing relief materials and resettling the Lake Nyos gas disaster survivors living in camps out of the disaster area. The resettlement efforts by HPI were facilitated by a collaboration with the Presbyterian Church in Cameroon

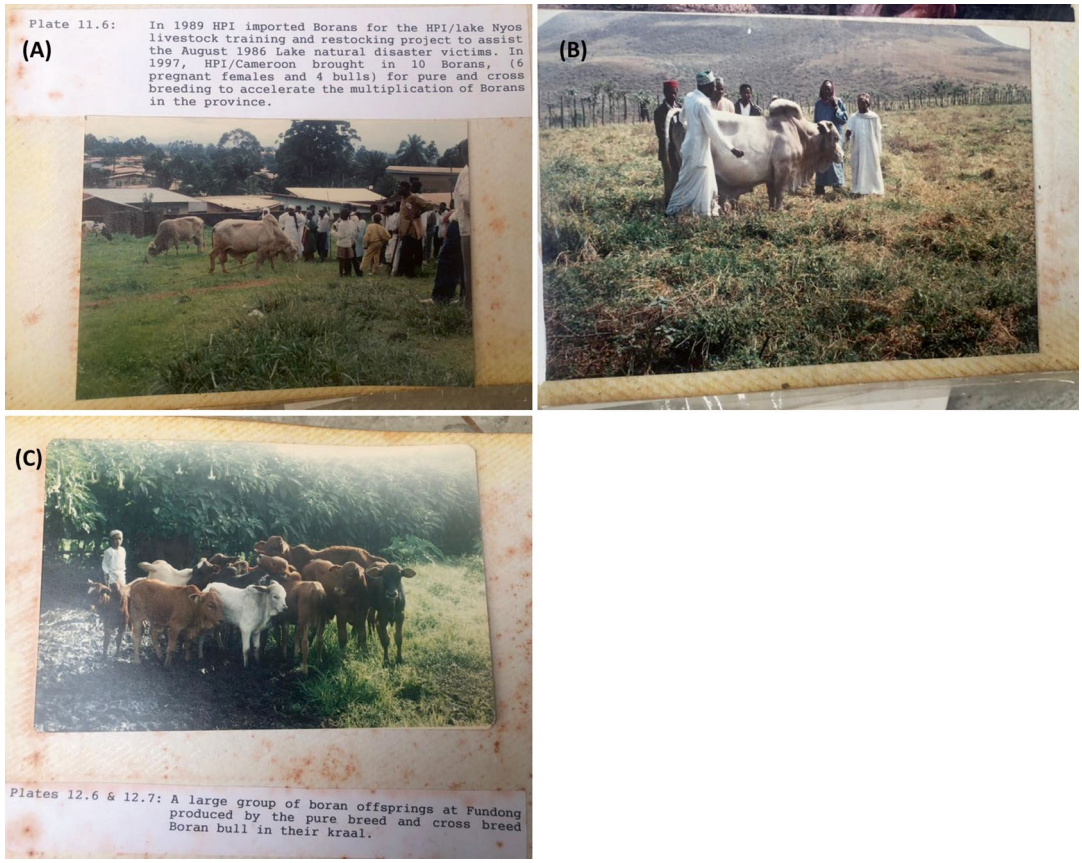

Fig. 31.5 Boran animals imported from Kenya (**a**, **b**) and offspring of Boran × Zebu (**c**) distributed to farmers under "*Lake Nyos Livestock Restocking Project*". (Photos by HI, extracted from HPI Cameroon archives and provided by Emmanuel Bassam (HPI Director of Program))

to mutually undertake smallholder agricultural and livestock projects in the country, a cooperation that lasted until 1994. To achieve resettlement objectives, HPI worked in collaboration with several individuals and organizations such as Wum Catholic Mission with Rev Fred Ten Horn, Wum Area Development Authority, Peace Corps, and Equatorial Foundation to provide livestock and assorted crop seeds, among others, to survivors at resettlement camps in Waindo, Buabua, Essu, Kumfutu, Yemge, Kimbi, and Epalem for planting as a source of food security. These activities strengthen HPI's yearning for sustainable integrated agriculture, with staff and farmer capacity-building initiatives. In 1989 and 1990, ethno-veterinary and Women in Livestock Development (WiLD) projects, respectively, were initiated.

In the period 1990–1995, HPI funded the SAJOCAH project with Aidfund assistance provided by Mr, Jeop Duynstee. The Aidfund assistance to SAJOCAH included livestock (13 heads of dairy cattle, one pair of oxen, 60 rabbits, and 300-day-old chicks), agricultural equipment (locally made brooders and brooder guards, locally made poultry drinkers, cement troughs for cattle, rabbit cages, cement feeding troughs for pigs, corn shelter machine with spare parts and maintenance services, equipment for small scale milk processing, grinding mill, and fence), and yearly operating cost to sustain the project. During the same period, HPI in collaboration

with Laboratoire National Vétérinaire (LANAVET) and Pan-African Rinderpest Campaign (PARC), initiated the Project of Organization for African Unity/Inter-African Bureau for Animal Resources in 1993 to promote the use of heat-stable Rinderpest vaccine by Community-Based Animal Healthcare agents in Cameroon. Meanwhile, a partnership established with Mieke and Joep from Holland in 1994 enabled HPI to operate a regional strategy-based umbrella project that extended its activities to the West and Southwest Regions under British High Commission sponsorship with funds from the Department for Foreign and International Development. In the same year (1994), HPI started a consolidated small scale Dairy Development Project, managed semi-intensively or by zero-grazing, with emphasis on improved productivity on minimum land and quality animal management and breeding through farmer-managed artificial insemination centres. Purebred Holstein and Friesian cattle were used in the zero-grazing production system with the aim to achieve milk production levels comparable to those of developed countries. The main forage species fed to animals were Brachiaria, Guatemala, elephant grass, Desmodium and Stylosanthes, and concentrates. Milk produced was sold mainly to SOTRAMILK, established through a loan granted by the RABO Bank of Holland. SOTRAMILK mainly served farmers in Mezam division due to proximity to the factory, while farmers in Bui and Donga/Mantung divisions were not served due to distance. However, the marketing of milk was hampered by many problems such as the dispersed location of farms and low yields causing problem of collection and transportation to the factory. Figure 31.6 shows project participants showing off their milk to government officials and veterinarians during the 40th anniversary celebration of HPI presence in Cameroon.

An evaluation of the Dairy Development Value Chain project in the Northwest and Western regions of Cameroon to improve livelihoods for the period 1995–2009 is presented in Box 31.2.

HPI continued field projects and activities in Cameroon until 2015 which culminated with its 40th-anniversary celebration (26 June 2015), field staff departure, asset disposal (August 2015), and closure of Heifer Cameroon Program (December 2015). Today, HPI continues to work in 19 countries across four continents including nine African countries (Ethiopia, Kenya, Malawi, Nigeria, Rwanda, Senegal, Tanzania, Uganda, and Zambia).

HPI's four decades work in Cameroon was facilitated by partnerships and funding from indi-

Box 31.2

Performance indicators of HPI Dairy Development Value Chain in the Northwest and Western regions of Cameroon to improve livelihoods from 1995 to 2009.

Project location: Noun Division in the West Region and Mezam and Bui Divisions in the North West Region. The North West and West Regions make up the Western Highlands agroecological Zone.

Variables:

- Number of farm families supported: 20 (1995) to 971 (2009)
- Number of purebred dairy cattle: 20 (1995) to 633 (2009)
- Average daily milk yield/cow: 6–10 L (up to 1994) to 16–21 L (2009)
- Average calving interval: 16–18 months (up to 1994) to 12–15 months (2009)
- Objective of dairy farming: largely subsistence (up to 1994) and market-oriented (2009)
- Number of groups assisted: 1 (1995) to 22 (2009)

Successes recorded:

1. Milk production improved with increasing parity: first lactation yield ranged from 10 to 22 L with an average of 13.7 L daily; second lactation yield ranges from 10 to 25 L of milk with an average of 15.7 L of milk daily.
2. Sustainably improved household socio-economic growth/development: about 404 farm families recorded increased household income through earnings from sale of milk and livestock; increased income used to improve livelihoods through the purchase of household furniture/assets, farm tools and inputs, farmland, and motorcycles and build new homes.
3. Socio-economic empowerment of women and improved gender relations in supported household: about 167 women owned dairy cattle as direct project partners, supported their husbands by providing basic household needs, and paying children's school fees; women increasingly involved in household decision making at all levels in their households; and about 37% (61 out of 167) of participating women occupied leadership positions within dairy cooperatives/common Initiative Groups and other community groups.
4. Improved education of children in supported households: A total of 709 children (358 boys and 351 girls) from 259 farm families acquired an education (basic, secondary, vocational, high School, and university education) with income from project activities; and academic performance of children improved through regular attendance of classes and having adequate school needs.
5. Increased use of animal manure-enhanced soil nutrient and structure: (1) Majority of supported farm families (89.1%) used ecologically sustainable farming practices such as animal manure, composting, use of crop residues in feeding livestock, planting of leguminous trees, contouring, and ridging across the slopes. Moreover, a cumulative of 642 non-assisted members in assisted project communities adopted composting and use of crop residues. (2) Participating farm families (404) planted 121,200 environmentally friendly trees like Calliandra, Acacia, and Leucaena and established 303 hectares of Bracharia and Guatemala forage plots. These practices in addition to other environmentally friendly practices reduced soil erosion and improved soil fertility leading to increased crop yields. There was increased crop yields (from the same size of land) by majority of farm families (76%).

6. Mitigation of the impact of HIV and AIDS: Participating families sensitized on HIV and AIDS prevention and care; persons (565 men and 296 women) within 404 project partners adopted responsible sexual behaviours. In addition, a cumulative of 2666 non-Heifer-assisted persons within project communities adopted responsible sexual behaviours.
7. Organization of assisted farmers in dairy cooperatives and common initiative groups: Beginning with one Dairy Cooperative in 1995, HPI Cameroon supported small-scale dairy development program working with 15 dairy cooperatives and seven (7) Common Initiative Groups, organized under the umbrella of the Cameroon Union of Dairy Cooperative Societies.
8. Other project spread effects: Private Dairy Processing Plans such as Cameroon Dairy Industry and SOTRAMILK established as a result of the project; other private individuals and institutions started dairy development within and without project region; project built the capacity of students within and outside Cameroon; project inspired the initiation of a national dairy development program by the government.

vidual donations, organizations, community organizations and groups, national government, other NGOs, and international organizations. To support its activities, HPI brought in various experts into Cameroon (administrators, experts in various areas of livestock production, agronomist, economist, etc.) who worked in collaboration with IRZV (now IRAD), MINREL, MESRES, MINEPIA, USAID, local farmers, local farmer groups/associations, local institutions, Christian institutions, and other Government departments. Funding of its activities came from many sources including USAID, International Foundation for Science (Sweden), BOTHAR (Ireland), WILD GEESE (Holland), ASSIA (Holland), and Bread for the World (Germany), etc. For example, USAID invested 1.3 million USD during the period 1980–1985 for the construction of laboratory and research facilities and other infrastructures at IRZV Mankon and promoted small farmer livestock and poultry projects with the training of 14 personnel for short- and long-term courses; while between 1974 and 1985, HPI spent about *USD 1,494,625.85* as a direct investment on livestock purchase/imports, purchase of equipment and supplies and training, among others.

HPI's activities in Cameroon clearly demonstrate multi-partnership engagement in resourcing livestock improvement. Clearly, HPI positively impacted the livestock industry in Cameroon and can be regarded as the initiator of the development of the livestock sector in Cameroon using improved and pure breeds of cattle, pig, guinea pig, rabbit, poultry, and goat, and indigenous livestock breeds. Despite the success of the HPI partnership with other institutions to deliver livestock improvement in Cameroon, many obstacles were evident. For example, limited funding, knowledge gaps, and a lack of clear livestock development policy and commitment by the government of Cameroon where the major limiting factors faced by HPI during her operations in Cameroon.

This report on HPI is based on HPI annual reports (1974–2015), a report on the contribution of HPI to Small Scale Dairy Development in Cameroon and a background report of HPI in Cameroon (written by HPI Cameroon Staff to mark the celebration of her 40 years of effective presence in the development space in Cameroon). These reports were provided by Mr. Emmauel Bassam, Director of Program at HPI (2012–2015).

31.4 Regional, Continental, and International Organizations

31.4.1 International Development Institutions

International institutions and funding bodies have played significant roles in resourcing animal improvement programs in Africa such as the Consultative Group on International Agricultural Research (CGIAR), ILRI, Biosciences eastern and central Africa (BecA), the EU, USAID, Canadian International Development Agency, among many others. The international agencies focusing on livestock genetic improvement in Africa include mostly research-based institutions such as the ILRI and BECA. While these agencies undertake a wide spectrum of research in line with the mandate from their funders, a lot of their work lend itself to support livestock genetic improvement. In many cases, they have very good facilities and skilled staff which facilitate training and manpower development in highly specialized fields of genetics and livestock improvement. On many occasions, these agencies get funding to host key research projects directly related to livestock improvement.

The ILRI, as an example, has significantly impacted the livestock sector development and training in Africa (https://www.ilri.org/). ILRI, a CGIAR research centre located in Kenya and Ethiopia with offices in other African countries and Asia, focuses on improving livelihoods through livestock research and development in developing countries. In collaboration with its partners, ILRI works to (1) develop, test, adapt, and promote sustainable and scalable science-based practices to support better lives through livestock; (2) provide persuasive scientific evidence that clear and favourable policies and significant investments for livestock research can bring about significant socio-economic growth, positive health and environmental gains to farm families and developing nations; and (3) increase capacity building among key stakeholders to promote better utilization of investments in livestock and livestock science (knowledge) for enhanced livelihoods. With funding from hosting nations and international partners, ILRI's research activities in livestock have directly or indirectly impacted the African livestock sector. For example, ILRI in collaboration with multiple partners including western research institutions, national dairy genetic companies, international dairy genetic companies, farmer organizations, national livestock seed regulators, national agricultural research and extension systems planned and implemented the "The African Dairy Genetics Gains (ADGG) (https://portal.adgg.ilri.org/)" and "African Chicken Genetic Gains (ACGG) (https://africacgg.net/)" projects aimed at enhancing productivity in smallholder farming systems (ILRI 2022). The ADGG program supported by Bill and Melinda Gates Foundation and CGIAR trust fund drives improvements in national breeding schemes by analysing performance data collected in the production environments to produce and publish breeding values for enhanced productivity and adaptation. It has established centralized dairy performance recording centre's in Kenya and Tanzania with an initial 12,000 smallholder dairy herds; developed desktop, web, mobile tablet and sms-based solutions with dynamically defined user roles; and established a pilot information and communication technology-based platform for collation, evaluation, and feedback on phenotypic and genomic data from smallholder farms in Tanzania and Ethiopia (Ojango et al. 2022; Mrode et al. 2020). Following the evaluation of pedigree data collected in 2020, restricted selection indexes and a genomic prediction pipeline for animals in smallholder production environments were developed and results shared with farmers through extension messages sent digitally through the iCow system. The timely sharing of genomic evaluation and breeding management support messages helps farmers make informed decisions for improving the productivity of their animals.

The ACGG, an African-wide multistakeholder initiative led by ILRI, aimed to provide improved chicken genetics to smallholder farmers in Africa. Specifically, develop high genetic producing breeds well adapted to low-input production systems; make available breeds preferred by farm-

ers; develop innovation platforms and solutions across the chicken-value-chain; encourage the active participation of women and promote public-private partnerships for improvement; and multiplication and delivery of improved chicken genetics to needing communities. The success of the ACGG project includes the following: (1) enhanced poultry productivity (for example, the results of on-station and on-farm tests show 200% and 300% increase in egg production and body weight, respectively, from indigenous and tropically adapted chicken breeds); (2) made available locally adapted more productive chicken breeds preferred by farmers; (3) empowered women; (4) delivered training in poultry farming; (5) developed tools that enhanced poultry farming and contributed to improving the livelihoods (nutrition and income) of participating households; (6) created linkages across the chicken production value chain in all three project countries (Ethiopia, Nigeria and Tanzania); and (7) developed and maintained notable stakeholder engagement that ensured the success of the program. The DCGG at its inception in 2014 initially focused on three countries (Ethiopia, Tanzania, and Nigeria) but has recently extended its activities to six other countries (Kenya, Ghana, Zimbabwe, Cambodia, Myanmar, and Vietnam) causing a change in appellation from ACGG to Tropical Poultry Genetic Solutions (TPGS). The TPGS intends to continue the implementation of the successfull ACGG program in all nine countries and, in addition, will address nutrition, health, finance, and policy aspects of chicken production. The ACGG/TPGS activities are facilitated with funding from the Bill and Melinda Gates foundation and CGIAR Trust fund and its multi-partners (e.g. the *Federal University of Agriculture Abeokuta, Nigeria*; National Animal Production Research Institute, Nigeria; Obafemi Awolowo University, Nigeria; Ethiopian Institute of Agricultural Research; Haramaya University, Ethiopia; Tanzania Livestock Research Institute; Sokoine University of Agriculture, Tanzania; Emerge Centre for Innovations-Africa (previously PICO-Eastern Africa); Animal Breeding and Genomics Centre, Wageningen University, Netherlands; Koepon Foundation; farmer groups; among others).

These projects (ACGG and TCGG) have demonstrated, most importantly, that the numerous challenges in bringing about livestock genetic improvement in Africa can be overcome through multistakeholder engagement. They also demonstrated that with the genomic revolution, genetic improvement in Africa can follow other paths that can be more efficient and climate-friendly. A good example from the ADGG project is that multi-county genetic evaluation with centralized regional facilities is feasible in Africa (Mrode et al. 2019). Moreover, the emergence of the African Animal Breeding Network (AABNet) with "multi-county genetic evaluation" as one of its pillars (Djikeng et al. 2025) further supports this concept.

31.4.2 Global Initiatives for Genetic Evaluations and Sustainable Livestock Improvement

While individual national or regional organizations facilitate data collection, storage, management, and utilization within their respective countries/regions, collective efforts through coming together under one umbrella organization facilitate international cooperation and collaboration. Examples of such international cooperations are the International Bull Evaluation centre (INTERBULL), the International Committee for Animal Recording (ICAR), and the Global Agenda for Sustainable Livestock (GASL). The INTERBULL is based in Uppsala, Sweden. It was set up specifically to undertake and regulate international evaluation of dairy bulls. It specializes in providing international genetic evaluation of dairy bulls across countries so that these can be ranked on the same scale across countries. This ranking of bulls on the same scale facilitates across-country comparison and trade in dairy cattle genetic resources. The initiative facilitates international trade in dairy bull semen such that farmers in Ireland can choose to buy and use semen from a bull in New Zealand and another

bull in Canada in addition to bulls in Ireland. Using bull semen across countries allows rapid improvement of national stock performance in line with defined breeding objectives and facilitates the creation of genetic links across countries which make international genetic evaluation even more accurate. The INTERBULL project has been so successful that it has now been extended to beef cattle with the establishment of INTERBEEF (https://www.icar.org/index.php/technical-bodies/working-groups/interbeef-working-group/).

The ICAR, based in Rome, Italy, is an international non-governmental agency (NGO) which aims to support the development of animal identification systems and the recording of animal performance, both of which are directly relevant for genetic evaluation and livestock improvement. By providing guidelines and international standards for animal identification and recording of performance, ICAR helps to develop unique animal identification systems and standardized systems for measuring performance. For example, it certifies the equipment used for milk recording and testing so that data collected globally can be compared on the same scale and hence suitable for across-country analysis. ICAR supports individual member countries/organizations in developing unique animal identification systems and hence the traceability of individual animals. This is critical in situations where individual animals such as bulls have offspring in different countries and production systems. Unique identification allows the daughters of the bull to be tracked in the different countries and by helping to standardize recording equipment, the performance of such bull daughters in different countries and production systems can be compared on the same scale.

Organizations like INTERBULL and ICAR will be critical in the development of genetic improvement programs in Africa where across-country genetic evaluations have been advocated as a means of minimizing cost by pooling resources across countries to facilitate continent-wide genetic improvement of livestock. Both these organizations are global in outreach, hence membership is open to all countries or group of countries with a joint evaluation. Presently, South Africa through the South African Studbook is a member of both the INTERBULL and ICAR. While participating in INTERBULL international evaluations requires the country to meet some basic requirements, ICAR can accept new entrants without any requirement and can help new member nations develop their infrastructure. It is logical to first join ICAR and then subsequently join INTERBULL when facilities for national genetic evaluations are in place and functioning.

The Global Agenda for Sustainable Livestock (GASL, www.livestockdialogue.org) is an example of multi-stakeholder partnership in resourcing global livestock improvement. Founded in 2011, the GASL is a partnership that capitalizes on the strength of the private and public sectors, producers, academic and research institutions, NGOs, foundations, social movements, and community-based organizations who have pulled forces to address human health, global food and nutrition security at the animal-human-environment interface, equity and growth including viable growth in value chains, and resources and climate change mitigation. The goals of the multi-stakeholder partnership include: (1) voluntary commitment to work together towards a common goal; (2) facilitate dialogue between numerous stakeholders across a broad range of sectors; (3) derive mutual benefits from working together through win-win agreements; (4) learn from each other; (5) strive for equitable representation and inclusiveness for all relevant stakeholders; (6) agree on modalities of governance such as rules and modalities of cooperation; and (7) ensure accountability and transparency.

The GASL is playing a key role in the implementation of the UN 2030 sustainable development goals (SDGS) (FAO 2015) by catalyzing and guiding the sustainable development of the livestock sector focusing on the economic, social, and environmental outcomes. The GASL prioritizes SDGS 1, 2, 3, 5, 8, 12, 13, 15, and 17 identified as having direct links to the livestock sector. Ending 2022, the GASL had 121 official partners, including 20 governments, 24 private sector organizations, 7 multilateral and intergovern-

mental organizations, 27 academic and research institutions, 5 social movements, 29 NGOs, and 9 donors (Confédération Nationale de l'Élevage, France; Agriculture and Agri-Food Canada, Government of Canada; Ministry of Foreign Affairs, Government of France; Department of Agriculture, Food and the Marine, Government of Ireland; Swiss Federal Office for Agriculture, Government of Switzerland; Ministry of Economic Affairs, Government of the Netherlands; Bill and Melinda Gates Foundation; United States of America Aid, Ethiopia; and Global Dairy Platform). Funding by the donor organizations is vital for the achievement of the objectives of the GASL.

31.4.3 Continental and Regional Communities and Regional Collaboration for Livestock Development

The African Union (AU) plays a very important role in livestock genetic improvement in the continent through its agencies, the African Union–Inter-African Bureau for Animal Resources (AU-IBAR), the Forum for Agricultural Research in Africa (FARA) (https://faraafrica.org/) (See Chapter 30), and others.

The AU-IBAR was founded in 1951 with the mandate to study the epidemiological situation and fight rinderpest in Africa. Today, the AU-IBAR's mandate covers all aspects of animal resources, including livestock, fisheries, and wildlife, across the entire African continent. The objectives of the AU-IBAR include coordination of the improved utilization of livestock species in the continent through setting enabling policies and providing support to member states. It encourages regional economic communities to set common livestock policies to facilitate the movement and trade in livestock. The AU-IBAR documents the AnGR in the content, supports training and dissemination of information, and maintains a database of the livestock genetic resources in Africa. To achieve its objectives, the AU-IBAR developed a 20-year Livestock Development Strategy for Africa (LiDeSA) to address Africa's development needs and challenges in the livestock sector. The Strategy is aligned with regional strategies, policy frameworks, and guidelines and coherent with the Comprehensive Africa Agriculture Development Programme, Frameworks, and Agenda (see Chapter 30). The main goal of the strategy is to transform the livestock sector by energizing its under-utilized potential through (i) encouraging increased investments from both public and private sources for the transformation of the sector to enhance its contribution to socio-economic development and equitable growth; and (ii) accelerate reforms in the sector.

The FARA is the apex continental organization responsible for coordinating and advocating for agricultural research for development. FARA serves as the technical arm of the Africa Union Commission on matters concerning agricultural science, technology, and innovation. The FARA has the mandate to provide leadership and guidance in agricultural research and development at the continental level. They achieve these through five key mandates; Policy and advocacy, research management and leadership, knowledge management and outreach, capacity development and agri-preneurship, observation and coordination, and finally multi-stakeholder partnerships. In July 2021, FARA became the hosting organization to facilitate the activities of the African Seed and Biotechnology Partnership Platform (ASBPP). This is the regional body tasked with the responsibility of helping to coordinate policy formulation on plant and animal seed generation and utilization across the continent based on sound research evidence (African Union 2021). The animal seed working group of ASBPP will take leadership advocating and guiding the formulation of policy regarding livestock genetic resource development and hence the resourcing of genetic improvement programs in Africa. Through the ASBPP, therefore, it is hoped that FARA will start to have an impact on improvement of livestock production in line with recorded success in crop production in Africa.

The various economic communities of African states (Economic community of West African States (ECOWAS), Common Market for Eastern

and Southern Africa (COMESA), Southern African Development Community (SADC), etc.) have established common livestock policies with main goal of increasing productivity and trade in livestock between member states (See Chapter 30). For example, the ECOWAS through its Agricultural Policy established a Livestock Action Plan for 2011–2020 with the goals to: promote the livestock, meat, and dairy sector; structure the livestock production sector; create a favourable environment for the development of livestock, meat, and dairy products (ECOWAS 2010). Current initiatives include facilitating pastoralism and ending livestock-crop farmer conflicts. An intergovernmental organization for Strengthening Agricultural Research in Eastern and Central Africa (ASARECA) (15 member states) has the mandate to (1) strengthen, catalyse, facilitate, and coordinate regional agricultural research for development activities; (2) improve delivery of national and regional research-driven initiatives for sustainable agricultural transformation and development outcomes; (3) enhance sustainable livelihoods for all; (4) support value addition of selected commodities; (5) develop climate smart agricultural practices; (6) enable smallholder farmers to deal with climate change issues; (7) enhance livelihoods among regional pastoral communities; (8) help member states develop agricultural development plans; (9) coordinate ASARECA Regional Agricultural Market Information System, and (10) manage Agricultural Digital Transformation for Development Hub.

31.4.4 Relevant International Agricultural Agencies

The Food and Agricultural Organization (FAO) of theUnited Nations (UN) sets the global agenda for the cataloguing, development, and conservation of AnGR as a means of ensuring food security and maintaining world biodiversity. The FAO maintains a database of AnGR and drives the AnGR agenda through policies, information collation, and sharing. With the adoption of the Global Plan of Action for AnGR (FAO 2007) in 2007, the world recognized the vital importance of AnGR biodiversity and in particular livestock biodiversity for agriculture, rural development, and food and nutrition security. Activities pertaining to sustainable use and conservation of biodiversity for food and agriculture are overseen by the Commission on Genetic Resources for Food and Agriculture (https://www.fao.org/cgrfa/meetings/commission/es/). Considering that livestock are central to achieving many of UN's 17 Sustainable Development Goals (SDGs) (FAO 2015; Schneider and Tarawali 2021), the FAO in collaboration with national governments, NGOs, and other support organizations is providing information and training in all areas of livestock production. The FAO actively collates and disseminates information on global livestock genetic resources. It maintains the Domestic Animal Diversity Information Systems (DAD-IS) data base (https://www.fao.org/dad-is/) . The DAD-IS is a searchable database of global livestock breeds, and breed-related information with links to other online resources on livestock diversity. This database allows the exploration of the diversity of livestock breeds at national, regional, and global levels as well as gives information on the status of breeds regarding their risk of extinction. Another database, the Domestic Animal Genetic Resources Information System (DAGRIS), is developed and administered by the ILRI. The DAGRIS facilitates the compilation, organization, and dissemination of data from research findings on the origin, distribution, diversity, use, and risk status of indigenous farm animal genetic resources. The FAO compiles and publishes on a regular basis books and reports on AnGR. Table 31.4 presents sample FAO books and reports on livestock.

31.5 The Place of Policy, Funding, and Technology in Facilitating Sustainable Livestock Production

Chapter 30 examines the global policy and strategy landscape on AnGR that is relevant for Africa, the extent to which these are being trans-

[b]A livestock database maintained by ILRI

lated into strategies, plans, and institutionalized practices by African countries, and the challenges being faced and opportunities for interventions.

The policy and institutional environments that drive characterization, improvement, conservation, and sustainable use of animal genetic resources are influenced by actions at multiple levels. At the global level, the FAO facilitates and catalyses interventions, cross-cutting technical issues, using a lens that also takes account of interactions with other aspects of natural-resources management, production-system

dynamics, and general socio-economic development and markets. A flagship contribution of FAO in this regard has been the development of the Global Plan of Action (GPA) which has provided a framework that countries can use to develop and operationalize policies for characterization, conservation, and use of AnGR. FAO has also played an important role in helping countries, especially in developing regions, including Africa, in domesticating the global instruments relevant for animal genetic resources, namely the Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization to the Convention on Biological Diversity (CBD), and the Cartagena Protocol on Biosafety.

At the continental level, the AU-IBAR works with AU Member States and the Regional Economic Communities (RECs) to which the Member States belong to catalyse and facilitate development of policies, strategies, and plans for the livestock sector, covering the domains of animal health and animal production, including characterization, conservation, and use of animal genetic resources.

The chapter 30 concludes that, while the AU, through the AU-IBAR, in partnership with Regional Economic Communities, has created significant awareness in Africa around global AnGR policy frameworks and instruments as well as actions needed at national levels, these efforts have delivered only limited change—with only a few countries having developed or in the process of developing policies and strategies, but even these largely remain on shelves, with little evidence of implementation. The technological developments and specific examples for Africa are discussed in Chapters 20, 21, 22, 23 and 24.

31.6 Towards Sustainable Livestock Breeding Programmes

Approaches for the development of sustainable livestock breeding programmes have been discussed in other chapters (Chapters 15, 16, 17, 18 and 19). This section presents a summary of key considerations for establishing sustainable breeding programmes in Africa:

(a) Across-country genetic evaluation: This is considered a potentially powerful tool to improve genetic evaluations in Africa by increasing the number of animals involved, hence accuracy of evaluations. It entails putting data together to estimate breeding values (EBV) for individual sires and dams, followed by ranking based on their genetic merit in the different environments (e.g. countries and herds). The across-country ranking is used to account for the presence of genotype by environment interactions (G × E). This approach can be used to determine whether animals selected in one environment can perform effectively in another environment. The general increase in the value of genetic parameter estimates and accuracy of selection, especially where there are insufficient data available in individual countries, is a very attractive proposition for different livestock producing countries. Pooling data for across countries is not only important for genetic evaluations, but can also help to inform individual countries on their farm management practices. Also, the sharing of information is an important component to inform future breeding strategies and genetic gain. This approach can also bring on board countries that are currently not undertaking any animal evaluations, because of lack of capacity, or other challenges. Across-country genetic evaluation for joint genetic evaluation is feasible also through sharing already determined breeding values ranked accordingly.

(b) Establishment and maintenance of adapted indigenous breeds: Although importation of exotic breeds is a relatively quick genetic improvement pathway that can change the gene and genotypic frequency of the base population, it has been shown not to be sustainable. A more practical and sustainable approach would be through the development of new tropically adapted breeds. For example, creating a synthetic breed in conjunction with local farmers using crossbred sires

selected from within the local herds. This strategy is different from previous strategies where synthetic breeds have been developed on government research farms and later distributed to farmers. This strategy allows for the creation of synthetic breeds in a process in which farmers are involved—through a systematic and continuous crossing of females with improved crossbred sires selected within a population.

(c) Harness the power of technological advances and innovations for novel phenotyping and genomics: The production environment in the tropics and specifically in Africa is confronted with disturbances that include high temperatures, heat stress, inadequate and low nutritional value feeds, seasonal and unpredictable rainfall, as well as disease and parasite burdens. These environmental disturbances compromise the ability of animals to perform optimally and also affect the welfare of the animals. Monitoring of body signals and biomarkers, such as saliva cortisol, blood lactate, heart rate variability, and temperature profiles, passively without disturbing the animal, is a great way to help the farmer make sound management decisions based on information directly coming from the animals (Guevara et al. 2022; Neethirajan 2017). These methods can detail the change and trajectory of change in the animal's physiological parameters and the biophysical conditions of the animal. In cases where the target parameters are difficult to measure, proxies and indicators can be used. These direct measurements also allow assessment of the welfare of animals, although scoring systems are also widely used. At the same time, these data can provide an excellent platform to define and capture novel phenotypes. For example, traits related to thermal stress can be measured using techniques such as thermal imagery. New ITC is helping develop farmer-centred decision-support tool/solution that integrates data from different sources. In the future, this will also include "digital twinning"—and to apply the twinning as a continuum from a static animal breeding modelling to full-fledged pairing with breeding populations including bi-directional data flows. Specific breeding populations and breeding programmes can be used to inform novel phenotypes through more in-depth qualitative data (thick data) and high-throughput quantitative data generated by ICT (big data). In the area of big data, future breeding programmes can also embrace the potential contribution of other technologies, including the Internet of Things, artificial intelligence, extended reality, and cloud storage (See Chapter 20).

Advances in genome-wide scanning technologies and computational capacity have increased the range of tools available in animal breeding. Tools to detect patterns of single nucleotide polymorphisms (SNPs) that became prevalent in genomes because of environmental selection pressure (signatures of selection) are becoming readily available. These signatures provide fundamental insights into the genome dynamics of a species and trace possible causative links to productivity and resilience traits in livestock. Genomics is also assisting in identifying the specific genes underlying difference traits. Whole genome sequences have greatly increased the ability to precisely infer population genetic parameters, demographic processes, and selection signatures (See Chap. 20). In future breeding programmes, genomics will not only present the opportunity to increase the accuracy of selection but also accelerate the genetic gains[53] (See Chapter 20). This calls for concerted efforts to catalogue the genomic variations in African livestock species and relate same with traits of interest to support the accurate estimation of genomic breeding values for the acceleration of the rate of genomic progress in livestock breeding programs. The recently initiated African BioGenome Project (AfricaBP, https://africanbiogenome.org/), which aims to sequence the genomes of 105,000 endemic animals, plants fungi, protists, and other eukaryotes species on the African continent (Ebenezer et al. 2022) (see Chap. 29), is a

positive step towards the characterization of the genomic variations in African livestock.

(d) Account for farmer and consumer needs: To account for farmer, consumer, religious and cultural needs, future breeding goals should include consumer preferences (e.g. healthy fatty acid profiles, more muscle, high protein content, etc.) and attitudes towards animal-derived food products. Consumer willingness to pay for food safety and quality and animal welfare costs is increasing due to increased income per capita. There is a need to explore how consumer value-specific animal food attributes linked to food safety and nutrition for incorporation in animal breeding goals.

(e) Ecosystem perspective: On the one hand, land-use pressures, including conversion of rangelands, fencing, and fragmentation of land, pose a major challenge to some of the traditional livestock production systems such as pastoralism. On the other hand, moderate levels of livestock grazing in some parts of Africa (e.g. East Africa) have been associated with beneficial outcomes in terms of wildlife biodiversity and soil quality. Meanwhile, the expansion of livestock populations in some areas has been associated with negative effects such as wildlife population declines. Future breeding strategies should include traits (e.g. feed and water efficiency, methane emissions, disease resistance, etc.) that demonstrate that livestock are part of the ecosystem.

(f) Adaptation to climate change: Changing climatic conditions is among factors militating against livestock productivity. Rising temperatures accompanying limited rainfall, drought conditions, expanding desert lands, limited feed resources and quality, and high disease burden are the direct consequences of changing climatic conditions. To maintain/increase livestock productivity under these conditions, traits such as heat and drought resistance must be considered in future breeding strategies for resilient livestock.

(g) Gender: When characterizing the production environment, gender roles and power relations should be analysed sufficiently to gain an understanding of intra-household issues that develop with the introduction of innovative breeding technologies. This will enable the selection of traits to target women or men specifically, in order to meet their specific needs. The roles of male, female, and young farmers and their interaction with new technologies, which may create a synergistic effect in society, should be considered in breeding programmes. This calls for participatory approaches in design of breeding programmes, ensuring that the voices of men, women, and the youth are intentionally incorporated. Gender-responsive strategies aim at incorporating diverse gender roles and needs.

(h) Economic perspective: The economic aspect of livestock production is not entrenched in the livestock productivity goals of smallholder livestock farmers, whose interest is to keep a few animals for food and for sale when a need arises. To exploit the economic potential of livestock production, training in the various aspects of the livestock-value-chain should be actively promoted. A realization of the huge economic potentials of livestock production, for example, the production of livestock products to meet specific market niches may be a driving force to increased production.

These points are not exhaustive, but they provide a starting point for upscaling using a sustainable business model in an affordable way. The implementation of these programs and commercialization of animal production require the cooperation and joint program delivery by stakeholders involved in the livestock production value chain.

31.7 Conclusion and Future Perspectives

Livestock has been identified as a major pillar in the fight against hunger and poverty alleviation in Africa. The overarching message of this book is that sustainable development of the African live-

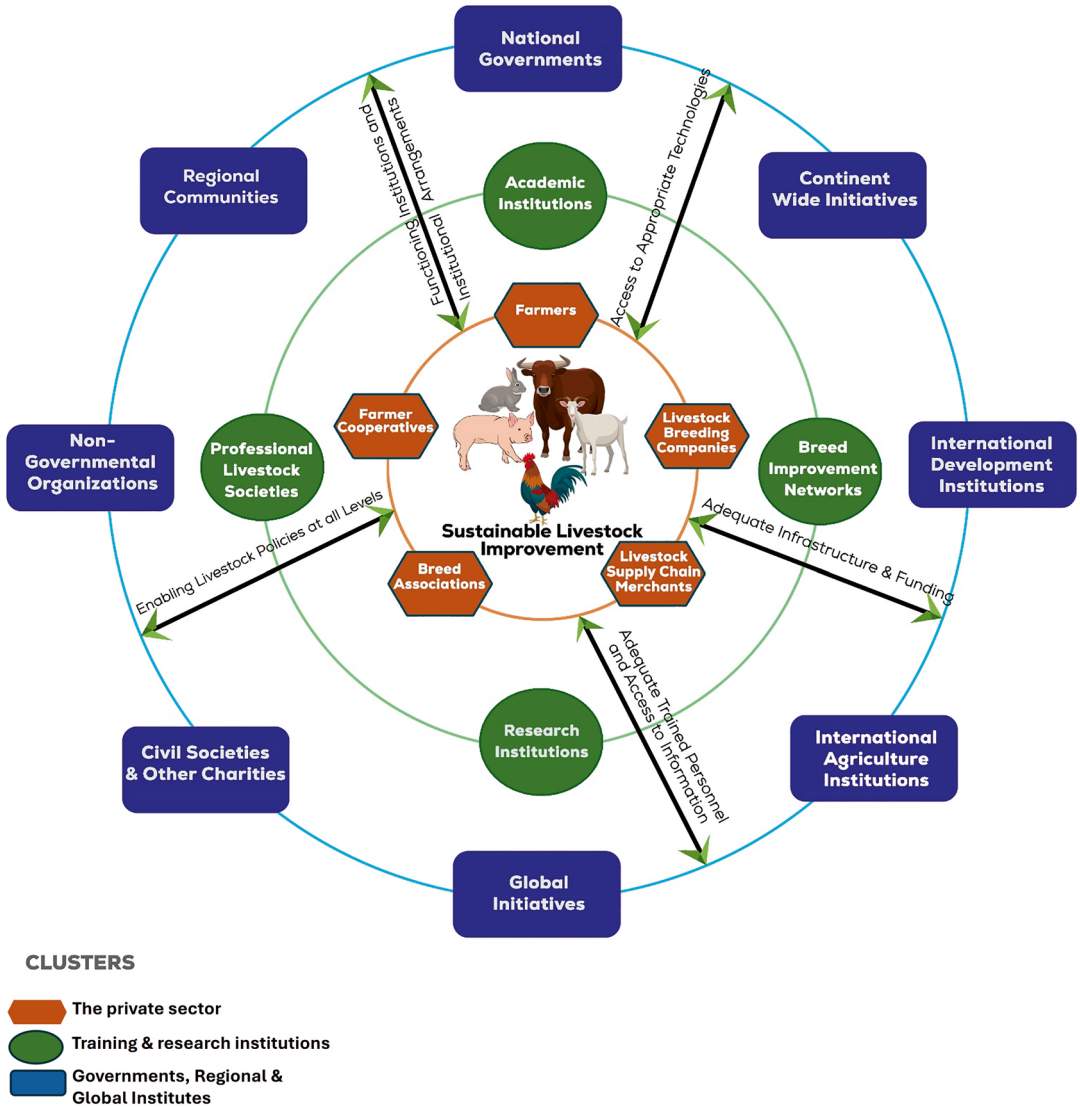

Fig. 31.7 Collaboration web for successful delivery of sustainable livestock development in Africa

stock sector requires attention to efforts towards enhancing the genetics of livestock, an area that has been historically neglected. For this to happen, there is need to pay attention to the development of enabling policies and functioning institutions that specifically address the current challenges to development and implementation of effective strategies, plans, and programmes that address animal genetic resources challenges, including conservation of indigenous breeds and sustainable genetic improvements that respond to needs of specific contexts. Access to appropriate modern technologies and adequate resourcing of priority programmes are critical pieces. Some of the items in the puzzle are already in place needing the right coordination, policies, and resourcing to drive sustainability of the sector. To be successful, functioning linkages and viable collaborations between stakeholders (discussed in previous sections) are critical (Fig. 31.7).

The recently created African Animal Breeders Network (AABNet) (Djikeng et al. 2025) (http://www.animalbreeding-africa.org) will be a key player in this regard. The AABNet proposes a

bold ambition to develop into a unique platform of highly skilled and experienced animal breeders and professionals with the capability to provide highly needed support and advice on animal genetics and sustainable livestock improvement across the African continent, paying attention to human capacity development, advocacy and resource mobilization, and to foster partnerships with global and African institutions to advance livestock genetic improvement in Africa. Its main goals are to (1) coordinate livestock improvement program(s) within and across African regions, and (2) facilitate collaborations with key stakeholders, investors, development agencies, international institutions, and relevant non-governmental organizations to drive a sustainable transformative agenda of Africa's livestock industry. The AABNet's transformative agenda for the development of the African livestock industry is achievable through four core activities: (i) spearhead multi-country genetic evaluation linked to the design of breeding programs for the optimization of genetic gains; (ii) actively participate in professional development through talent and technology incubation; (iii) advocacy, create awareness, and facilitate the business development of the livestock sector; and (iv) actively create collaboration, networking, and partnerships with stakeholders. As part of its objectives of participating in professional development and creating awareness, the AABNet has already initiated training programs on various topics on sustainable livestock production and business development with courses already delivered in the following areas: (1) Practical animal breeding, (2) Data science and bioinformatics for tackling animal breeding, (3) Biothermoimaging tools for management of climate smart and precision livestock-assisted reproduction, etc. In particular, its inaugural 3-weeks training activity exposed 48 participants (early career animal breeders) from 30 countries to practical skills in animal breeding and genetics. AABNet's strategy focuses on demand-led capacity development, starting with highest priority capacity gaps. This book is one of AABNet's flagship projects to characterize the African livestock genetic resources, production systems, and breeding strategies by documenting what is already known and identify gaps that needs to be addressed.

In conclusion, the currently underutilized African livestock genetic resources can be sustainably transformed. The basic elements and requirements for the implementation of sustainable and resilient livestock improvement programmes in Africa have been presented in this volume, and the key drivers that will underpin sustainable and resilient livestock sector transformation in Africa are enabling policies, functional institutional arrangements, access to appropriate technologies, funding and information, and adequate infrastructure and trained personnel.

Breeding goals for low input systems, 698
Breeding products, 740, 760, 761, 763, 766, 777, 778
Breeding program, 7, 46, 108, 121, 219, 304, 349, 362, 441, 490, 583, 604, 623, 692, 708, 760, 787, 820, 855, 914, 993, 1023, 1051, 1073, 1093, 1112, 1126, 1151, 1206, 1235
Breeding strategies in Africa, 7, 230, 452–491, 499–585, 691–701, 707–751, 760–779, 787–812, 820–844
Breeding technologies, 584, 743, 823, 856, 865, 871–875
Breeds, 4, 15, 186, 242, 358, 400, 453, 500, 596, 639, 692, 708, 760, 787, 820, 854
Breed substitution, 329, 715–726, 802–803
Busia pig, 359, 363, 370

C
Caballus, 499, 500, 503
Camel, 22, 25, 26, 30, 32, 36, 39, 360, 398–402, 408–410, 419–422, 424, 426, 432, 438, 439, 443, 444, 452, 477, 482, 491, 529, 547, 551, 574, 696, 710, 811, 871
Capacity building, 9, 51, 60, 374, 382, 386, 388, 391, 490, 584, 712, 715, 823, 827, 842–843, 857, 1063, 1201
Characterization/characterisation, 45, 46, 59, 109, 189–227, 230, 242, 269, 298–301, 313, 329, 330, 347, 362, 366–369, 371–374, 380, 389–391, 407, 439, 453, 458, 459, 477–479, 490, 512, 514, 526, 534, 553, 574–576, 579, 580, 604, 607–610, 625, 635, 646–650, 662–665, 683, 726, 739, 765, 779, 788, 823, 830, 831, 875, 1201

E. M. Ibeagha-Awemu et al. (eds.), *African Livestock Genetic Resources and Sustainable Breeding Strategies*, Sustainable Development Goals Series, https://doi.org/10.1007/978-3-031-92076-9

Climate change, 7, 23, 29, 30, 34, 45, 46, 48–49, 52, 56, 58, 142, 220, 332, 345, 382, 438, 443, 501, 621, 623, 665, 676–677, 680, 684, 685, 701, 709, 750, 751, 801, 802, 823, 827, 834, 835, 856, 865, 921, 1214
Community-based breeding program (CBBP), 308, 381, 613, 700, 736–739, 773, 836, 866, 1076
Conservation, 8, 49, 189, 242, 329, 358, 419, 453, 505, 612, 623, 726, 761, 798, 827, 870
Conservation and utilization, 336, 381
Conservation of African livestock genetic resources, 8–9
Core facilities, 1166–1172
Crossbreeding, 8, 47, 50, 51, 159, 190, 191, 216, 219, 243, 246, 258, 266, 271, 277, 278, 288, 289, 295, 303, 306–308, 314, 328, 329, 332, 349, 350, 363, 374, 375, 378, 380, 383, 386–387, 389, 404, 421, 422, 444, 461, 503, 506, 509, 516–518, 520, 523, 526, 528, 531–533, 535, 536, 540, 541, 543, 545, 555, 576, 583, 584, 643, 695–697, 699, 700, 708, 712, 714–726, 728, 730, 738–741, 744, 764, 766, 767, 769, 771, 773, 789, 796–798, 802, 803, 806, 822, 823, 828, 831, 832, 836, 854–855, 887
Crossbreeding system, 173, 789, 797, 802
Cryoconservation, 347, 1077, 1173, 1208
Cultural values, 14, 514, 621, 693–695, 709

D
Databases, 329, 439, 443, 510–512, 515–517, 519–521, 523, 524, 526, 528–530, 538, 580, 599, 610, 647, 694, 708, 760, 830, 858, 866, 874
Digital tools, 694, 708, 866, 891
Disease, 25, 68, 121, 187, 276, 329, 358, 402, 459, 500, 600, 623, 683, 693, 707, 762, 789, 820, 853, 911, 992, 1023, 1050, 1073, 1092, 1112, 1128, 1153, 1188, 1238
Disease surveillance, 388
Diversity, 4, 29, 186, 254, 328, 361, 398, 453, 522, 597, 626, 682, 700, 715, 760, 807, 830
Donkey, 4–7, 14, 15, 22, 23, 25, 29, 40, 360, 421, 423, 429, 452–491, 499, 543, 546, 554, 555, 557, 573, 583, 601, 696, 697
Dromedary, 4–7, 360, 397–444, 580, 871

E
Ecological settings, 69, 72, 75–78, 80–86, 107–108, 117, 119, 124, 125, 129–131, 153
Ecological zones, 83, 206, 230, 255, 256, 262, 634, 663, 716
Economic valuation, 9, 1095
Enabling livestock policies, 51, 55–56
Enabling policies, 10, 51, 52
Exotic cattle breeds, 68, 70, 118–177
Ex-situ conservation, 45, 303, 347, 348, 581, 612, 842, 844, 1207

F
Farmers participation, 701, 736, 746, 750
Food security, 4, 43, 51, 58, 227, 228, 314, 331, 345, 351, 358, 362, 380, 381, 389, 392, 438, 610, 665, 666, 676–677, 685, 707, 751, 812, 823, 833, 842, 844, 1227
Frameworks, 4, 9, 10, 46, 48, 51, 55, 60, 347, 443, 477, 552, 603, 697, 737, 761, 825, 1195, 1218, 1249–1250

G
Gene banks, 347, 381, 666, 828, 842, 843
Gene editing, 710, 741–743, 853, 875, 876, 878–882
Gene mapping, 600–603
Genetic characteristics, 89, 187, 191–197, 201–203, 205, 206, 208, 209, 214, 216–220, 222, 253, 255, 263, 269, 270, 272, 275–283, 286, 287, 290–295, 303, 334–344, 836
Genetic diversity, 7, 9, 19, 50, 51, 187, 189–227, 242, 254, 298, 300–304, 308, 314, 328–331, 338, 341, 346, 348, 349, 360–362, 369, 370, 389, 397, 441–443, 478–479, 500, 515, 516, 576–578, 580, 581, 584, 597, 604–610, 612, 621, 623, 634, 647–648, 664–666, 708, 728, 765, 777, 787, 831, 836, 840, 852, 855, 877
Genetic improvement, 9, 30, 51, 58, 216, 219, 224, 305–308, 311, 313, 314, 338, 350, 352, 380, 389, 390, 401, 436, 551, 580, 583–584, 600, 663, 684, 698, 699, 707, 708, 713, 715, 718–720, 722, 723, 726–729, 732, 733, 735–737, 739–750, 764, 779, 787–791, 794, 795, 797–801, 803, 805, 807–812, 820, 824, 825, 828, 830–832, 837, 839, 841, 853, 855, 858, 865, 871, 873–875, 886, 890, 892, 1059, 1126, 1128, 1131–1134, 1189, 1221, 1249, 1253, 1255–1265
Genetic parameters, 311, 728, 731, 733, 764, 765, 795, 797
Genetic resources, 3–10, 15–23, 49, 51, 186–230, 240–315, 328–352, 358–392, 397–444, 452–491, 499–585, 604, 611–613, 621, 632–635, 639–645, 697, 726, 727, 736, 737, 760, 761, 763, 766, 770, 771, 773, 776, 787, 789, 803, 812, 821–822, 830–833, 835, 842–844, 1199
Genetics, 6, 15, 187, 242, 328, 359, 397, 453, 500, 597, 625, 683, 692, 707, 762, 787, 820, 853
Genomic BLUP (GBLUP), 710, 874, 998, 1028
Genomics, 8, 9, 46, 47, 50, 51, 54, 187, 223–225, 229, 254, 299, 301, 302, 304, 306, 314, 330, 381, 398, 583, 639, 647, 648, 708–710, 713, 715, 741–743, 751, 765, 769, 778, 779, 791, 797–801, 804, 805, 807–809, 826, 828, 831, 839–841, 844, 852–854, 856, 866–886, 890, 891, 1025, 1246
Genotype-by environment interaction, 821, 835

Germplasm centres, 1173–1175
Goats, 4, 14, 186, 243, 360, 398, 452, 500, 599, 676, 693, 760, 810, 854, 995
Goliath frog, 7, 621–623, 665, 666
Greenhouse gas emissions, 676–686, 714, 835, 865, 884

H
Honeybee, 7, 620, 650–665
Horse production and breeding systems, 545–550
Human resource development, 1199
Husbandry practices, 40, 44, 49, 136, 146, 193, 200, 202, 203, 206, 207, 210, 211, 216–219, 257, 271, 272, 280, 284, 285, 289, 334–345, 367, 371, 374, 378, 388, 443, 505, 506, 610–611, 730, 737, 738, 918, 938, 1063, 1085

I
Improve disease management, 490
Improved utilization and modern technologies, 8
Improve management, 866
Indigenous breeds, 7, 14, 30, 36, 39, 41, 43, 45, 50–52, 158, 195, 201–206, 267, 295, 307, 308, 335–340, 343, 344, 346, 363, 365, 366, 371–373, 378, 380, 387, 389, 525, 528, 530, 574, 584, 644, 645, 699, 700, 709, 712, 718, 719, 722, 727, 728, 737, 765–767, 769, 771, 773, 774, 778, 779, 793, 803, 829, 831, 832, 843, 855, 1096
Indigenous livestock, 34, 36, 45, 46, 50, 51, 58, 230, 697, 735, 854, 855, 870
Indigenous pig breeds, 36, 362–364, 367–374, 380, 391, 821, 822, 828, 831, 832, 836, 837, 844
Information systems, 364, 858–859
In situ conservation, 303, 347, 380–382, 581, 611, 612, 737, 828, 837, 842
Institutional, 8, 9, 23, 44, 46, 48, 51, 52, 351, 358, 362, 379, 381, 385, 387–389, 391, 712, 728, 729, 737, 744, 746, 765, 771, 774, 776, 790, 811, 812, 822, 823, 828, 841–844, 857, 1204
Institutional arrangements, 9–10, 52, 762–764

K
Kolbroek, 359, 362, 363, 366, 372–373

L

Production efficiency, 15, 711, 712, 741, 767, 807, 823, 843, 877, 914–916

Q
Quantitative and genomic technologies, 1162

R
Rabbit, 4–7, 14–16, 19, 26, 34, 37, 360, 620, 639–650, 665, 666, 696, 747, 871, 875, 876, 881

Reproduction, 8, 40, 47, 48, 54, 122, 226–227, 298, 305–307, 309, 347, 377, 421, 434–436, 477, 488, 490, 521, 551, 552, 579–580, 604, 607, 608, 622, 631, 632, 634–637, 639, 649, 693, 701, 707, 713, 714, 728, 731, 736–738, 740, 745–748, 762–764, 788–793, 795, 796, 801, 804, 806, 810, 825, 833, 835, 840, 843, 852–854, 858, 861, 882, 887–889, 891, 1236
Reproductive and molecular technologies, 741–749, 764, 779
River buffalo, 360, 595–599, 601, 603, 610
Ruminants, 7, 14, 15, 19, 21, 24, 31, 37, 47, 49, 54, 56, 58, 187, 188, 206, 228, 314, 332, 358, 400, 424, 427, 431, 434, 436, 606, 608, 676–680, 682–684, 698, 709, 729, 735, 747, 760–779, 810, 856, 862, 865, 866, 886, 888, 889

S

Selection, 4, 6, 7, 9, 15, 46, 47, 49–51, 54, 125, 131, 172, 197, 202, 208, 212, 216, 217, 221, 224, 226, 242, 254, 279, 282, 289, 292, 298, 302, 305–311, 328, 330, 346, 381, 387, 400, 402, 418, 421–422, 431, 432, 437, 439, 444, 477, 488, 520, 532, 535, 537–539, 541, 543, 574, 579, 582, 584, 649, 664, 684, 692, 694–697, 699, 700, 707–709, 715, 717–719, 721–723, 726–743, 747, 748, 750, 762, 764–767, 773–776, 778, 787, 789–810, 820, 822, 824–826, 828, 830, 832–837, 839–841, 844, 854, 862–864, 870, 871, 873–875, 886, 1075, 1098, 1220
Sheep, 4–8, 14–17, 21–30, 32, 34, 36, 40, 41, 55, 193, 202, 206, 210, 228, 229, 240–315, 360, 421, 430, 438, 452, 454, 475, 500, 547, 557, 574, 599, 676, 679–681, 684, 693, 695, 696, 700, 734, 744, 749, 760–775, 778–779, 811, 854–856, 861, 863, 871–873, 875, 876, 878, 886, 887, 890, 1012, 1061, 1081, 1096, 1097, 1225, 1242, 1260
Snail, 6, 7, 37, 620, 624–639, 665, 666
Social and economic benefits, 9, 51, 711
Social, cultural and economic use, 711
Socio-cultural values, 711, 762, 820
Stakeholders, 5, 10, 45, 46, 50, 51, 54, 55, 59, 60, 313, 358, 373, 374, 381, 383, 386–388, 390, 391, 443, 491, 581, 582, 623, 711, 726, 727, 748, 763, 764, 779, 821, 824, 825, 828, 836, 839, 841–843, 1266
Strategies, 3–10, 15, 30, 45, 47, 48, 50–52, 54–58, 216, 227, 228, 230, 242, 302–309, 311, 314, 336, 346, 347, 352, 370, 380, 382, 385, 390, 406, 419, 421, 422, 432, 435, 436, 438, 443, 452–491, 499–585, 604, 611, 635–637, 649, 666, 678, 680, 682–684, 692–701, 707–751, 760–779, 787–812, 819–844, 853, 864, 866–868, 947, 1195, 1209, 1218
Subsistence livestock farming, 59
Sus scrofa, 358–361, 364
Sustainable Development Goals (SDGs), 19, 1125, 1127, 1129, 1267
Sustainable genetic improvement, 304–309, 313–314, 853
Sustainable livestock production, 8, 10, 46, 52, 58, 854, 856, 857, 974
Sustainable use, 9, 45, 51, 303–304, 347, 358, 362, 363, 374, 377–382, 387–391, 443, 623, 761, 766, 773, 810–812, 827, 831, 842–844, 857, 1201

T

Technological innovation, 52, 428
Technology, 5, 15, 219, 304, 347, 358, 424, 579, 604, 660, 698, 713, 762, 790, 821, 852
Total economic value (TEV), 652
Trained personnel, 10, 763
Traits of economic importance, 8, 381, 743, 788, 805, 808, 820, 823, 833–836, 864, 870, 871
Tropical climates, 95, 204

U

Uses, 7, 33, 139, 140, 155, 156, 166, 187, 201, 205, 220, 228, 242, 263, 272, 299, 362, 380, 398, 400, 427, 428, 430–434, 444, 453, 466, 480–485, 502, 511–515, 517–521, 523, 524, 526–529, 531–535, 537, 538, 550, 553–562, 573, 653–654, 807, 861, 868, 882–884, 934, 942, 966, 1092

W

Welfare and management, 919

Z

Zebu cattle, 41, 68, 118–147, 280, 709, 714, 716, 720, 721, 726, 732, 737–739, 746
Zebu-Taurine derivatives, 7
